We propose and demonstrate a modulation transfer protocol to increase the detection sensitivity of a Rydberg RF receiver to fields out of resonance from the transition between Rydberg levels. This protocol is based on a phase modulation of the control field used to create the Electromagnetically Induced Transparency (EIT) signal. The nonlinear wave-mixing of the multi-component coupling laser and the probe laser transfers the modulation to the probe laser, which is used for RF-field detection. The measurements compare very well to semi-classical simulations of atom-light interaction and show an improvement in the RF bandwidth of the sensor and an improved sensitivity of the response to weak fields.

Research on RF receivers based on optical detection methods using thermal Rydberg atoms has strongly developed in the last decade. From a three-level EIT scheme in Rubidium 87 (<sup>87</sup>Rb) vapor, this RF detection method based on the induced Autler-Townes splitting of Rydberg levels has been expanded to Rubidium 85 (<sup>85</sup>Rb), Cesium (Cs) vapors [1–4] and four-level EIT schemes [5–8]. It is capable of detecting the signal from the sub-Gigahertz range [5] to Terahertz frequencies[6] using the numerous allowed atomic transitions between Rydberg states in alkali atoms [9]. The large electric dipole moments of these transitions make Rydberg RF receivers very sensitive to resonant microwave fields, with sensitivities in the range of  $\mu V/m$  in the GHz frequency range. However, the signal quickly decreases when the detuning of the RF signal from the atomic transition increases. An RF reference field serving as a local oscillator can help retrieve more sensitivity [10– 12], but this method is more cumbersome and requires an auxiliary antenna, which prevents the system from being purely dielectric and can, therefore, induce RF field distortion.

We propose an all-optical method based on a modulation transfer by four-wave mixing in the atomic medium [13], which improves the sensitivity of the atom-based RF receiver to detuned fields. Although such a modulation transfer method is popular for laser frequency stabilization using two-level systems [14–16], there are very few experimental demonstrations of this technique applied to three- or four-level systems[17]. Here, we consider such a modulation transfer method in the case of a three-level ladder EIT phenomenon in <sup>85</sup>Rb and investigate its capability of increasing the detection bandwidth of the corresponding Rydberg RF receiver.

In the present letter, we thus implement both the conventional and the modulation transfer protocols and compare their responses to RF fields with different detunings. We focus on the low-field domain where the Autler-Townes (AT) splitting is hardly visible, and we interpret the experimental results with numerical simulation.

We use <sup>85</sup>Rb, which has the highest abundance in a natural mixture of 85 and 87 isotopes. A probe laser around 780 nm couples its ground state  $|1\rangle =$  $[5^{2}S_{1/2}(F = 3; m_{F})]$  to the intermediate state  $|2\rangle =$  $[5^{2}P_{3/2}(F = 4; m_{F})]$  (Fig. 1. (a)). A 480 nm laser couples this intermediate state manifold to the Rydberg state  $|3\rangle = [50^{2}D_{5/2}(F = 3, 4, 5; m_{F})]$ . We couple this Rydberg state to the state  $|4\rangle = [51^{2}P_{3/2}(F =$  $2, 3, 4; m_{F})]$  with the RF field around 17.0424 GHz that we wish to detect.

In the conventional protocol, the probe and coupling laser beams are single-frequency fields and can be modeled by  $E_{p,c} = \mathcal{E}_{p,c} e^{-i\omega_{p,c}t} + \text{c.c.}$  (see Fig. 1. (b)). The transmitted probe beam after the vapor cell then remains single-frequency and can be written  $E'_p = \mathcal{E}'_p e^{-i\omega_{p,c}t} + \text{c.c.}$ 

In the modulation transfer protocol, the coupling laser is phase-modulated and exhibits sidebands with opposite signs (see Fig. 1. (c)):

$$E_{c} = -\mathcal{E}_{c_{1}} \mathrm{e}^{-\mathrm{i}(\omega_{c}-\omega_{mod})t} + \mathcal{E}_{c_{0}} \mathrm{e}^{-\mathrm{i}\omega_{c}t} + \mathcal{E}_{c_{1}} \mathrm{e}^{-\mathrm{i}(\omega_{c}+\omega_{mod})t} + \mathrm{c.c.} \quad , \tag{1}$$

where  $\omega_{mod}$  is the modulation frequency. Close to EIT resonance, the modulation is transferred from the coupling beam to the probe beam via the atomic medium nonlinearities so that one now expects the transmitted probe laser output to also exhibit sidebands at  $\omega_{mod}$  from the carrier:

$$E'_{p} = \mathcal{E}'_{p-1} e^{-i(\omega_{p} - \omega_{mod})t} + \mathcal{E}'_{p_{0}} e^{-i\omega_{p}t} + \mathcal{E}'_{p+1} e^{-i(\omega_{p} + \omega_{mod})t} + c.c.$$
(2)

Figure 2 schematizes the experimental setup used to test this idea. The probe and coupling lasers counterpropagate through a quartz cell containing a natural mixture of Rubidium (with 73% of <sup>85</sup>Rb and 27% of <sup>87</sup>Rb) at room temperature. Inside the cell, the probe (coupling) beam has a waist diameter of 0.3 (0.4) mm

Photodetectors 1 (PD1) and 2 (PD2) monitor the probe laser before and after the vapor cell, respectively. In the conventional protocol, the detected signal is DC. In the modulation transfer protocol, we demodulate the AC part of the detected probe signal using the phase-shifted modulation as a reference.

with an 11.5 (14.5) cm Rayleigh length, which is longer than the 7.5 cm vapor cell length. The probe input power is 0.4  $\mu$ W, and the coupling one is 54 mW. A horn antenna (MVG QR18000) is placed 57.5 cm away from the vapor cell and emits an RF field perpendicularly to the laser path. RF absorbing panels isolate the antenna and the vapor cell from other elements. The probe, coupling, and RF fields are linearly polarized along  $\hat{x}$ , so that all the magnetic sub-levels between the two Rydberg states are coupled [18].

We use a Toptica tunable diode laser to provide the 780 nm probe laser and a Toptica amplified and frequency-doubled tunable diode laser (TA-SHG) system to generate the 480 nm coupling laser. The probe laser is stabilized by Modulation Transfer Spectroscopy [14] on the atomic frequency  $\omega_{21}$  that corresponds to the transition between the levels  $|1\rangle$  and  $|2\rangle$ . Using an auxiliary cell, the coupling laser is then locked using the EIT resonance in the ladder system [19], which enforces the condition  $\omega_p + \omega_c = \omega_{31}$ , where  $\omega_{31}$  is the frequency difference between the atomic levels  $|1\rangle$  and  $|3\rangle$ . Considering the RF frequency value, which gives a symmetrical AT splitting, we obtain  $\omega_{34}/2\pi \simeq 17.0424$  GHz for the RF transition between the levels  $|3\rangle$  and  $|4\rangle$ . The RF signal is provided by a R&S SMF100A signal generator,

Figure 3. Experimental spectra of RF receiver response for (a) the conventional protocol and (b) the modulation transfer protocol at modulation frequency  $\omega_{mod}/2\pi = 3$  MHz. The RF electric field amplitude is at  $E_{RF} = 0.4155$  V/m, and the RF frequency is at  $\omega_{RF}/2\pi = 17.0424$  GHz. The coupling laser is at resonance with the transition between  $|2\rangle$  and  $|3\rangle$ . Corresponding simulation results for (c) conventional and (d) modulation transfer protocols.

and the RF electric field amplitude  $E_{RF}$  at the vapor cell position is estimated after taking into account cable and insertion losses, the gain of the antenna and its distance to the vapor cell. The cell perturbation factor [20], which decreases the average RF field inside the cell, is estimated to be about 0.6 from a finite-difference timedomain (FDTD) electromagnetic simulation around 17 GHz with our vapor cell.

Let us now examine the signal obtained with the conventional and modulation transfer protocols as a function of probe laser detuning  $\Delta_p = \omega_p - \omega_{21}$ . We scan the probe laser frequency around  $\omega_{21}$  by  $\pm 100$ MHz thanks to two double-pass acousto-optic modulators (AOM) [21]. The AOMs are driven by VCOs, with a 10 Hz scanning rate. A fast APD (Thorlabs APD410A/M) of 10 MHz instantaneous bandwidth and  $1.2 \times 10^7$  V/W sensitivity at 780 nm detects the probe laser after the vapor cell. Another photodetector monitors the probe laser before the vapor cell so that we can record the corresponding background. We average the received signal over 128 scanning rounds to reduce electronic noise. Knowing the photodetector sensitivity and the electronic attenuation, we can derive the probe laser transmission  $|\mathcal{E}'_p|^2/|\mathcal{E}_p|^2$  from the probe input and output intensities. We can then compute the probe transparency by subtracting the probe laser transmission from the one measured without any coupling laser. One example of such an EIT transparency signal in the presence of a weak resonant RF field is plotted in Fig. 3(a), together with the result of the corresponding simulation in Fig. 3(c).

These simulations are obtained by the density matrix formalism using an effective four-level atomic system [22]. Rabi frequencies are derived considering the effective electric dipole elements for linear transitions between Zeeman sublevels  $(m_F \rightarrow m'_F = m_F)$ . The electric dipole elements and decay rates for the first transition  $(|1\rangle \rightarrow |2\rangle)$  are taken from well-established data [23]. For the second  $(|2\rangle \rightarrow |3\rangle)$  and third  $(|3\rangle \rightarrow |4\rangle)$ transitions, we obtain these parameters from an opensource Python package [24, 25]. To take into account the atomic medium optical thickness [26] (linear transmission equal to 0.41), we divide the cell into a hundred layers, for which the thin medium approximation can be considered valid. We include the Doppler effect of the thermal vapor by integrating over velocity classes, and the transit rate of atoms through the laser beam by corresponding decay and feeding rates [27]. The simulation results, shown in Figs. 3(c) and (d), are in very good agreement with the measurements for both protocols, which validates our theoretical approach. In order to simulate the modulation transfer protocol, a Floquet expansion and the continued fraction method [28, 29] allow handling the oscillating terms in the optical Bloch equations.

Now, to implement the modulation transfer protocol experimentally, we need to modulate the phase of the coupling beam. To this aim, the coupling beam travels through two single-pass AOMs. The first one shifts the coupling light frequency by -180 MHz. The second one is driven by a signal at 180 MHz with a phase modulation at a smaller frequency  $\omega_{mod}$ . It thus shifts the light frequency by 180 MHz but also imprints a phase modulation at frequency  $\omega_{mod}$  [30] on it. The coupling laser thus exhibits two opposite sidebands at  $\pm \omega_{mod}$  from the carrier (see Eq. 1). Thanks to the 16 MHz phase-modulation bandwidth of the AOM and the 10 MHz instantaneous bandwidth of the photodetector, we could test several phase modulation frequencies  $\omega_{mod}/2\pi = 3, 6, 9$  MHz. The phase modulation amplitude of the RF signal injected into the AOM is  $\pi/3$ . A scanning Fabry-Perot interferometer allowed to measure a 0.6 ratio  $\left|\mathcal{E}_{c_{\pm 1}}/\mathcal{E}_{c}\right|$  between the amplitudes of the sidebands and the carrier.

Once the transmitted probe beam and its intensity modulation are detected, we demodulate the signal at  $\omega_{mod}$  and filter it to obtain the relative modulation amplitude (RMA), which is defined as  $\operatorname{Re}((\mathcal{E}'_{p_{-1}} + \mathcal{E}'_{p_{+1}})\mathcal{E}'^*_{p_0})/|\mathcal{E}_p|^2$ . This demodulation and filtering is performed with an analog electronic circuit. Figure 3(b) shows a typical RMA signal evolution versus probe detuning in the presence of the RF field. The signal of Fig. 3(b) now contains many more features than the usual DC signal of Fig. 3(a), which we will

Figure 4. Recorded signal as a function of electric field amplitude  $(E_{RF})$  for different RF detunings  $(\Delta_{RF})$ . (a) Conventional protocol at  $\Delta_p/2\pi = 2$  MHz. (b) Modulation transfer protocol at  $\Delta_p/2\pi = 0$  MHz and  $\omega_{mod}/2\pi = 3$ MHz. (c) and (d) Corresponding simulation results.

exploit in the following. Notice also that the signal of Fig. 3(b) is in excellent agreement with the simulations of Fig. 3(d).

Let us now investigate the system response to RF fields at different RF detunings  $\Delta_{RF} = \omega_{RF} - \omega_{34}$ . In the following, for both protocols, the probe laser detuning  $\Delta_p = \omega_p - \omega_{21}$  is fixed, and the RF electric field amplitude  $E_{RF}$  is scanned at a rate of 10 Hz. A fast oscilloscope characterizes the amplitudemodulated RF field to ensure that the modulation parameters provide a linear scan. Different sets of data were recorded for  $\Delta_p/2\pi = 0, \pm 2, \pm 4$  MHz, and for  $\Delta_{RF}/2\pi = 0, 5, 10, 20, 30 \,\mathrm{MHz}$ . We choose to reproduce here those corresponding to the probe detuning, which gives the best sensitivity for detuned RF fields  $(\Delta_{RF} > 0)$  for each protocol. Figures 4(a) and (b) thus show the results obtained for  $\Delta_p/2\pi = 2$  MHz for the conventional protocol and  $\Delta_p/2\pi = 0$  MHz for the modulation transfer one. The corresponding simulations (Figs. 4(c) and (d)) accurately reproduce the behavior of the system.

When the RF field is at resonance, it is clear that the conventional protocol gives the best sensitivity to variations of the RF field amplitude: the slope of the blue curve of Fig. 4(a) is very large. However, as soon as the RF field is detuned by a few MHz, the response of this signal to variations of  $E_{RF}$  becomes very flat (see the curves for  $\Delta_{RF} \neq 0$  in Fig. 4(a)), indicating a poor sensitivity of the standard protocol to detuned RF field variations. On the contrary, the signal obtained from the modulation transfer protocol (see the curves for  $\Delta_{RF} \neq 0$  in Fig. 4(b)) exhibits a strong slope for RF detunings even as large as 30 MHz. Moreover, the comparison with the simulations of Figs. 4(c,d) is very accurate and confirms the apparent superiority of the modulation transfer protocol for detuned RF field detection.

Figure 5. Simulated signal slope versus RF field amplitude for different RF field detunings. Full lines: conventional DC signal. Dashed line: Modulation transfer protocol.

Since the comparison with the experiments shows that our simulations are accurate, we rely on those simulations to characterize more quantitatively the detection sensitivity of very weak detuned RF fields. This is also more convenient because our experiment takes place in an electromagnetically noisy environment, in which we can never reach an RF field close to zero. We thus derive the signal slope amplitudes from the simulation data of Figs. 4(c) and (d).

Figure 5 compares such slopes for different RF detunings for both protocols. The slope obtained by the modulation transfer protocol is always larger than the one obtained with standard DC signals. Moreover, the response of the modulation transfer protocol is better for a larger range of RF field amplitudes than the one of the standard protocol. This clearly indicates that the new protocol proposed here can provide an improvement in RF detection systems compared with the standard approach.

In this article, we have thus proposed and demonstrated an RF detection method using Rydberg-EIT in the presence of phase modulation of the coupling beam. We have shown theoretically and experimentally that this modulation is transferred to the probe beam in the presence of EIT, and that, once demodulated, the probe modulation can improve the sensitivity of an EIT-based Rydberg RF receiver to weak and detuned fields. With our parameters, the transfer of modulation to the probe provides a new response to the RF field, leading to a higher sensitivity for small RF fields observed for detunings as large  $\Delta_{RF}/2\pi = 30$  MHz. Moreover, the response of the modulation transfer protocol is shown to be more sensitive than the standard one over a larger range of field amplitudes. Another potential application is to tailor a constant sensitivity by using a quadrature with a well-chosen modulation configuration. Our experimental results are well-reproduced by simulations, so modulation parameters can be adapted to slightly different cases, corresponding to another alkali atom or
