Abstract We report a daylight km-range free space QKD demonstration at 850nm obtaining a QBER of 1.9% and a raw key-rate of 14 kbit/s. We used the BB84 protocol with polarisation encoding and two supporting optical beams for classical communication and clock synchronisation. ©2024 The Author(s)

Introduction

Quantum key distribution (QKD) is a simple and effective technique to distribute encryption keys over optical links. Space based QKD, first demonstrated by the Micius satellite mission^[1], has the potential to enable global quantum secure communication and has thus been the focus of numerous studies.^[2]

Despite the high level of security, the key rate which is achievable with long range free space QKD is still quite low, below one megabit per second.^[3] Some of the limitations are intrinsic to the use of single photons, however the challenges posed by the atmospheric turbulence and the need of filtering out the environmental background photons can be technologically improved upon.^[4]

The atmospheric turbulence modulates the light wavefront, reducing the ability of focusing the received optical beam. This issue can be partly offset using adaptive optics, at the cost of increased system complexity. The background environmental photons are a more severe challenge. They directly increase the quantum bit error rate (QBER) and can even impede the communication when the QBER increases over a threshold set by the chosen protocol (about 10% for the protocol BB84^[5]). This is especially problematic for free space QKD and it can prevent day-light operations. One possible mitigation is choosing the QKD wavelength in the infrared region of the spectrum, where the solar background is reduced, yet the photon energy is still high enough to enable efficient single photon detection.

The telecom wavelength of 1550 nm is a natural choice, benefiting from the compatibility with the components developed for the terrestrial optical fibre networks. However, efficiently detecting single photons at 1550 nm requires using expensive superconducting nanowire detectors operating in vacuum at cryogenic conditions. For this reason, despite the benefits of using near-IR and even visible light for daylight QKD were evidenced before,^[6] many demonstrations including the Micius mission cited above, are done in the near infrared, where the cheaper and efficient silicon avalanche photodiodes can be used.^[1]

In this contribution, we present preliminary results from tests on free-space daylight quantum key distribution (QKD) at 850 nm, employing the BB84 protocol with polarization encoding. The measurements were performed over link distances of up to 780 m, inside the Airbus campus near Munich. In the following paragraphs, we will describe the setup, the methods and results achieved in terms of quantum bit error rate (QBER) and keyrate.

Methods

The communication terminals used for the QKD experiments allowed for simultaneous classical and quantum communication. We used three free space optical channels: a quantum channel at 850 nm and two classical channels near 1550 nm. One of the classical channels was used for bidirectional (1530.33 nm & 1548.51 nm) data transmission at 10 Gbps and the other one for clock synchronisation (1550 nm). The classical channels were amplified and multiplexed such that they could be transmitted and received through the same optics. We used a combination of spatial, temporal and spectral filtering for efficiently rejecting the environmental light. Spatial filtering was achieved by coupling the received optical beams into single mode fibers. Spectral filtering was done using commercial-off-the-shelf narrow band-pass filters. Filtering in the time domain was achieved by post-selecting the received photons based on their arrival time. The block diagram of the setup used in the second point-to-point link is shown in Fig. 1.

The QKD photon source was developed at the Ludwig Maximilian University of Munich (LMU) in the group of Prof. Weinfurther and it has been described in previous publications.^[7] Briefly, four vertical-cavity surface-emitting lasers (VCSEL) generated poissonian pulses, with a wavelength of 852 nm, pulse duration of about 200 ps and repetition rate of 100 MHz. After each VCSEL four polarizes, oriented at 0°, 90°, 45° and -45°, encoded the qubit state in the horizontal-vertical and diagonal bases. A photonic circuit was then used to combine the output of the four VCSELs

into a single mode fibre, which was coupled to free space.

The QKD detector consisted of a small optical bench to compensate for any drift in polarisation as well as to separate the four polarisation states, four silicon avalanche single photon diodes and a high resolution time-tagger.

The software for controlling the experiments and executing the BB84 protocol was implemented with a combination of python scripts and commercial libraries in C++.

Test Campaign Results

We set-up two free space QKD experiments with link distances of 320 m and 780 m. The first demonstration was performed between two buildings in the Airbus campus in Taufkirchen (Germany) with the help of a retro-reflector positioned 160 m away. Fig.2a shows a picture of the link location with the beam path highlighted in purple. A picture taken from the transmitter side and look-

ing towards the retro-reflectors is shown in Fig. 2b. The beam paths for the quantum and classical beams are highlighted with green and orange lines, respectively. Two different retro-reflectors, a "cateve" and a corner-cube were used for the guantum and classical channel, as shown in Fig.2c. A "cat-eye" retro-reflector was preferred for the quantum channel to minimise wavefront and polarisation distortions. It consisted of a plane mirror mounted in the focal plane of a commercial IR objective, which yielded superior optical performance compared to the COTS corner-cube type. Different apertures were used for the transmitted and received beams. Since those two beams propagated along the same paths, we separated them using 50% beam-splitters, which resulted in an additional 6 dB loss with respect to a direct link.

The experimental conditions, and the measured QBER and raw key-rate values are summarised in Tab. 1. It should be noted that the link performance was limited by the malfunctioning of one of the VCSELs in the photon source, which significantly reduced the average photon number per pulse for the vertical polarisation.

Using a retro-reflector in an experiment results in slightly different measurement conditions with respect to a direct link, and the results might not be directly comparable. First, the retro-reflector itself may distort the propagated wavefront and, second, a potential double pass through identical turbulence cells may occur which does not occur in actual point-to-point links.

For these reasons, we conducted a second test campaign, where we connected the north and south parts of the Airbus campus with a point-topoint free-space QKD link over a distance of 780 m at a height above ground of roughly 16 m. The optical setup is shown Fig.3. For these new experiments, the average photon number per pulse was tuned to 0.1, which was higher than the value used for the retro-reflector link, though the latter could not be known precisely due to uncertainty

in the current calibration of the photon source. In order to minimise the geometrical loss over the increased link distance, for the 850 nm quantum channel we slightly increased the beam diameter by replacing the fiber collimator used in the retro-reflector setup with a larger beam-expander. The resulting transmitted beam diameter at $1/e^2$ was 3.48cm and the maximum receivable beam diameter determined by the beam expander and the fiber's numerical aperture was 4.20cm at $1/e^2$. The latter value was determined by the clear aperture of the beam expanded and by the numerical aperture of the single mode fiber. For comparison, we also repeated the experiment with the same set of fiber collimators used in the retro-reflector link, which yielded a beam diameter at $1/e^2$ of 1.45 cm. The measurement results recorded with the two sets of optics are presented in Tab.2: In summary we obtained a QBER of about 1.9% and a sifted key rate of 13794 b/s.

Conclusions

These preliminary results confirm the feasibility of free space daylight QKD at 850 nm, across link distances in the kilometer range. They also show that utilizing a near-infrared quantum and a C-band classical channel makes it easier to spectrally isolate them and simultaneously perform classical and quantum communications.
