We report on the magnetic properties of the layered perovskite PbVO₃. The results of magnetic susceptibility and specific heat measurements as well as band structure calculations consistently suggest that the S=1/2 square lattice of vanadium atoms in PbVO₃ is strongly frustrated due to next-nearest-neighbor antiferromagnetic interactions. The ratio of next-nearest-neighbor (J_2) to nearest-neighbor (J_1) exchange integrals is estimated to be $J_2/J_1\approx 0.2-0.4$. Thus, PbVO₃ is within or close to the critical region of the J_1-J_2 frustrated square lattice. Supporting this, no sign of long-range magnetic ordering was found down to 1.8 K.

PACS numbers: 75.47.Pq, 75.30.Et

The spin-1/2 square lattice provides a number of simple and important models for theoretical physics. If one uses the Heisenberg Hamiltonian and considers nearestneighbor (NN) interactions only, a well-known Heisenberg square lattice (HSL) is formed. This model has been successfully applied to many transition-metal compounds (in particular, undoped high- T_c superconductors) and much of its physics is now well understood. A number of new phenomena appear if next-nearest-neighbor (NNN) interactions are taken into account. If both NN (J_1) and NNN (J_2) interactions are antiferromagnetic, the spin lattice is frustrated since J_1 and J_2 tend to establish different types of magnetic order. The properties of the system are controlled by the value of $\alpha = J_2/J_1$. If α is small, Néel order is favorable and the limit of HSL is realized. If α is large, columnar antiferromagnetic order is established. However, the main interest is attracted to the intermediate region that lies close to the quantum critical point at $\alpha_c = 0.5$. The nature of the ground state in this region is still disputed. Theoretical studies suggest different spin-liquid scenarios (e.g. RVB ground state). 2,3,4

Most of the compounds realizing S=1/2 square lattice are well described with HSL since NNN interactions are usually negligible. Recently two new systems with $\alpha \gg 1$ (Li₂VOXO₄, X = Si, Ge) were a subject of extensive studies and revealed columnar antiferromagnetic order.^{5,6,7,8} However, no compounds in the critical region close to $\alpha_c = 0.5$ have been reported so far.

Below we present magnetic properties of a novel compound, $PbVO_3$, 9,10 that reveals S=1/2 frustrated square lattice (FSL). Both experimental and computational studies show that this compound lies close to the critical region of FSL and does not undergo long-range magnetic ordering down to 1.8 K.

PbVO₃ adopts a layered perovskite-type structure (space group P4mm, a=3.8001 Å, c=4.6703 Å) shown in Fig. 1. This structure combines the absence of an inversion center with a magnetic V⁺⁴ cation, therefore PbVO₃ attracts considerable attention as a possible multiferroic.^{11,12,13,14} Magnetic properties of PbVO₃

FIG. 1: (Color online) Perspective view (left panel) of the crystal structure of $PbVO_3$ and projection along the [001] direction (right panel). VO_5 square pyramids share common corners, lead atoms are indicated by large spheres

have not been reported so far.

Polycrystalline samples of PbVO $_3$ were prepared by a high-temperature high-pressure technique in a belt-type apparatus. Stoichiometric mixtures of PbO and VO $_2$ were placed into gold capsules and treated at 950 °C for 2 hours under a pressure of 5 GPa. The phase composition of the prepared samples was checked by XRD.

The magnetic susceptibility of PbVO₃ was measured between 1.8 and 400 K in the fields $\mu_0 H$ of 0.1, 1, and 5 T using a Quantum Design SQUID magnetometer. The specific heat was studied in the temperature range from 1.8 to 270 K with a commercial PPMS.

The study of the magnetic properties of PbVO₃ is complicated by the presence of magnetic impurities in the samples under investigation. All of the measured susceptibility curves revealed anomalies at 90 and/or 350 K corresponding to PbV₆O₁₁ and VO₂ respectively, ¹⁵ although these impurities were not necessarily visible in XRD patterns. Fig. 2 presents one of the best $\chi(T)$ curves (no anomaly at 90 K) below 300 K, since the high-temperature part is affected by VO₂. The features of this curve are typical for all PbVO₃ samples within a variation of the temperature-independent background from sample to sample due to different amount of VO₂. These features

FIG. 2: (Color online) Magnetic susceptibility of PbVO₃ measured at 5 T, arrows denote the curves obtained at heating and cooling. The dashed and solid curves in the inset show the fits by high-temperature series expansion for HSL model and FSL model with $J_2/J_1 = 0.38$, respectively.

are: i) a very broad maximum near $190-200~\mathrm{K}$; ii) the difference between the zfc and fc curves below about $50~\mathrm{K}$ with small humps near $43~\mathrm{K}$ (or heating/cooling hysteresis visible at Fig. 2). One should note that the anomalies at $45-50~\mathrm{K}$ may appear due to the influence of trapped oxygen that undergoes condensation at about $50~\mathrm{K}$. These anomalies are especially strong if the intrinsic signal is very small (as in the case of our study). Nevertheless, the susceptibility data alone do not allow to decide unambiguously whether the anomaly at $50~\mathrm{K}$ is intrinsic to PbVO_3 (e.g. indicating a phase transition) or not. Therefore, we turn to other experimental data in order to check the extrinsic nature of this anomaly.

The specific heat curve (Fig. 3) is smooth between 1.8 and 270 K and suggests the absence of phase transitions in PbVO₃ in this temperature range. The conclusion is supported by thermal expansion¹⁰ and resistivity^{9,16} data. Finally, a neutron diffraction study at 1.5 K shows the absence of long-range magnetic ordering.⁹ Thus, we conclude that the susceptibility anomaly at 50 K has extrinsic nature.

Square-pyramidal coordination of vanadium is known to give rise to a non-degenerate d_{xy} ground state for V^{+4} (see Refs. 5,17). The d_{xy} orbitals lie parallel to the V–O layers, therefore one may expect that PbVO₃ is a 2D spin system. Indeed, the broad maximum in the susceptibility curve (Fig. 2) is typical for 2D spin systems while the upturn at low temperatures is usually ascribed to the paramagnetic contribution of impurities and defects. Unfortunately most of the regions of the curve are unsuitable for fitting since the low-temperature part is affected by impurity contributions while the metalinsulator transition of VO₂ prevents us from using the data above $300~\mathrm{K.^{18}}$ Thus, only the narrow region between the maximum $(T_{max} = 190 - 200 \text{ K})$ and 300 K is appropriate for the fitting. Since the leading exchange integral J is comparable to T_{max} , high-temperature series

FIG. 3: (Color online) Specific heat of PbVO₃. The inset shows the comparison with the diamagnetic reference compound PbTiO₃.

expansions (HTSE) are applicable in this region.

We use two types of HTSE corresponding to HSL and FSL models, respectively. 6,19 A temperature-independent contribution was added to the series as an adjustable parameter (χ_0) in order to account for the contribution of VO₂ as well as other (diamagnetic or van Vleck) contributions of this type. Both models resulted in fits of similar quality with reasonable values of $\chi_0 \approx 2.5 \cdot 10^{-4}$ emu/mol. We find J=190 K for HSL and $J_1=203$ K, $\alpha=J_2/J_1=0.38$ for FSL. The g value was fixed at g=2 in order to get a more stable fit. Basically, we see that the susceptibility curve is consistent with both scenarios – HSL or FSL.

Specific heat data may provide additional quantitative information about the spin system of PbVO $_3$. However, one has to estimate and subtract the phonon part of the specific heat in order to reveal the magnetic contribution. The leading exchange integral in PbVO $_3$ is about 200 K therefore the magnetic contribution does not fall to zero even at high temperatures and can not be separated from the phonon part by a simple Debye-fit. A reference diamagnetic compound has to be found in order to give a reliable estimate of the phonon contribution.

We tried to use $\mathrm{PbTiO_3}$ as a non-magnetic reference. The crystal structures of $\mathrm{PbVO_3}$ and $\mathrm{PbTiO_3}$ look similar but vanadium and titanium adopt different coordination (square pyramid and octahedron, respectively). This difference seems to be crucial: the $c_p(T)$ curves have crossings at low temperatures (see the inset of Fig. 3) indicating quite different phonon spectra. We are not aware of any non-magnetic compound with layered perovskite-type structure perfectly matching that of $\mathrm{PbVO_3}$. Therefore, presently we can not estimate the magnetic contribution to the specific heat of $\mathrm{PbVO_3}$.

Experimental data provide rather limited information about the magnetic properties of PbVO₃, therefore we turn to computational techniques. Band structure calculations are known as a useful tool for esti-

FIG. 4: (Color online) LDA band structure of PbVO₃ near the Fermi level. Dots show the contribution of V $3d_{xy}$ states, thick solid line presents the fit of the tight-binding model. The inset shows the density of states for PbVO₃ near the Fermi level.

mating exchange integrals and understanding the properties of low-dimensional spin systems. In particular, computational results were helpful in the study of FSL compounds Li_2VOXO_4 and provided the first realistic estimate⁵ $\alpha \gg 1$ (supported by later neutron experiments, see Ref. 7) in contrast to the early experimental reports.⁸

Scalar relativistic band-structure calculations were performed using the full-potential local-orbital scheme (FPLO, version 5.00-19)²⁰ and the parametrization of Perdew and Wang for the exchange and correlation potential.²¹ A k mesh of 1152 points in the Brillouin zone (224 in the irreducible part) was used.

We start with the LDA band structure (Fig. 4). The highest occupied band reveals a significant contribution of V d_{xy} orbital consistent with the square-pyramidal coordination of V^{+4} (see Refs. 5,17). A simple oneband tight-binding model is fitted to this band. We find $t_1 = 0.132$ eV and $t_2 = 0.077$ eV for NN and NNN hoppings, respectively (see Fig. 1). Long-range in-layer hoppings do not exceed 0.004 eV and hence may be neglected. The inter-layer hopping is also extremely small $(t_{\perp} = 0.0012 \text{ eV})$ suggesting a strongly two-dimensional spin system in $PbVO_3$. The t values are used to estimate antiferromagnetic contributions to exchange integrals as $J_i^{\text{AFM}} = 4t_i^2/U_{\text{eff}}$ (U_{eff} is an effective on-site Coulomb repulsion). Assuming $U_{\text{eff}} = 4$ eV we find $J_1 = 203$ K, $J_{\perp} \approx 0.01 \text{ K}, \ \alpha = t_2^2/t_1^2 = 0.34 \text{ in a perfect agreement}$ with the FSL fit of the susceptibility data. Note that the α value is a direct result of the tight-binding fit and does not depend on U_{eff} .

Thus, the tight-binding model supports the FSL scenario for PbVO₃. However, this model assumes that all the interactions in the system are antiferromagnetic. Sometimes it is not the case and one may calculate total energies for different spin states in order to check possible ferromagnetic contributions to the exchange inte-

TABLE I: The total energies of different spin states of PbVO₃ (the values are given in meV relative to the energy of FM state).

U_d (eV)	A-AFM	C-AFM	G-AFM

grals. LSDA calculations for several simple spin states have been reported, ^{11,12} and we list these results in the first line of Table I.

LSDA results for transition metal compounds are known to suffer from an unreasonable neglect of correlation effects. Below we show that the relative values of total energy are considerably changed if one takes into account strong Coulomb correlation for vanadium 3d shell. The most simple way to introduce such correlation within DFT is provided by LSDA+U technique.²² We apply several physically reasonable values of U (further named U_d in order to distinguish it from U_{eff}) and fix J=1 eV.

Table I reveals quantitative rather than qualitative dependence of the LSDA+U results on the U_d value. The energy differences $(E_{\text{A-AFM}}-E_{\text{FM}})$ and $(E_{\text{C-AFM}}-E_{\text{G-AFM}})$ corresponding to inter-layer coupling J_{\perp} are now comparable and small in contrast to the LSDA results. The sign of the inter-layer interaction still is not clear but the absolute value of J_{\perp} has the order of units of K. The in-layer interaction exceeds J_{\perp} at least by an order of magnitude. Thus, the spin system of PbVO₃ is two-dimensional consistent with the crystal structure and the tight-binding results.

Now we use LSDA+U to estimate in-layer interactions J_1 and J_2 . The results listed in Table II are in a reasonable agreement with the experimental data and the tight-binding model, although the α value is somewhat lower than 0.34-0.38. Nevertheless, LSDA+U indicates considerable NNN interaction. Thus, band structure calculations strongly support the FSL rather than the HSL scenario

Additional evidence for the frustration in PbVO₃ is found if one considers the presence of long-range magnetic ordering in this compound. The HSL tends to long-range order even at very weak inter-layer coupling (for instance, Néel temperatures $T_{\rm N}$ of undoped high- T_c superconductors have the order of hundreds of K, see Ref. 23). If J_{\perp} in PbVO₃ is as small as 0.01 K (tight-binding result) $T_{\rm N} \sim 0.2 J_1 \approx 40$ K.²⁴ The phase transition at 40 K can

hardly be missed while analyzing experimental results. However, frustration effectively reduces $T_{\rm N}$ or even prevents the system from long-range magnetic ordering at all.

Summarizing, all the experimental data available for bulk samples of ${\rm PbVO_3}$ do not provide evidence for long-range magnetic ordering down to 1.8 K. Thermodynamic data (magnetic susceptibility, specific heat, thermal expansion, and resistivity) do not show any indications for intrinsic phase transitions, while low-temperature neutron diffraction reveals the absence of long-range spin ordering at 1.5 K.

Note that the recently reported thin films of ${\rm PbVO_3^{13,14}}$ show a different magnetic behavior with a possible magnetic ordering at 100–140 K. However, bulk phase and thin film may have distinct properties due to slightly different structures and strain effects. Detailed structural information for thin films of ${\rm PbVO_3}$ is not available, but the reported difference of the c parameter of the unit cell (4.67 and 5.02 Å in bulk and thin film, respectively) suggests considerable change of the structure in thin film as compared to bulk solid.²⁵

Thus, we conclude that magnetic frustration of the square lattice is a crucial feature of PbVO₃. If $\alpha > \alpha_{c1}$ [$\alpha_{c1} = 0.34$ (Ref. 2) or 0.24 (Ref. 3)] long-range ordering is suppressed and some kind of spin-liquid ground state is formed. Unfortunately, we can not give a more precise estimate of the α value for PbVO₃, hence we can not conclude if PbVO₃ falls into the spin-liquid region or is just close to its boundary. Anyway, the frustration in PbVO₃

is strong enough to suppress $T_{\rm N}$ considerably (at least by an order of magnitude as compared to the HSL estimate) or provide a disordered (spin-liquid or spin-glass) ground state.

Summarizing, this study provides strong evidence that PbVO₃ is the first example of S=1/2 square lattice system lying within or close to the critical region of the FSL phase diagram and lacking for long-range magnetic ordering down to low temperatures ($T_{\rm N}/J < 0.01$). A further study of the ground state and low-temperature properties of this system is of high interest. Unfortunately, we have to point out considerable difficulties in the synthesis of bulk single-phase samples (and, moreover, single crystals) of PbVO₃. The recent study of epitaxial thin films of PbVO₃^{13,14} provides an alternative route for the preparation of this interesting compound but thin films and bulk solids may have strikingly different properties as we have mentioned above.

In conclusion, we have shown that PbVO₃ reveals significant frustration of the square lattice that prevents this compound from long-range spin ordering down to 1.8 K. PbVO₃ lies very close to the critical region of the FSL phase diagram, and it may provide the first realization of disordered ground state for S=1/2 square lattice.

¹⁵ PbV₆O₁₁ undergoes ferromagnetic ordering at 90 K²⁶ while VO₂ reveals a metal-insulator transition at about 350 K. The latter transition is accompanied by a jump in the magnetic susceptibility (see, e.g. Ref. 27).

The resistivity curve reported in Ref. 9 shows an anomaly at 90 K. We assign this anomaly to ferromagnetic ordering

of PbV₆O₁₁ impurity, see Ref. 9 for details.
