Estimation of n non-identical unitary channels

Caleb O'Loan*

School of Mathematics and Statistics, University of St Andrews, KY16 9SS † (Dated: February 6, 2020)

We investigate the simultaneous estimation of n not necessarily identical unitary channels using multi-partite entanglement. We examine whether it is possible for the rate at which the mean square error decreases to be greater than that using the channels individually. For a reasonably general situation, in which there is no functional dependence between the channels, we show that this is not possible. We look at a case in which the channels are not necessarily identical but depend on a common variable. In this case, the mean square error decreases more rapidly using multi-partite entanglement.

PACS numbers: 03.65.Ta, 03.67.-a

Introduction. Estimation of quantum states and channels is of fundamental importance to quantum information theory. Estimation of unitary channels, when n copies are available, has received a lot of attention; for an accessible overview see [1]. Many schemes have been devised for which the error decreases at a much faster rate, compared to a straightforward approach of using each channel separately [2, 3]. This is analogous to the problem of transmitting a reference frame [4, 5, 6, 7]. This increase in the rate of estimation is possible both with [2, 3, 4, 5, 6] and without [7, 8] the use of entanglement.

As far as we are aware, no work has been done on the situation in which there are n non-identical channels. In this paper we investigate whether an increase in the rate of estimation is possible in this case. We look at the following two cases: (i) there are n unitary channels belonging to SU(d) specified by the parameters $\theta^1, \ldots, \theta^n$, (ii) there are n not necessarily identical one-parameter unitary channels which depend on a common variable. In the former scheme an increase in the rate of estimation is not possible; in the latter scheme it is.

To quantify the performances of estimation schemes we use the asymptotic limit of the mean square error $E[(\theta^i - \hat{\theta}^i)(\theta^j - \hat{\theta}^j)]$. Using the maximum likelihood estimator, as the number of measurements $N \to \infty$, the mean square error is approximately $(1/N)F_M^{-1}(\theta)$ [9], where $F_M(\theta)$ is the Fisher information matrix obtained from a single measurement M. The Fisher information for the parameter $\theta = (\theta^1, \dots, \theta^p)$ is the $p \times p$ matrix with entries

$$F_M(\theta)_{jk} \equiv \int p(\xi;\theta) \left(\frac{\partial \ln p(\xi;\theta)}{\partial \theta^j} \right) \left(\frac{\partial \ln p(\xi;\theta)}{\partial \theta^k} \right) d\xi.$$

The Cramér–Rao inequality states that the mean square error of an unbiased estimator t(x) is less than or equal to the inverse of the Fisher information,

$$\text{m.s.e.}_{\theta}[t(x)] \ge F_M(\theta)^{-1}. \tag{1}$$

It has been shown [10] that the SLD quantum information $H(\theta)$ is an upper bound on the Fisher information, i.e. $F_M(\theta) \leq H(\theta)$. The SLD quantum information for the parameter $\theta = (\theta^1, \dots, \theta^p)$ is defined as the matrix with entries

$$H_{jk} = \Re \operatorname{tr} \{ \lambda^j \rho \lambda^k \},$$

where λ^j is any self-adjoint solution to the matrix equation

$$\frac{d\rho}{d\theta^j} = \frac{1}{2} (\rho \lambda^j + \lambda^j \rho). \tag{2}$$

Given a state ρ_{θ} depending on some unknown parameter θ , and a POVM $\{M_m\}$ we get a measurement outcome x. The quantum Cramér–Rao inequality states that the mean square error of an unbiased estimator t(x) of θ is less than or equal to the inverse of the SLD quantum information, i.e.

$$\text{m.s.e.}_{\theta}[t(x)] \ge H^{-1}(\theta). \tag{3}$$

When $p \geq 2$, there exist families of states ρ_{θ} and σ_{θ} for which neither $H(\rho_{\theta}) \geq H(\sigma_{\theta})$ or $H(\rho_{\theta}) \leq H(\sigma_{\theta})$ is true. To deal with this, we compare the traces $\operatorname{tr}\{H(\theta)\}$ of the SLD quantum information.

Previous work has looked at how the error scales with the number of times U is used. We look at how the error scales with the number of input states used, as this is more convenient for us.

I. 'INDEPENDENT' CHANNELS

First we look at estimating n unitary channels from SU(d). The jth channel is specified by the parameter $\theta^j = (\theta^j_1, \dots, \theta^j_{d^2-1})$. These channels are supposed 'independent' in that there is no functional relationship between $\theta^1, \theta^2, \dots, \theta^{n-1}$ and θ^n . Estimation of the channels is a parametric problem.

We look at the mapping

$$\rho_0 \mapsto \otimes_{j=1}^n (U_{\theta^j} \otimes \mathbb{I}_R) \rho_0(U_{\theta^j}^{\dagger} \otimes \mathbb{I}_R). \tag{4}$$

 $^{^{\}dagger}\mathrm{URL}$: http://www.st-andrews.ac.uk/~cjo2

We show in Appendix A that using a tensor product of maximally entangled input states $\rho_0 = \bigotimes_{j=1}^n \rho_{mes}^j$ is sufficient to maximize the trace of the SLD quantum information of the output states of (4). This is not a necessary condition, as the 2n-partite entangled state $1/\sqrt{d}\sum_i |e_i\rangle \otimes \cdots \otimes |e_i\rangle$ also attains the maximum SLD quantum information. However, since these states are significantly harder to produce, we are better off using maximally entangled states. The SLD quantum information using a tensor product of maximally entangled states is attainable [11], so asymptotically the mean square error is $(1/N)H^{-1}(\theta)$.

For the mapping (4), an optimal estimation procedure for n 'independent' unitary channels, in terms of $\operatorname{tr}\{H\}$, is to estimate each one individually using a maximally entangled input state. The optimality of this procedure, in terms of $\operatorname{tr}\{H(\theta)\}$ has been shown by Ballester [11].

II. 'DEPENDENT' CHANNELS

We look at the case where we have n not necessarily identical channels which depend on a common parameter θ . These channels are of the form

$$U_{\theta}^{1} = \begin{pmatrix} 1 & 0 \\ 0 & e^{if_{1}(\theta)} \end{pmatrix}, \dots, \quad U_{\theta}^{n} = \begin{pmatrix} 1 & 0 \\ 0 & e^{if_{n}(\theta)} \end{pmatrix}, \quad (5)$$

where $0 \leq \theta \leq t$ and $\mathcal{H} = \mathbb{C}^2$. We can use each channel N times. We impose the following conditions on the functions f_j : (a) $f_j(\theta) : \mathbb{R} \mapsto \mathbb{R}$, (b) $df_j(\theta)/d\theta \geq 0$, and (c) $0 \leq \sum_j f_j(\theta) \leq \pi$, for all j and θ . We look at the mapping

$$\rho_0 \mapsto \otimes_{j=1}^n (U_\theta^j \otimes \mathbb{I}_R) \rho_0(U_\theta^{j\dagger} \otimes \mathbb{I}_R), \tag{6}$$

where $\rho_0 \in S(\otimes^n(\mathcal{H} \otimes \mathcal{H}_R))$; we denote by $S(\mathcal{H})$ the set of states on \mathcal{H} . We compare the SLD quantum information between (i) using a tensor product of maximally entangled states, (ii) using a 2n-partite entangled state. In this case using 2n-partite entanglement gives considerably larger SLD quantum information.

Using the input state $\rho_0 = \rho_{mes}^1 \otimes \cdots \otimes \rho_{mes}^n$, where $\rho_{mes}^j = |\psi_u^j\rangle\langle\psi_u^j|$, $|\psi_u^j\rangle = 1/\sqrt{2}(|00\rangle + |11\rangle)$, gives an SLD quantum information of $\sum_{j=1}^n (df_j/d\theta)^2$, which is attainable using a tensor product of the POVM $\{M_0^j = |\psi_u^j\rangle\langle\psi_u^j|, M_1^j = \mathbb{I} - |\psi_u^j\rangle\langle\psi_u^j|\}$.

 $|\psi_u^j\rangle\langle\psi_u^j|, M_1^j=\mathbb{I}-|\psi_u^j\rangle\langle\psi_u^j|\}.$ If we use the input state $\rho_0=|\psi_0\rangle\langle\psi_0|$, where $|\psi_0\rangle=1/\sqrt{2}(|00..0\rangle+|11..1\rangle)$, we get an SLD quantum information of $(\sum_{j=1}^n df_j/d\theta)^2$. As $df_j/d\theta\geq 0$ for all j, this is considerably larger than the SLD quantum information using a tensor product of maximally entangled states.

The phase ϕ of the output state is in one-to-one correspondence with θ , because of conditions (b) and (c); in fact $\phi = \sum_{j=1}^{n} f_j(\theta)$. Using the POVM $\{M_0 = |\psi_0\rangle\langle\psi_0|, M_1 = \mathbb{I} - |\psi_0\rangle\langle\psi_0|\}$ we get $p(0;\phi) = \cos^2(\phi/2)$. We perform (6) N times and each time use this POVM. From the measurement outcomes we get an estimate $\hat{\phi}$

of ϕ by $\cos^2(\hat{\phi}/2) = n_0/N$, where n_0 is the number of times we get the outcome x=0. Because of condition (c) on the functions $f_j(\theta)$, $\cos^2(\hat{\phi}/2)$ is in one-to-one correspondence with $\hat{\phi}$ and hence $\hat{\theta}$. This POVM gives a Fisher information equal to the SLD quantum information. Hence as $N \to \infty$ we get a mean square error of $1/(N(\sum_{j=1}^n df_j/d\theta)^2)$ compared to $1/(N\sum_{j=1}^n (df_j/d\theta)^2)$ using a tensor product of maximally entangled input states.

It is known that when we have n identical simple unitary channels, we can obtain an increase in the rate of estimation without using entanglement [1]. A simple way is to use each of the n channels in sequence on a single input state. Consider the unitary channel $U_{\theta} = \mathrm{Diag}(1, e^{i\theta})$, i.e.

$$\rho_0 \mapsto U_\theta^n \rho_0 U_\theta^{n\dagger}, \quad U_\theta^n = U_\theta U_\theta \cdots U_\theta.$$
(7)

We repeat (7) N times using the input state $\rho_x = |\psi_x\rangle\langle\psi_x|$ where $|\psi_x\rangle = 1/\sqrt{2}(|0\rangle + |1\rangle)$, and the POVM $\{|\psi_x\rangle\langle\psi_x|, \mathbb{I} - |\psi_x\rangle\langle\psi_x|\}$. We call this the sequential scheme. As $N\to\infty$, we obtain a mean square error that scales as $1/(Nn^2)$. We can use this sequential scheme with n non-identical channels, i.e.

$$\rho_0 \mapsto (U_\theta^1 \cdots U_\theta^n) \rho_0 (U_\theta^1 \cdots U_\theta^n)^{\dagger}, \tag{8}$$

where $\rho_0 \in S(\mathcal{H})$. Using the input state $\rho_x = |\psi_x\rangle\langle\psi_x|$ where $|\psi_x\rangle = 1/\sqrt{2}(|0\rangle + |1\rangle)$, and the POVM $\{|\psi_x\rangle\langle\psi_x|, \mathbb{I} - |\psi_x\rangle\langle\psi_x|\}$ we get $p(0;\phi) = \cos^2(\phi/2)$. Performing (8) N times we get an estimate $\hat{\phi}$ and hence $\hat{\theta}$. We get the same Fisher information as (6) using a 2n-partite entangled state, and hence the same mean square error.

Since multi-partite entanglement is difficult to create, we are better off using the sequential scheme (8).

Conditions (b) and (c) for the functions $f_j(\theta)$ are very strict. We can still get a considerable increase in the rate of estimation without these conditions. If condition (c) does not hold, the phase ϕ of the output state is not in one-to-one correspondence with $p(0;\phi) = \cos^2(\phi/2)$. If we modify condition (c) to $0 \le \sum_j f_j(\theta) \le 2\pi$, we can still find ϕ but we shall need to perform an extra measurement $\{|\psi_y\rangle\langle\psi_y|, \mathbb{I}-|\psi_y\rangle\langle\psi_y|\}$, where $|\psi_y\rangle = 1/\sqrt{2}(|0\rangle + i|1\rangle)$, a small number of times to determine the sign of $\cos(\phi/2)$. Then we can estimate ϕ and hence θ . If $0 \le \sum_j f_j(\theta) \le 2\pi$ does not hold, the phase ϕ of the output state is not in one-to-one correspondence with θ . We can get around this using a method similar to that of Zhengfeng et al [1], based on Rudolph and Grover [7].

Zhengfeng et al [1] looked at the case where $f_j(\theta) = 2\pi\theta$ for all j. Their scheme involves first using a single channel n times to get an interval in which θ almost certainly lives. Then they use two or three channels in sequence to 'amplify' θ . This is repeated n times until they get a narrower interval for θ . This is continued until all channels are being used simultaneously. The mean square error scales as $(\log N'/N')^2$, where N' is the total number of times U_{θ} is used.

In our case, the situation is more complex, as the functions $f_i(\theta)$ are more general and not necessarily identical. The finer details of how we go about this and how the mean square error would behave, depend on the functions $f_i(\theta)$. We give a very brief overview of a possible procedure. We start by using a single unitary U_1 n times to get an interval for $f_1(\theta)$ and hence θ . Then we use U_2U_1 to get an estimate of $f_1(\theta) + f_2(\theta)$ and hence a more accurate estimate of θ . We continue this process till we are using all the channels simultaneously and we have a very narrow interval for θ . We expect that asymptotically, the mean square error is approximately $1/(N(\sum_{j=1}^n df_j/d\theta)^2)$, where N is the number of input states used. We leave a more in-depth analysis for further work.

If neither (b) nor (c) are satisfied we propose the following scheme: (i) Use each of the channels individually n times to get an estimate $\hat{\theta}$, (ii) Divide the channels into two groups: $A = \{U_{\theta}^{j}, df_{j}/d\theta \geq 0 \text{ at } \hat{\theta}\},$ $B = \{U_{\theta}^{k}, df_{k}/d\theta < 0 \text{ at } \hat{\theta}\}, \text{ (iii) Use an iterative pro-}$ cedure for the two groups separately, but sharing information about θ to make the confidence intervals shorter.

APPENDIX A: PROOF

We are looking at unitary channels of the form $U_{\theta} = \exp(i\sum_{j}\theta_{j}t_{j})$ where $t_{j} = t_{j}^{\dagger}$, $\operatorname{tr}\{t_{j}\} = 0$ and $\operatorname{tr}\{t_j t_k\} = \delta_{jk}$. We denote by $H_{\theta^j}(\rho_0)$, the SLD quantum information for the *j*th channel

$$\rho_0 \mapsto (U_{\theta^j} \otimes \mathbb{I}) \rho_0(U_{\theta^j}^{\dagger} \otimes \mathbb{I}).$$

The SLD quantum information of (4) using a tensor product of maximally entangled states is $H_{\theta}(\otimes_{i=1}^{n}\rho_{mes}) =$ $\operatorname{Diag}(H_{\theta^1}(\rho_{mes}),\ldots,H_{\theta^n}(\rho_{mes})).$

Lemma 1 For all unitary channels of the form

$$\rho_0 \mapsto (U_\theta \otimes \mathbb{I})\rho_0(U_\theta^\dagger \otimes \mathbb{I}), \tag{A1}$$

the trace of the SLD quantum information is maximized by a maximally entangled state, i.e.

$$\operatorname{tr}\{H_{\theta}(\rho_0)\} \le \operatorname{tr}\{H_{\theta}(\rho_{mes})\}. \tag{A2}$$

Equality holds in (A2) if and only if ρ_0 is a maximally entangled state.

Proof. From the appendix of Ballester [12] we know that for the channel (A1)

$$\operatorname{tr}\{(H_{\theta}(\rho_{mes}))^{-1}H_{\theta}(\rho_{0})\} \le d^{2} - 1.$$
 (A3)

It is simple to show that for unitary channels of the form $U_{\theta} = \exp(i \sum_{j} \theta_{j} t_{j})$ we have $H_{\theta}(\rho_{mes}) = (4/d) \mathbb{I}_{d^{2}-1}$. Substituting into (A3) we get

$$\operatorname{tr}\{H_{\theta}(\rho_0)\} \le \frac{4(d^2 - 1)}{d} = \operatorname{tr}\{H_{\theta}(\rho_{mes})\}.$$
 (A4)

Since equality holds in (A3) if and only if ρ_0 is a maximally entangled state [12], equality holds in (A4) if and only if ρ_0 is a maximally entangled state.

Lemma 2 The trace of the SLD quantum information for (4) is maximized by a tensor product of maximally entangled states, i.e.

$$\operatorname{tr}\{H_{\theta}(\rho_{0})\} \leq \operatorname{tr}\{H_{\theta}(\otimes_{j=1}^{n} \rho_{mes}^{j})\}, \quad (A5)$$

$$\rho_{0} \in S(\otimes^{n}(\mathcal{H} \otimes \mathcal{H}_{R})), \quad \rho_{mes}^{j} \in S(\mathcal{H} \otimes \mathcal{H}_{R}).$$

For pure states a solution of (2) is $\lambda^j = 2d\rho_\theta/d\theta^j$. It is not difficult to show that for the set of states $U_{\theta} \rho_0 U_{\theta}^{\dagger}$ the SLD quantum information is the matrix with entries

$$H_{\theta_{jk}}(\rho_0) = 4\Re \operatorname{tr}\{U_{\theta}^{j}\rho_0 U_{\theta}^{k\dagger}\} + 4\operatorname{tr}\{U_{\theta}^{j}\rho_0 U_{\theta}^{\dagger}\}\operatorname{tr}\{U_{\theta}^{k}\rho_0 U_{\theta}^{\dagger}\}, \quad (A6)$$

where $U_{\theta}^{j} = \partial_{\theta^{j}} U_{\theta}$. In (4) $U_{\theta} = \bigotimes_{j=1}^{n} U_{\theta^{j}} \otimes \mathbb{I}_{R}$. Consider an arbitrary diagonal element of the SLD quantum information, i.e. $H_{\theta_{mm}}$, where $m(j,k) = (j - 1)^{-1}$ 1)p + k, corresponding to the parameter θ_k^j . From (A6),

$$H_{\theta_{mm}}(\rho_0) = 4\operatorname{tr}(U_{\theta}^{j_k}\rho_0 U_{\theta}^{j_k\dagger}) + 4\left(\operatorname{tr}(U_{\theta}^{j_k}\rho_0 U_{\theta}^{\dagger})\right)^2,$$

where $U^{j_k} = \partial_{\theta_j^j} U_{\theta_j}$. For convenience we label the Hilbert space on which $U_{\theta^i} \otimes \mathbb{I}_R$ acts as \mathcal{H}_i and so the Hilbert space on which U_{θ} acts is $\bigotimes_{i=1}^{n} \mathcal{H}_{i}$. Taking the partial trace over $\mathcal{H}_{B_j} = \bigotimes_{i \neq j}^n \mathcal{H}_i$, we get

$$H_{\theta_{mm}}(\rho_0) = 4\operatorname{tr}\left((U_{\theta^j}^{j_k} \otimes \mathbb{I})\rho^A(U_{\theta^j}^{j_k\dagger} \otimes \mathbb{I})\right) + 4\left(\operatorname{tr}(U_{\theta^j}^{j_k} \otimes \mathbb{I})\rho^A\left(U_{\theta^j}^{\dagger} \otimes \mathbb{I}\right)\right)^2, (A7)$$

where $\rho^A = \operatorname{tr}_{\mathcal{H}_{B_i}} \{\rho_0\}$, the reduced state of ρ_0 . In general, ρ^A is mixed, and so $\rho^A = \sum_{i=1}^{d^2} p_i \rho_i$, where ρ_i are pure and orthogonal. Substituting $\rho^A = \sum_{i=1}^{d^2} p_i \rho_i$ into

$$H_{\theta_{mm}}(\rho_0) = \sum_{i=1}^{d^2} p_i \bigg(4 \operatorname{tr}(U^{j_k} \otimes \mathbb{I}) \rho_i (U^{j_k \dagger} \otimes \mathbb{I}) + 4 \left(\operatorname{tr}(U^{j_k} \otimes \mathbb{I}) \rho_i (U^{\dagger} \otimes \mathbb{I}) \right)^2 \bigg),$$

and hence by (A6)

$$H_{\theta_{mm}}(\rho_0) = \sum_{i=1}^{d^2} p_i (H_{\theta^j}(\rho_i))_{kk}.$$

Summing over k we get

$$\sum_{k} H_{\theta_{m(j,k)m(j,k)}}(\rho_{0}) = \sum_{k=1}^{d^{2}-1} \sum_{i=1}^{d^{2}} p_{i}(H_{\theta^{j}}(\rho_{i}))_{kk}$$

$$= \sum_{i=1}^{d^{2}} p_{i} \operatorname{tr}\{H_{\theta^{j}}(\rho_{i})\}.$$

$$< \operatorname{tr}\{H_{\theta^{j}}(\rho_{mes})\}.$$
