Abstract

The various sources of Rational Terms contributing to the one-loop amplitudes are critically discussed. We show that the terms originating from the generic $(n - 4)$ -dimensional structure of the numerator of the one-loop amplitude can be derived by using appropriate Feynman rules within a tree-like computation. For the terms that originate from the reduction of the 4-dimensional part of the numerator, we present two different strategies and explicit algorithms to compute them.

1 Introduction

In the last few years, a big effort has been devoted by several authors to the problem of computing one-loop amplitudes efficiently [1]. Besides Standard techniques, where tensor reduction/computation is performed, numerically or analytically, new developments emerged, originally inspired by unitarity arguments (the so called unitary and generalized unitarity methods) [2] - [5], in which the tensor reduction/computation is substituted by the problem of determining the *coefficients* of the contributing scalar one-loop functions. This possibility relies on the fact that the basis of one-loop integrals is known in terms of Boxes, Triangles, Bubbles and (in massive theories) Tadpoles, in such a way that, schematically, one can write a Master Equation for any one-loop amplitude \mathcal{M} such as:

$$\mathcal{M} = \sum_i d_i \text{Box}_i + \sum_i c_i \text{Triangle}_i + \sum_i b_i \text{Bubble}_i + \sum_i a_i \text{Tadpole}_i + \text{R}, \quad (1)$$

where d_i , c_i , b_i and a_i are the coefficients to be determined.

Nevertheless, in practice, only the part of the amplitude proportional to the one-loop scalar functions can be obtained straightforwardly in the unitary cut method. The remaining Rational Terms, RTs, (R in the above equation) should be reconstructed by other means, either by direct computation [6, 7] or by bootstrapping methods [8]. In [9] the RTs are obtained by explicitly computing the amplitude at different integer value of the space-time dimensions. On the other hand, in another recently proposed method, OPP [10], a class of terms contributing to R can be naturally derived in the same framework used to determine all the other coefficients.

In this paper, we critically analyze the various sources of RTs appearing in one-loop amplitudes, by classifying them in two categories: $\text{R} = \text{R}_1 + \text{R}_2$, also presenting a few computational methods. In the next section, we investigate the origin of R_2 and develop a practical computational strategy. In Section 3, after a brief recall of the OPP method, we present a way to compute R_1 , strictly connected to the OPP framework. In Section 4, we describe yet another method that relies on cuts in n -dimensions. This second method is proven more suitable for numerical applications within the OPP algorithm and may also be applied in a more general framework. Finally, in the last section, we outline our conclusions.

2 The origin of R_2

Our starting point is the general expression for the *integrand* of a generic m -point one-loop (sub-)amplitude [10]

$$\bar{A}(\bar{q}) = \frac{\bar{N}(\bar{q})}{\bar{D}_0 \bar{D}_1 \cdots \bar{D}_{m-1}}, \quad \bar{D}_i = (\bar{q} + p_i)^2 - m_i^2, \quad p_0 \neq 0. \quad (2)$$

In the previous equation, dimensional regularization is assumed, so that we use a bar to denote objects living in $n = 4 + \epsilon$ dimensions. Furthermore $\bar{q}^2 = q^2 + \tilde{q}^2$, where \tilde{q}^2

is ϵ -dimensional and $(\tilde{q} \cdot q) = 0$. The numerator function $\bar{N}(\bar{q})$ can be also split into a 4-dimensional plus a ϵ -dimensional part

$$\bar{N}(\bar{q}) = N(q) + \tilde{N}(\tilde{q}^2, q, \epsilon). \quad (3)$$

$N(q)$ is 4-dimensional (and will be discussed in the next section) while $\tilde{N}(\tilde{q}^2, q, \epsilon)$ gives rise to the RTs of kind R_2 , defined as

$$R_2 \equiv \frac{1}{(2\pi)^4} \int d^n \bar{q} \frac{\tilde{N}(\tilde{q}^2, q, \epsilon)}{\bar{D}_0 \bar{D}_1 \cdots \bar{D}_{m-1}} \equiv \frac{1}{(2\pi)^4} \int d^n \bar{q} \mathcal{R}_2. \quad (4)$$

To investigate the explicit form of $\tilde{N}(\tilde{q}^2, q, \epsilon)$ it is important to understand better the separation in Eq. (3). From a given *integrand* $\bar{A}(\bar{q})$ this is obtained by splitting, in the numerator function, the n -dimensional integration momentum \bar{q} , the n -dimensional γ matrices $\bar{\gamma}_{\bar{\mu}}$ and the n -dimensional metric tensor $\bar{g}^{\bar{\mu}\bar{\nu}}$ into a 4-dimensional component plus remaining pieces:

$$\begin{aligned} \bar{q} &= q + \tilde{q}, \\ \bar{\gamma}_{\bar{\mu}} &= \gamma_{\mu} + \tilde{\gamma}_{\bar{\mu}}, \\ \bar{g}^{\bar{\mu}\bar{\nu}} &= g^{\mu\nu} + \tilde{g}^{\bar{\mu}\bar{\nu}}. \end{aligned} \quad (5)$$

Notice that, when a n -dimensional index is contracted with a 4-dimensional (observable) vector v_{μ} , the 4-dimensional part is automatically selected. For example

$$\bar{q} \cdot v = q \cdot v \quad \text{and} \quad \bar{\psi} = \psi. \quad (6)$$

A practical way to compute R_2 is determining, once for all, tree-level like Feynman Rules for the theory at hand by calculating, with the help Eq. (5), the R_2 part coming from one-particle irreducible amplitudes up to four external legs. The fact that four external legs are enough is guaranteed by the ultraviolet nature of the RTs, proven in [6].

As an illustrative example, we derive the complete set of the Feynman Rules needed in QED. Along such a line R_2 can be straightforwardly computed in any theory. We start from the one-loop $\gamma e^+ e^-$ amplitude in Fig. 1. The numerator can be written as follows

$$\begin{aligned} \bar{N}(\bar{q}) &\equiv e^3 \left\{ \bar{\gamma}_{\bar{\beta}} (\bar{Q}_1 + m_e) \gamma_{\mu} (\bar{Q}_2 + m_e) \bar{\gamma}^{\bar{\beta}} \right\} \\ &= e^3 \left\{ \gamma_{\beta} (Q_1 + m_e) \gamma_{\mu} (Q_2 + m_e) \gamma^{\beta} \right. \\ &\quad \left. - \epsilon (Q_1 - m_e) \gamma_{\mu} (Q_2 - m_e) + \epsilon \tilde{q}^2 \gamma_{\mu} - \tilde{q}^2 \gamma_{\beta} \gamma_{\mu} \gamma^{\beta} \right\}, \end{aligned} \quad (7)$$

where all ϵ -dimensional γ -algebra has been explicitly worked out ¹ in order to get the desired splitting. The first term in the l.h.s of Eq. (7) is $N(q)$, while the sum of the remaining three define $\tilde{N}(\tilde{q}^2, q, \epsilon)$ for the case at hand. By inserting $\tilde{N}(\tilde{q}^2, q, \epsilon)$ in Eq. (4)

¹ ϵ -dimensional γ matrices freely anti-commute with four-dimensional ones: $\{\gamma_{\mu}, \tilde{\gamma}_{\nu}\} = 0$.

Figure 1: QED $\gamma e^+ e^-$ diagram in n dimensions.

and using the fact that

$$\begin{aligned} \int d^n \bar{q} \frac{\tilde{q}^2}{\bar{D}_0 \bar{D}_1 \bar{D}_2} &= -\frac{i\pi^2}{2} + \mathcal{O}(\epsilon), \\ \int d^n \bar{q} \frac{q_\mu q_\nu}{\bar{D}_0 \bar{D}_1 \bar{D}_2} &= -\frac{i\pi^2}{2\epsilon} g_{\mu\nu} + \mathcal{O}(1), \end{aligned} \quad (8)$$

gives

$$R_2 = -\frac{ie^3}{8\pi^2} \gamma_\mu + \mathcal{O}(\epsilon), \quad (9)$$

that can be used to define the following effective vertex:

Figure 2: QED $\gamma e^+ e^-$ effective vertex contributing to R_2 .

With analogous techniques, taking also into account the integrals given in Eq. (17), one gets all the remaining QED effective vertices given in Fig. 3.

To summarize, the problem of computing R_2 is reduced to a tree level calculation and we consider it fully solved. The R_1 part is, instead, deeply connected to the structure of the one-loop amplitude, as we shall see in the next section. It is worthwhile to mention that only the full $R = R_1 + R_2$ constitutes a physical gauge-invariant quantity in dimensional regularization.

3 The OPP method and the origin of R_1

The OPP reduction algorithm provides a useful framework to understand the origin of the RTs of kind R_1 . The starting point of the method is an expansion of $N(q)$ in terms of

4-dimensional denominators $D_i = (q + p_i)^2 - m_i^2$

$$\begin{aligned}
N(q) &= \sum_{i_0 < i_1 < i_2 < i_3}^{m-1} \left[d(i_0 i_1 i_2 i_3) + \tilde{d}(q; i_0 i_1 i_2 i_3) \right] \prod_{i \neq i_0, i_1, i_2, i_3}^{m-1} D_i \\
&+ \sum_{i_0 < i_1 < i_2}^{m-1} \left[c(i_0 i_1 i_2) + \tilde{c}(q; i_0 i_1 i_2) \right] \prod_{i \neq i_0, i_1, i_2}^{m-1} D_i \\
&+ \sum_{i_0 < i_1}^{m-1} \left[b(i_0 i_1) + \tilde{b}(q; i_0 i_1) \right] \prod_{i \neq i_0, i_1}^{m-1} D_i \\
&+ \sum_{i_0}^{m-1} \left[a(i_0) + \tilde{a}(q; i_0) \right] \prod_{i \neq i_0}^{m-1} D_i \\
&+ \tilde{P}(q) \prod_i^{m-1} D_i.
\end{aligned} \tag{10}$$

Inserted back in Eq. (2), this expression simply states the multi-pole nature of any m -point one-loop amplitude. The fact that only terms up to 4 poles appear is due to the fact that m -point scalar loop functions with $m > 4$ are always expressible in terms of boxes up to contributions $\mathcal{O}(\epsilon)$. The last term with no poles, $\tilde{P}(q)$, has been inserted for generality, but is zero in practical calculations where m -point amplitudes behave such as $N(\lambda q) \rightarrow \lambda^m$ when $\lambda \rightarrow \infty$. The coefficients of the poles can be further split in two pieces. A piece that still depend on q (the terms $\tilde{d}, \tilde{c}, \tilde{b}, \tilde{a}$), that vanishes upon integration due to Lorentz invariance, and a piece that do not depend on q (the terms d, c, b, a). Such a separation is always possible, as shown in [10], and, with this choice, the latter set of coefficients is therefore immediately interpretable as the ensemble of the coefficients of all possible 4, 3, 2, 1-point one-loop functions contributing to the amplitude.

Once Eq. (10) is established, the task of computing the one-loop amplitude is then reduced, in the OPP method, to the algebraical problem of fitting the coefficients d, c, b, a by evaluating the function $N(q)$ a sufficient number of times, at different values of q , and then inverting the system. Notice that this can be performed *at the amplitude level* and that one does not need to repeat the work for all Feynman diagrams, provided their sum

$$\begin{aligned}
\mu \begin{array}{c} \xrightarrow{p} \\ \text{wavy} \\ \bullet \\ \text{wavy} \\ \nu \end{array} &= -\frac{ie^2}{8\pi^2} g_{\mu\nu} (2m_e^2 - p^2/3) \\
\begin{array}{c} \xrightarrow{p} \\ \text{solid} \\ \bullet \\ \text{solid} \end{array} &= \frac{ie^2}{16\pi^2} (-\not{p} + 2m_e) \\
\begin{array}{c} \mu \text{ wavy} \nearrow \\ \bullet \\ \sigma \text{ wavy} \searrow \\ \nu \text{ wavy} \nearrow \\ \rho \text{ wavy} \searrow \end{array} &= \frac{ie^4}{12\pi^2} (g_{\mu\nu} g_{\rho\sigma} + g_{\mu\rho} g_{\nu\sigma} + g_{\mu\sigma} g_{\nu\rho})
\end{aligned}$$

Figure 3: QED $\gamma\gamma$, ee and $\gamma\gamma\gamma\gamma$ effective vertices contributing to R_2 .

is known.

The OPP expansion is written in terms of 4-dimensional denominators. On the other hand, n -dimensional denominators \bar{D}_i appear in Eq. (2), that differ by an amount \tilde{q}^2 from their 4-dimensional counterparts

$$\bar{D}_i = D_i + \tilde{q}^2 \quad (11)$$

The result of this is a mismatch in the cancellation of the n -dimensional denominators of Eq. (2) with the 4-dimensional ones of Eq. (10) (the OPP expansion), that originates a Rational Part. In fact, by inserting Eq. (11) into Eq. (10), one can rewrite it in terms of n -dimensional denominators (therefore restoring the exact cancellation), but at the price of adding an extra piece $f(\tilde{q}^2, q)$. The RTs of kind R_1 are defined as

$$R_1 \equiv \frac{1}{(2\pi)^4} \int d^n \bar{q} \frac{f(\tilde{q}^2, q)}{D_0 \bar{D}_1 \cdots \bar{D}_{m-1}}. \quad (12)$$

The explicit form of the function $f(\tilde{q}^2, q)$ can be easily and explicitly obtained, in the framework of the OPP method, by rewriting any denominator appearing in Eq. (2) as follows

$$\frac{1}{\bar{D}_i} = \frac{\bar{Z}_i}{D_i}, \quad \text{with} \quad \bar{Z}_i \equiv \left(1 - \frac{\tilde{q}^2}{D_i}\right). \quad (13)$$

This results in

$$\bar{A}(\bar{q}) = \frac{N(q)}{D_0 D_1 \cdots D_{m-1}} \bar{Z}_0 \bar{Z}_1 \cdots \bar{Z}_{m-1} + \mathcal{R}_2, \quad (14)$$

where \mathcal{R}_2 is the integrand function introduced in Eq. (4). Then, by inserting Eq. (10) in Eq. (14), one obtains

$$\begin{aligned} \bar{A}(\bar{q}) &= \sum_{i_0 < i_1 < i_2 < i_3}^{m-1} \frac{d(i_0 i_1 i_2 i_3) + \tilde{d}(q; i_0 i_1 i_2 i_3)}{D_{i_0} D_{i_1} D_{i_2} D_{i_3}} \prod_{i \neq i_0, i_1, i_2, i_3}^{m-1} \bar{Z}_i \\ &+ \sum_{i_0 < i_1 < i_2}^{m-1} \frac{c(i_0 i_1 i_2) + \tilde{c}(q; i_0 i_1 i_2)}{D_{i_0} \bar{D}_{i_1} \bar{D}_{i_2}} \prod_{i \neq i_0, i_1, i_2}^{m-1} \bar{Z}_i \\ &+ \sum_{i_0 < i_1}^{m-1} \frac{b(i_0 i_1) + \tilde{b}(q; i_0 i_1)}{D_{i_0} \bar{D}_{i_1}} \prod_{i \neq i_0, i_1}^{m-1} \bar{Z}_i \\ &+ \sum_{i_0}^{m-1} \frac{a(i_0) + \tilde{a}(q; i_0)}{D_{i_0}} \prod_{i \neq i_0}^{m-1} \bar{Z}_i \\ &+ \tilde{P}(q) \prod_i^{m-1} \bar{Z}_i + \mathcal{R}_2. \end{aligned} \quad (15)$$

R_1 is then produced, after integrating over $d^n \bar{q}$, by the \tilde{q}^2 dependence coming from the various \bar{Z}_i in Eq. (15). This strategy have been adopted in [11], where also all needed integrals have been carefully classified and computed.

Although rather transparent, the above derivation of R_1 has two drawbacks. First of all, it requires the knowledge of the spurious terms ². Secondly, it is not suitable when combining diagrams together because, when taking common denominators, additional terms containing \tilde{q}^2 appear in the numerator, that may give rise to new rational parts. The bookkeeping of such new structures is equivalent to the treatment of each diagram separately, jeopardizing the ability of the 4-dimensional OPP technique of dealing directly with the amplitude. For these reasons we present, in the next section, a different way of attacking this problem that does not rely on spurious terms and that also allows one to combine diagrams *before* fitting the coefficients d, c, b, a . This second method is better suited for a numerical implementation, and it has been already successfully implemented in a Fortran code [12].

4 The n -dimensional cuttings to compute R_1

The Rational Terms R_1 can be computed by looking at the implicit mass dependence (namely reconstructing powers of \tilde{q}^2) in the coefficients d, c, b of the one-loop functions, once \tilde{q}^2 is reintroduced through the mass shift

$$m_i^2 \rightarrow m_i^2 - \tilde{q}^2. \quad (16)$$

This procedure is formally equivalent, in the generalized unitarity framework, to the applications of n -dimensional cuts, and is obtained, in the OPP language, by simply performing the OPP expansion of Eq. (10) directly in terms of the n -dimensional denominators of Eq. (11). By doing so, all coefficients of the OPP expansion start depending on \tilde{q}^2 . The spurious terms keep being spurious, because they vanish due to Lorentz invariance (that is untouched when including powers of \tilde{q}^2), while the coefficients d, c, b generate the following extra integrals [10]

$$\begin{aligned} \int d^n \bar{q} \frac{\tilde{q}^2}{\bar{D}_i \bar{D}_j} &= -\frac{i\pi^2}{2} \left[m_i^2 + m_j^2 - \frac{(p_i - p_j)^2}{3} \right] + \mathcal{O}(\epsilon), \\ \int d^n \bar{q} \frac{\tilde{q}^2}{\bar{D}_i \bar{D}_j \bar{D}_k} &= -\frac{i\pi^2}{2} + \mathcal{O}(\epsilon), \\ \int d^n \bar{q} \frac{\tilde{q}^4}{\bar{D}_i \bar{D}_j \bar{D}_k \bar{D}_l} &= -\frac{i\pi^2}{6} + \mathcal{O}(\epsilon). \end{aligned} \quad (17)$$

One can prove that

$$\begin{aligned} b(ij; \tilde{q}^2) &= b(ij) + \tilde{q}^2 b^{(2)}(ij), \\ c(ijk; \tilde{q}^2) &= c(ijk) + \tilde{q}^2 c^{(2)}(ijk). \end{aligned} \quad (18)$$

²After multiplication with the \bar{Z}_i , they give non vanishing contributions.

Furthermore, by using Eq. (16), the first line of Eq. (10) becomes

$$\mathcal{D}^{(m)}(q, \tilde{q}^2) \equiv \sum_{i_0 < i_1 < i_2 < i_3}^{m-1} \left[d(i_0 i_1 i_2 i_3; \tilde{q}^2) + \tilde{d}(q; i_0 i_1 i_2 i_3; \tilde{q}^2) \right] \prod_{i \neq i_0, i_1, i_2, i_3}^{m-1} \bar{D}_i, \quad (19)$$

and the following expansion holds

$$\mathcal{D}^{(m)}(q, \tilde{q}^2) = \sum_{j=2}^m \tilde{q}^{(2j-4)} d^{(2j-4)}(q), \quad (20)$$

where the last coefficient is independent on q

$$d^{(2m-4)}(q) = d^{(2m-4)}. \quad (21)$$

In practice, once the 4-dimensional coefficients have been determined, one simply redoes the fits for different values of \tilde{q}^2 , in order to determine $b^{(2)}(ij)$, $c^{(2)}(ijk)$ and $d^{(2m-4)}$. Such three quantities are the coefficients of the three extra scalar integrals listed in Eq. (17), respectively, so that

$$\begin{aligned} R_1 &= -\frac{i}{96\pi^2} d^{(2m-4)} - \frac{i}{32\pi^2} \sum_{i_0 < i_1 < i_2}^{m-1} c^{(2)}(i_0 i_1 i_2) \\ &\quad - \frac{i}{32\pi^2} \sum_{i_0 < i_1}^{m-1} b^{(2)}(i_0 i_1) \left(m_{i_0}^2 + m_{i_1}^2 - \frac{(p_{i_0} - p_{i_1})^2}{3} \right). \end{aligned} \quad (22)$$

In Appendix A, we prove Eqs. (18)-(21), we single out the origin of $d^{(2m-4)}$ as the coefficient of the last integral of Eq. (17) and we show how it can be also derived outside the OPP technique. Finally, yet another way of computing $d^{(2m-4)}$ can be obtained by noticing that

$$d^{(2m-4)} = \lim_{\tilde{q}^2 \rightarrow \infty} \frac{\mathcal{D}^{(m)}(q, \tilde{q}^2)}{\tilde{q}^{(2m-4)}}. \quad (23)$$

This last method is also implemented in the code of Ref. [12].

We close this section by stressing that the way of computing the coefficients appearing in Eq. (22) is immaterial. Therefore the method to extract R_1 described in this section, namely by looking at the mass dependence of the coefficients of the scalar loop functions, can be used independently on the OPP technique. In particular, one can derive all needed coefficients also with the help of analytical methods.

5 Conclusions

We have discussed and clarified the origin of the Rational Terms appearing in one-loop amplitudes, showing that they can be classified in two classes. The first class (R_2) can be computed by defining tree-level like Feynman rules for the theory at hand. We precisely outlined the way to derive the needed extra Feynman rules, listing them explicitly in the

case of QED. We therefore consider the problem of computing R_2 completely solved. The second piece (R_1) can be calculated in two different ways. We presented a first technique that relies on the OPP method and a second, more general, computational strategy. Both methods have been successfully tested within the OPP method. The second one, however, is more suitable for a numerical implementation, and it has been used in the numerical code `CutTools`.

Appendices

A The \tilde{q}^2 dependence of the OPP coefficients

Our starting point is a rank r tensor m -point *integrand* defined as

$$A_{m;r} \equiv \frac{q_{\mu_1} \cdots q_{\mu_r}}{D_0 \cdots D_{m-1}} \quad (m > 3, r > 1). \quad (24)$$

By expressing the integration momentum q in terms of the basis of the external vectors, with coefficients linearly depending on the propagator function appearing in the denominator [10], one ends up in an expression that it is identical to the OPP master equation plus terms containing higher-point scalar amplitudes $A_{k;0}$ $k = 5, \dots, m$. Since all reductions formula used so far are simple polynomial in terms of \tilde{q}^2 , the same is true for all coefficients appearing in that expansion. This, in conjunction with the fact that the maximum rank allowed $r = m$, easily proves first of all Eq. (18). In the next step one reduces the k -point scalar terms $k = 5, \dots, m$ in terms of the 4-point ones at the integrand level. After that step the individual d and \tilde{d} coefficients become rational functions of \tilde{q}^2 . Nevertheless, since the $\mathcal{D}^{(m)}(q, \tilde{q}^2)$ of Eqs. (19) and (20) is nothing more than the combined numerator of all scalar terms with $k = 4, \dots, m$, and all coefficients are polynomials in \tilde{q}^2 , so is the $\mathcal{D}^{(m)}(q, \tilde{q}^2)$ function. Finally it is straightforward to see that in the OPP expansion in terms of n -dimensional propagators, the $\tilde{q}^2 \rightarrow \infty$ behavior of

the individual d terms is \tilde{q}^4 , which means that the only integral involved is the last one of Eq. (17).

Another way to derive the same results is by using the reduction at the *integrand* level introduced in [13]. One can express $A_{m;r}$ as a linear combination, with tensor coefficients, of five classes of lower rank tensors: $A_{m;r-1}$, $\tilde{q}^2 A_{m;r-2}$, $A_{m;r-2}$, $A_{m-1;r-1}$ and $A_{m-1;r-2}$. To keep things as transparent as possible, we omit explicitly writing the coefficients and we denote such a linear combination using the following notation ³

$$A_{m;r} = \left\{ A_{m;r-1} | \tilde{q}^2 A_{m;r-2} | A_{m;r-2} | A_{m-1;r-1} | A_{m-1;r-2} \right\} . \quad (25)$$

Analogously, it was proven that

$$\begin{aligned} A_{m;1} &= \{ A_{m;0} | A_{m-1;0} \} \quad (m > 4) , \\ A_{4;1} &= \{ A_{4;0} | A_{3;0} | \tilde{d}(q) A_{4;0} \} , \end{aligned} \quad (26)$$

where $\tilde{d}(q)$ is defined such as

$$\int d^n \bar{q} \tilde{d}(q) A_{4;0} = 0 . \quad (27)$$

By using Eqs. (25) and (26) it is easy to constructively prove Eqs. (20) and (21). We explicitly give the derivation for the case $m = 6$ and $r = 6$. By iteratively applying Eqs. (25) and (26), one ends up with

$$\begin{aligned} A_{6;6} &= \sum_{j=4,5,6} \left\{ A_{j;0} | \tilde{q}^2 A_{j;0} | \tilde{q}^4 A_{j;0} \right\} + \left\{ \tilde{q}^6 A_{6;0} \right\} + \left\{ \tilde{d}(q) A_{4;0} | \tilde{d}(q) \tilde{q}^2 A_{4;0} \right\} \\ &+ \mathcal{O}(A_{3;r_3}) , \end{aligned} \quad (28)$$

where $\mathcal{O}(A_{3;r_3})$ means that we are neglecting contributions with 3 or less denominators. By power counting, only the term $\tilde{q}^4 A_{4;0}$ contributes to R_1 . Notice also that its coefficient (that we call z_4) is independent on q . Now we can take a common denominator in Eq. (28) by multiplying and dividing 5 and 4-point structures by the relevant missing n -dimensional propagators. In particular, for example, by calling \bar{D}_i and \bar{D}_j the 2 denominators that do not appear in $A_{4;0}$

$$z_4 \tilde{q}^4 A_{4;0} = z_4 \tilde{q}^4 \bar{D}_i \bar{D}_j A_{6;0} = z_4 \tilde{q}^4 (\tilde{q}^2 + D_i) (\tilde{q}^2 + D_j) A_{6;0} . \quad (29)$$

The numerator of the resulting expression is polynomial in \tilde{q}^2 and it is nothing but the function $\mathcal{D}^{(m)}(q, \tilde{q}^2)$ of Eqs. (19) and (20), with $m = 6$. Furthermore $d^{(8)} = z_4$, independent on q . The general case can be derived along the same lines.

Eq. (29) also clarifies why $d^{(2m-4)}$ is the coefficient of the 4-point like last integrals of Eq. (17). In fact, $m - 4$ among the m original n -dimensional denominators always

³Notice that each of the five terms of Eq. (25) may actually represent an entire class of contributions with different combinations of denominators. For example $A_{m-1;r-1}$ stands for all m rank $r - 1$ tensor *integrands* that can be obtained by omitting 1 among the original m possible denominators.

completely factorize in front of $d^{(2m-4)}$. Notice also that the origin of the coefficient $d^{(2m-4)}$ is uniquely coming from the mass dependence of the coefficients of the 4-point scalar functions after tensor reduction, but *before expressing m -point scalar functions with $m > 4$ in terms of boxes*. The reason why we do not reduce Eq. (28) to structures with 4-denominators is that this would bring a \tilde{q}^2 dependence in the denominator, when passing from 5 to 4 denominators. In our notation [14]

$$A_{5;0} = \left\{ \frac{1}{\tilde{q}^2 + c_i} A_{4;0} \left| \frac{1}{\tilde{q}^2 + c_i} \tilde{d}(q) A_{4;0} \right. \right\}, \quad (30)$$

with c_i constants. It is therefore much better to take, instead, common denominators. Finally, analogous techniques can be used to prove Eq. (18).
