Comment on "on a new definition of quantum entropy"

In the article [1], on a new definition of quantum entropy, Campisi has explained an operator for entropy based on quantum number operator.

$$\widehat{S}(t) = \ln(\widehat{N}(t) + \widehat{1}/2) \qquad (1)$$

It has been claimed that the expectation values for this operator increases for every non-quasi-static time dependent perturbations:

$$S_f \ge S_i \tag{2}$$

Where:

$$S(t) = Tr \Big[\widehat{\rho}(t) \widehat{S}(t) \Big]$$
 (3)

The idea is very exiting and interesting but we have found an example for a case that entropy with this definition does not increase through a spontaneous process. Suppose that we have "n" quantum systems each of them have "l" energy levels. We assume every particle is in highest energy level and density matrix is a pure state:

$$Tr\{\rho^2\} = 1 \tag{4}$$

and expectation value of the quantum number operator is:

$$Tr\{\widehat{N}(t_i)\widehat{\rho}(t_i)\}=l$$
 (5)

As time passes particles spontaneously relax to the lower levels. Density matrix evolves to a mix state[2]:

$$\widehat{\rho}(t) = \sum_{k=0}^{k=l} |b_k(t)|^2 |k,t\rangle\langle k,t| \qquad (6)$$

$$\sum_{k=0}^{k=l} |b_k(t)|^2 = 1 \qquad (7)$$

Therefore the expectation value for N will be given with the following equilibrium:

$$\langle \hat{N}(t_f) \rangle = \sum_{k=0}^{k=l} k |b_k(t_f)|^2$$
 (8)

According to inequalities if we have a set of n non-negative set of numbers a say

$$a_1, a_2, \ldots, a_n$$
 (9)

For M (a) weighted mean value of the set we have [3]:

 $Min (a) \le M (a) \le Max (a)$ (10) From equations 7, 8, 10 we have:

$$\langle \hat{N}(t_f) \rangle \le l \le \langle \hat{N}(t_i) \rangle$$
 (11)

We have shown that

$$\exp(S_i) \ge \exp(S_f) \qquad (12)$$

Because logarithm is a monotonic function it is clear that:

$$S_i \ge S_f$$
 (13)

In this example we see if entropy is defined with (1) in spontaneous emission entropy decreases, so we think this definition for entropy is not convenient.
