h 25, 2008)

Wilson's numeri
al renormalization group (NRG) method for solving quantum impurity models yields a set of energy eigenstates that have the form of matrix produ
t states (MPS). White's density matrix renormalization group (DMRG) for treating quantum lattice problems can likewise be reformulated in terms of MPS. Thus, the latter constitute a common algebraic structure for both approa
hes. We exploit this fa
t to ompare the NRG approa
h for the single-impurity Anderson model to a variational matrix product state approach (VMPS), equivalent to single-site DMRG. For the latter, we use an "unfolded" Wilson chain, which brings about a significant reduction in numerical costs compared to those of NRG. We show that all NRG eigenstates (kept and discarded) can be reproduced using VMPS, and compare the difference in truncation criteria, sharp vs. smooth in energy spa
e, of the two approa
hes. Finally, we demonstrate that NRG results an be improved upon systemati
ally by performing a variational optimization in the spa
e of variational matrix produ
t states, using the states produ
ed by NRG as input.

### I. INTRODUCTION

Wilson's numerical renormalization group (NRG) is a highly successful method for solving quantum impurity models which allows the non-perturbative calculation of stati and dynami properties for a variety of impurity models.<sup>1,2,3,4,5,6</sup> NRG is formulated on a "Wilson chain", i.e. a tight-binding fermionic quantum chain with hopping matrix elements that de
rease exponentially along the chain as  $\Lambda^{-n/2}$ , where  $\Lambda > 1$  is a discretization parameter defined below and  $n \geq 0$  is the chain's site index. It is thus not applicable to real space quantum lattice problems featuring onstant hopping matrix elements. For these, White's density matrix renormalization group (DMRG) is the method of the choice  $^{7,8,9}$  It has been known for some time<sup>10,11</sup> that the approximate ground states produ
ed by DMRG have the form of matrix produ
t states (MPS) (see Eq. [\(7\)](#page-3-0) below) that had previously arisen in certain stochastic models<sup>12</sup> and quantum information processing.<sup>13</sup> This fact can be exploited to reinterpret the DMRG algorithm (more precisely, its one-site nite-size version) as a variational optimization s
heme, in whi
h the ground state energy is minimized in the space of all matrix product states with specified dimensions.<sup>14</sup> To emphasize this fact, we shall refer to DMRG as "variational matrix product state" (VMPS) approa
h throughout this paper.

Quite recently it was understood<sup>15</sup> that NRG, too, in a natural way produ
es matrix produ
t states. In other words, when applied to the same Wilson chain, NRG and VMPS produ
e approximate ground states of essentially the same MPS structure. The two approximate ground states are not identi
al, though, sin
e the two methods use different truncation schemes to keep the size of the matri
es involved manageable even for very long Wilson chains: NRG truncation relies on energy scale separation, which amounts to discarding the highest-energy eigenstates of a sequence of effective Hamiltonians, say  $\mathcal{H}_n$ , describing Wilson chains of increasing length n and yielding spe
tral information asso
iated with the energy scale  $\Lambda^{-n/2}$ . This truncation procedure relies on the exponential de
rease of hopping matrix elements along the Wilson chain, which ensures that adding a new site to the Wilson chain perturbs it only weakly. In contrast, VMPS trun
ation relies on singular value de
omposition of the matri
es onsituting the MPS, whi
h amounts to discarding the lowest-weight eigenstates of a sequence of reduced density matrices. In ms procedure makes no speial demands on the hopping matrix elements, and indeed works also if they are all equal, as is the case of standard quantum hain models for whi
h DMRG was designed.

The fact that a *Wilson chain* model can be treated by two related but inequivalent methods immediately raises an interesting and fundamental methodologi
al question: How do the two methods ompare? More pre
isely, to what extent and under which circumstances do their results agree or disagree? How do the differences in truncation s
hemes manifest themselves? VMPS, being a variational method operating in the same spa
e of states as NRG, will yield a lower-energy ground state than NRG. However, it variationally targets only the ground state for the full Wilson chain, of length  $N$ , say. In contrast, NRG produces a set of eigenenergies  $\{E^n_\beta\}$  and eigenstates  $\{|E^n_\beta\rangle\}$  for each of the sequence of effective Hamiltonians  $\mathcal{H}_n$ , with  $n \leq N$ , mentioned above. From these, a wealth of information about the RG flow, fixed points, relevant and irrelevant operators, their scaling dimensions, as well as static and dynamic physical properties can be extracted. Are these accessible to VMPS, too?

The goal of this paper is to explore su
h questions. We shall exploit the common matrix product state structure

of the NRG and VMPS approa
hes to perform a systemati omparison of these two methods, as applied to the single-impurity Anderson model. It should be emphasized that our purpose is not to advo
ate using one method instead of the other. Instead, we hope to arrive at a balan
ed assessment of the respe
tive strengths and weaknesses of ea
h method.

In a nutshell, the main conclusion (which confirms and extends the results of Ref. [15](#page-18-10)) is the following: when applied to a Wilson hain with exponentially de
reasing hopping, the VMPS approach is able to fully reproduce all information obtainable from NRG, despite being variationally optimized with respe
t to the ground state only. ized by products of matrices of the form  $\prod_{n=0}^{N} B^{[\sigma_n]}$  (details will be explained below), where the matrices with the same index  $n$  contain information about the energy scale  $\Lambda^{-n/2}$ . As will be shown below, this information can be used to construct eigenenergies  $\{E^n_\beta\}$  and eigenstates  $\{|E^n_\beta\rangle\}$  for a sequence of effective Hamiltonians  $\mathcal{H}_n$ in omplete analogy with (but not identi
al to) those of NRG. The agreement between NRG and VMPS results for these eigenenergies and eigenstates is excellent quantitatively, provided sufficient memory resources are used for both (and  $\Lambda$  is not too close to 1, see below). In this sense, NRG and VMPS can be viewed as yielding essentially equivalent results when applied to Wilson hains amenable to NRG treatment. In particular, all physical properties obtainable from the eigenspe
tra and eigenstates of NRG an likewise be obtained from those of VMPS.

Nevertheless, NRG and VMPS do differ in performance, flexibility and numerical cost. Firstly, since NRG trun
ation relies on energy s
ale separation, it works well only if the discretization parameter  $\Lambda$  is not too close to 1 (although the ontinuum limit of the model is re
overed only in the limit  $\Lambda \to 1$ ). This restriction does not apply to VMPS. Indeed, we shall find that NRG and VMPS agree well for  $\Lambda = 2.5$ , but less well for  $\Lambda = 1.5$ . This in itself is not surprising. However it does illustrate the power of VMPS to get by without energy s
ale separation. This very useful feature an be exploited, for example, to obtain resolve sharp spectral features at high energies in dynamical correlation functions,<sup>16</sup> using projection operator techniques. However, the latter results go beyond the s
ope of the present paper and will be published separately.

Secondly, since VMPS does not rely on energy scale separation, it does not need to treat all terms in the Hamiltonian characterized by the same scale  $\Lambda^{-n/2}$  at the same time, as is required for NRG. This allows VMPS to achieve a significant reduction in memory cost compared to NRG for representing the ground state. To be specific: For NRG, we use the standard "folded" representation of the Wilson chain, in which each site represents both spin down and spin up ele
trons, with the impurity site at one end (see Fig. [1\(](#page-3-1)a) below). However, it turns out

that apart from the first few sites of the folded chain, the spin-down and -up degrees of freedom of ea
h site are ef-fectively not entangled with each other at all (see Fig. [3](#page-5-0)) below). For VMPS, we exploit this fact by using an "unfolded" representation of the Wilson chain instead,  $15,17$ in whi
h the spin up and spin down sites lie on opposite sides of the impurity site, which sits at the center of the hain (see Fig. [1\(](#page-3-1)b) below). This unfolded representation greatly redu
es the memory ost, as hara
terized by the dimensions,  $D$  for NRG or  $D'$  for VMPS, of the effective Hilbert spa
es needed to apture the low energy properties with the same precision: We find that with the choice  $D' = 2<sup>m</sup> \sqrt{D}$ , VMPS can reproduce the results of NRG in the following manner: (i) if  $m = 0$ , the NRG ground state is reproduced qualitatively; (ii) if  $m = 1$ , all the "kept" states of NRG are reproduced quantitatively; and (iii) if  $m = 2$  all the "kept" and "discarded" states of NRG are reprodu
ed quantitatively. However, in ases (ii) and (iii) the reduction in memory costs of VMPS is somewhat offset by the fact that the calculation of the excited eigenstates needed for the sake of dire
t omparison with NRG requires diagonalizing matrices of effective dimension  $D^{\prime 2}$ . Note, nevertheless, that all information needed for this omparison is already fully ontained within the VMPS ground state characterized by dimension  $D'$ , since its onstituent matri
es ontain information from all energy s
ales represented by the Wilson hain.

The paper is organized as follows: Section [II](#page-2-0) sets the s
ene by introdu
ing a folded and an unfolded version of the Wilson hain. In Se
tions [III](#page-2-1) and [IV](#page-5-1) we review the NRG and VMPS approaches for finding the ground state of a folded or unfolded Wilson hain, respe
tively, emphasizing their common matrix product state structure. We also explain how an unfolded MPS states may be "refolded", allowing it to be compared directly to folded NRG states. In Section [V](#page-7-0) we compare the results of NRG and VMPS, for ground state energies and overlaps (Section VA), excited state eigenenergies and density of states (Section VB), and the corresponding energy eigenstates themselves (Section VC). This allows us, in parti
ular, to obtain very vivid insights into the differences in the truncation criteria used by the NRG and VMPS approaches, being sharp or smooth in en-ergy space, respectively (Figs. [8](#page-11-0) to [10\)](#page-12-0). In Section [VI](#page-13-0) we demonstrate that NRG results for the ground state an be improved upon systematically by first producing an unfolded "clone" of a given NRG ground state, and subsequently lowering its energy by performing variational energy minimization sweeps in the spa
e of variational matrix product states. Finally, Section [VII](#page-14-0) contains our on
lusions and an assessment of the relative pros and ons of NRG and VMPS in relation to ea
h other.

# <span id="page-2-0"></span>II. FOLDED AND UNFOLDED REPRESENTATIONS OF WILSON CHAIN

For definiteness, we consider the single-impurity Anderson model. It describes a spinful fermionic impurity level with energy  $\epsilon_d$  and double occupancy cost U (with associated creation operators  $f_{0\mu}^{\dagger}$ , where  $\mu = \downarrow, \uparrow$  denotes spin), which acquires a level width  $\Gamma$  due to being coupled to a spinful fermionic bath with bandwidth  $W = 1$ . Since the questions studied in this paper are of a generi nature and do not depend much on the specific parameter values used, we onsider only the symmetri Anderson model and take  $U = \frac{1}{2} U/\pi \Gamma = 1.013$  and  $\epsilon_d = -\frac{1}{2}U$ throughout this paper. To a
hieve a separation of energy scales, following Wilson,<sup>1,2</sup> the bath is represented by a set of dis
rete energy levels with logarithmi
ally spa
ed energies  $\Lambda^{-n}$  (with associated creation operators  $f^{\dagger}_{n\mu}$ ), where  $n \geq 1$ ,  $\Lambda > 1$  is a "discretization parameter", and the limit  $\Lambda \to 1$  reproduces a continuous bath spectrum. The discretized Anderson model Hamiltonian can then be represented as

<span id="page-2-2"></span>
$$
\mathcal{H}_{AM} = \lim_{N \to \infty} \mathcal{H}_N , \qquad (1)
$$

where  $\mathcal{H}_N$  describes a Wilson chain of "length N" (i.e., up to and including site  $N$ ):

$$
\mathcal{H}_N = \mathcal{H}_{N\downarrow} + \mathcal{H}_{N\uparrow} + U(f_{0\uparrow}^{\dagger} f_{0\uparrow} f_{0\downarrow}^{\dagger} f_{0\downarrow} + \frac{1}{2}), \quad (2a)
$$

$$
\mathcal{H}_{N\mu} = \epsilon_d f_{0\mu}^{\dagger} f_{0\mu} + \sum_{n=0}^{N-1} t_n (f_{n\mu}^{\dagger} f_{(n+1)\mu} + \text{h.c.}) , (2b)
$$

with hopping coefficients given by

<span id="page-2-4"></span>
$$
t_n \equiv \begin{cases} \sqrt{\frac{2\Gamma}{\pi}} & \text{for } n = 0, \\ \frac{1}{2}(1 + \Lambda^{-1})\Lambda^{-(n-1)/2}\xi_n & \text{for } n \ge 1, \end{cases}
$$
(3)  

$$
\xi_n = (1 - \Lambda^{-n})(1 - \Lambda^{-2n+1})^{-1/2}(1 - \Lambda^{-2n-1})^{-1/2}.
$$

In passing, we note that for our numerics we have found it onvenient (following Refs. [17](#page-18-12) and [15\)](#page-18-10) to keep tra
k of fermioni minus signs by making a Jordan-Wigner  $transformation<sup>18</sup>$  of the Wilson chain to a spin chain, using  $f_{n\mu}^{\dagger} = P_{n\mu}s_{n\mu}^{+}$  and  $f_{n\mu} = P_{n\mu}s_{n\mu}^{-}$ . Here  $s_{n\mu}^{\pm}$  are a set of spin- $\frac{1}{2}$  raising and lowering operators, that for equal indices satisfy  $\{s_{n\mu}^-, s_{n\mu}^+\} = 1$ ,  $(s_{n\mu}^-)^2 = (s_{n\mu}^+)^2 = 0$ , but commute if their indices are unequal. The fermionic anticommutation relations for the  $f_{n\mu}$  are ensured by the operators  $P_{n\mu}=(-1)^{\sum_{(\bar{n}\bar{\mu})<(n\mu)}s^{\pm}_{\bar{n}\bar{\mu}}s^{-}_{\bar{n}\bar{\mu}}},$  where  $<$  refers to some implicitly specified ordering for the composite index  $(n\mu)$ . The  $P_{n\mu}$  need to be kept track of when calculating certain correlation functions, but do not arise explicitly in the onstru
tion of the matrix produ
t states that are the focus of this paper. This transformation will implicitly be assumed to have been implemented throughout the ensuing dis
ussion.

For the Anderson model, site  $n$  of the Wilson chain represents the set of four states  $|\sigma_n\rangle$ , with  $\sigma_n = (\sigma_{n\downarrow}, \sigma_{n\uparrow}) \in$ 

 $\{(00), (10), (01), (11)\},$  where  $\sigma_{n\mu} \in \{0, 1\},$  to be viewed as eigenvalue of  $s_{n\mu}^{+} s_{n\mu}^{-}$ , gives the occupancy on site  $n$ of electrons with spin  $\mu$ . Thus, the dimension of the spinful index  $\sigma_n$  is  $d = 4$ , and that of the spin-resolved index  $\sigma_{n\mu}$  is  $d' = 2$ . As a general rule, we shall use the absence or presence of primes,  $d$  vs.  $d'$  (and  $D$  vs.  $D'$ below), to distinguish dimensions referring to spinful or spin-resolved indi
es, respe
tively, and orrespondingly to folded or unfolded representations of the Wilson hain. For other quantum impurity models, su
h as the Kondo model or multilevel Anderson models, the dimension of the local impurity site, say  $d_0$ , differs from that of the bath sites,  $d_0 \neq d$ . It is straightforward to generalize the discussion below accordingly.

The Hamiltonian  $\mathcal{H}_N$  of a Wilson chain of length N is defined on a Hilbert space of dimension  $d^{N+1}$ . It is spanned by an orthonormal set of states that, writing  $|\sigma_n\rangle = |\sigma_{n\downarrow}\rangle |\sigma_{n\uparrow}\rangle$ , can be written in either spinful or spin-resolved form,

<span id="page-2-3"></span>
$$
|\boldsymbol{\sigma}^N\rangle = |\sigma_0\rangle |\sigma_1\rangle \dots |\sigma_N\rangle, \qquad (4a)
$$

$$
= |\sigma_{0\downarrow}\rangle |\sigma_{0\uparrow}\rangle |\sigma_{1\downarrow}\rangle |\sigma_{1\uparrow}\rangle \dots |\sigma_{N\downarrow}\rangle |\sigma_{N\uparrow}\rangle, \qquad (4b)
$$

corresponding to a "folded" or "unfolded" representation of the Wilson hain, illustrated by Figs. [1\(](#page-3-1)a) or (b), respe
tively. The unfolded representation of Fig. [1\(](#page-3-1)b) makes explicit that the Anderson Hamiltonian of Eq. [\(2\)](#page-2-2) has the form of two separate Wilson chains of specified spin, described by  $\mathcal{H}_{N\perp}$  and  $\mathcal{H}_{N\uparrow}$ , which interact only at site zero. This fact will be exploited extensively below. Note that the ordering chosen for the  $|\sigma_{n\mu}\rangle$  states in Eq. [\(4b\)](#page-2-3) fixes the structure of the many-body Hilbert space once and for all. The fact that the sites of the unfolded chain in Fig. [1](#page-3-1) are connected in a different order than that specified in Eq.  $(4b)$  is a statement about the dynamics of the model and of no consequence at this stage, where we simply fix a basis.

### <span id="page-2-1"></span>NRG TREATMENT OF FOLDED WILSON Ш. **CHAIN**

### A. NRG matrix produ
t state arises by iteration

Wilson proposed to diagonalize the folded Wilson hain numeri
ally using an iterative pro
edure, starting from a short hain and adding one site at a time. Consider a chain of length n, sufficiently short that  $\mathcal{H}_n$  can be diagonalized exa
tly numeri
ally. Denote its eigenstates by  $|E_{\alpha}^{n}\rangle_{\text{f}}$ , ordered by increasing energy  $(E_{\alpha}^{n})_{\text{f}}$ , with  $\alpha =$  $1, \ldots, D_n$  and  $D_n = d^{n+1}$ . (We use subscripts f and u to distinguish quantities obtained from a folded or unfolded Wilson hain, respe
tively; similarly, in later parts of the paper we will use the subscripts r and c for "refolded" and "cloned".) E.g., for a chain consisting of only the impurity site,  $n = 0$ , the *d* eigenstates can be written as linear combinations of the form  $|E_{\alpha}^{0}\rangle_{f} = \sum_{\sigma_{0}} |\sigma_{0}\rangle A_{1\alpha}^{[\sigma_{0}]}$ where the coefficients have been arranged into  $d$  matrices

<span id="page-3-1"></span>Figure 1: (Color online) (a) The standard spinful or "folded" representation of the Wilson chain of the single-impurity Anderson model, and (b) its spin-resolved or "unfolded" representation. The latter makes explicit that spin-down and -up states are oupled only at the impurity sites and not at any of the bath sites. The dashed boxes indi
ate the hains described by  $\mathcal{H}_1$  and  $\mathcal{H}_n$ , respectively.

 $A^{[\sigma_0]}$  of dimensions  $1 \times d$  (i.e., d-dimensional vectors), with matrix elements  $A_{1\alpha}^{[\sigma_0]}$ . Then add to the chain the site  $n+1$  and diagonalize  $\mathcal{H}_{n+1}$  in the enlarged Hilbert space spanned by the  $(D_n d)$  states  $|E_{\alpha}^n\rangle_f |\sigma_{n+1}\rangle$ . The new orthonormal set of eigenstates, with energies  $(E_{\beta}^{n+1})_f$ , an be written as linear ombinations of the form

<span id="page-3-2"></span>
$$
|E_{\beta}^{n+1}\rangle_{\mathbf{f}} = \sum_{\sigma_{n+1}=1}^{d} \sum_{\alpha=1}^{D_n} |E_{\alpha}^{n}\rangle_{\mathbf{f}} |\sigma_{n+1}\rangle A_{\alpha\beta}^{[\sigma_{n+1}]}, \quad (5)
$$

with  $\beta = 1, \ldots, (D_n d)$ . Here the coefficients specifying the linear ombination have been arranged into a set of d matrices  $A^{[\sigma_{n+1}]}$  of dimension  $D_n \times D_{n+1}$ , with matrix elements  $A_{\alpha\beta}^{[\sigma_{n+1}]}$ . The orthonormality of the eigenstates at each stage of the iteration,  ${}_{f}\langle E_{\beta}^{n}|E_{\beta'}^{n}\rangle_{f} = \delta_{\beta\beta'}$ , implies that the A-matri
es automati
ally satisfy the orthonormality ondition

<span id="page-3-3"></span>
$$
\sum_{\sigma_n} A^{[\sigma_n] \dagger} A^{[\sigma_n]} = 1 . \tag{6}
$$

We remark that it is possible to exploit symmetries of  $\mathcal{H}_n$  (e.g. under particle-hole transformation) to cast A in block-diagonal form to make the calculation more timeand memory-efficient. However, for the purposes of the present paper, this was not required.

Iterating the above pro
edure by adding site after site and repeatedly using Eq.  $(5)$ , we readily find that the NRG eigenstates of  $\mathcal{H}_N$  on the folded Wilson chain can be written in the form of a so-called *matrix product state*,  $\cdot$ 

<span id="page-3-0"></span>
$$
|E_{\beta}^{N}\rangle_{\mathbf{f}} = \sum_{\{\boldsymbol{\sigma}^{N}\}} |\boldsymbol{\sigma}^{N}\rangle (A^{[\sigma_{0}]} A^{[\sigma_{1}]} \dots A^{[\sigma_{N}]})_{1\beta} , \qquad (7)
$$

illustrated in Fig. [2\(](#page-4-0)a). Here matrix multiplication is implied in the product,  $(A^{[\sigma_n]}A^{[\sigma_{n+1}]})_{\alpha\beta} =$  $\sum_{\gamma} A_{\alpha\gamma}^{[\sigma_n]} A_{\gamma\beta}^{[\sigma_{n+1}]}$ , and  $\{\sigma^N\}$  denotes the set of all sequences  $\sigma_0, \sigma_1, \ldots, \sigma_N$ . This matrix multiplication generates entanglement between neighboring sites, with the apa
ity for entanglement in
reasing with the dimension  $D_n$  of the index being summed over.

### $\mathbf{B}$ . NRG truncation

In practice, it is of course not possible to carry out the above iteration strategy explicitly for chains longer than a few sites, because the size of the A-matrices grows exponentially with  $N$ . Hence Wilson proposed the following NRG truncation procedure: Once  $D_n$  becomes larger than a specified value, say  $D$ , only the lowest  $D$  eigenstates  $|E_{\alpha}^{n}\rangle_{\text{f}}$ , with  $\alpha = 1, \ldots, D$ , are retained or kept at each iteration, and all higher-lying ones discarded T. Explicitly, the upper limit for the sum over  $\alpha$  in Eq. [\(5\)](#page-3-2) is redefined to be

<span id="page-3-4"></span>
$$
D_n = \min(d^{n+1}, D) \tag{8}
$$

As a result, the dimensions of the  $A^{[\sigma_n]}$  matrices occur-ring in the matrix product state [\(7\)](#page-3-0) start from  $1 \times d$  at  $n = 0$  and grow by a factor of d for each new site until they saturate at  $D \times D$  after truncation has set in. The structure of the resulting states  $|E^{N}_{\beta}\rangle_{\mathrm{f}}$  is schematically depicted in Figs.  $2(a)$  $2(a)$  and  $2(b)$ , in which the site index is viewed as a single or composite index,  $\sigma_n$  or  $(\sigma_{n\downarrow}, \sigma_{n\uparrow})$ , respe
tively.

Wilson showed that this trun
ation pro
edure works well in practice, because the hopping parameters  $t_n$  of Eq. [\(3\)](#page-2-4) decrease exponentially with n: the resulting separation of energy s
ales along the hain ensures that highlying eigenstates from iteration  $n$  make only a small contribution to the low-lying eigenstates of iteration  $n+1$ , so that discarding the former hardly affects the latter. The output of the NRG algorithm is a set of eigenstates  $|E^n_\beta \rangle_{\rm f}$ and eigenenergies  $(E_{\beta}^n)_\mathrm{f}$  for each iteration, describing the physics at energy scale  $\Lambda^{-n/2}$ . The NRG eigenenergies are usually plotted in res
aled form,

<span id="page-3-5"></span>
$$
(\varepsilon_{\beta}^n)_{\mathbf{f}} = (E_{\beta}^n - E_1^n)_{\mathbf{f}} / \Lambda^{-n/2} , \qquad (9)
$$

as functions of  $n$ , to obtain a so-called NRG flow diagram; it converges to a set of fixed-point values as  $n \to \infty$ . Figure [7](#page-10-1) in Se
tion [V B](#page-10-1) below shows some examples. The ground state energy of the entire hain is given by the lowest energy of the last iteration,  $(E_G^N)_{f} = (E_1^N)_{f}$ .

Despite the great success of NRG, Wilsonian truncation is does have some drawba
ks. Firstly, its errors grow

<span id="page-4-0"></span>Figure 2: (Color online) (a) and (b) show the matrix product structure of the state  $|E^N_\beta\rangle_{\rm f}$  of Eq. [\(7\)](#page-3-0), depicting the site index as a single or composite index,  $\sigma_n$  or  $(\sigma_{n\downarrow}, \sigma_{n\uparrow})$ , respectively. (c) shows the matrix product structure of the state  $|\Psi^N\rangle$ <sub>u</sub> of Eq. [\(15\)](#page-5-2). (For the sake of illustrating Eq. [\(A9\)](#page-17-0) of Appendix [A 2,](#page-16-0) the labels  $(B_{n\downarrow})_{\nu\nu'}$  in the bottom row are purposefully typeset "upside down", so that they would be rightside up if the hain of boxes were all drawn in one row in the order indicated by Eq.  $(15)$ .) Each matrix A or B is represented by a box, summed-over indi
es by links, free indi
es by terminals, and dummy indi
es having just a single value, namely 1, by ending in a triangle. The dimensions  $(d, D, D)$  $d', D'$ , etc.) next to each link or terminal give the number of possible values taken on by the orresponding index, assuming Wilsonian truncation for (a) and (b), and VMPS truncation the dashed boxes in the former, containing  $B_{\nu\nu'}^{[\sigma_{n+1}]} \otimes B_{\eta'\eta}^{[\sigma_{n+1}]}$ play the role of the  $A_{\alpha'\alpha}^{[(\sigma_{n\downarrow}, \sigma_{n\uparrow})]}$  matrices in the latter. Their capacity for entangling neighboring sites is comparable if one chooses  $D'^2 \propto D$  [cf. Eq. [\(23\)](#page-8-2)], since neighboring dashed boxes in (c) are connected by two links of combined dimension  $D^2$ , whereas neighboring  $A$ -matrices in  $(b)$  are connected by only a single link of dimension D.

systematically as  $\Lambda$  tends to 1, because then the separation of energy scales on which it relies becomes less efficient. Secondly, it is not variational, and hence it is not guaranteed to produ
e the best possible approximation for the ground state within the spa
e of all matrix produ
t states of similar form and size. We shall return to this point later in Se
tion [VI](#page-13-0) and study quantitatively to what extent the NRG ground state wavefunction can be

improved upon by further variational optimization.

# <span id="page-4-2"></span>C. Mutual information of opposite spins on site  $n$

A ru
ial feature of the folded Wilson hain is that all degrees of freedom asso
iated with the same energy scale,  $\Lambda^{-n/2}$ , are represented by one and the same site and hen
e are all added during the same iteration step. Sin
e the spin-down and -up degrees of freedom asso
iated with each site are thus treated on an equal footing, the resulting matrix product state provides comparable amounts of resour
es for en
oding entanglement between local states of the same spin, involving  $|\sigma_{n\mu}\rangle|\sigma_{n+1\mu}\rangle$ , or between states of opposite spin (indi
ated by the bar), involving  $|\sigma_{n\mu}\rangle|\sigma_{n\bar{\mu}}\rangle$  or  $|\sigma_{n\mu}\rangle|\sigma_{n+1\bar{\mu}}\rangle$ . However, it turns out that for the Anderson model this feature, though <sup>a</sup> priori attractive, is in fact an unnecessary (and memoryostly) luxury: Sin
e the Anderson model Hamiltonian [\(2\)](#page-2-2) ouples spin-down and -up ele
trons only at the impurity site, the amount of entanglement between states of opposite spin rapidly decreases with  $n$ .

To illustrate and quantify this laim, it is instru
tive to calculate the so-called mutual information  $M_n^{\downarrow\uparrow}$  of the spin-down and -up degrees of freedom of a given site  $n$ . This quantity is defined via the following general construction.<sup>22</sup> Let C denote an arbitrary set of degrees of freedom of the Wilson hain, represented by the states  $|\sigma^C\rangle$ . Let  $\rho^C$  be the reduced density matrix obtained from the ground state density matrix by tracing out all degrees of freedom except those of C, denoted by  $N\setminus C$ :

$$
\rho^C = \sum_{\{\sigma^N\backslash C\}} \langle \sigma^{N\backslash C} | E_G^N \rangle_{\text{ff}} \langle E_G^N | \sigma^{N\backslash C} \rangle . \tag{10}
$$

For example, if C represents the spin-down and updegrees of freedom of site  $n$ , its matrix elements are:

$$
\rho_{\sigma_n \sigma_n'}^C = \sum_{\{\sigma^{N \setminus n}\}} (A^{[\sigma_N]\dagger} \dots A^{[\sigma_n]\dagger} \dots A^{[\sigma_0]\dagger})_{G1}
$$

$$
\times (A^{[\sigma_0]} \dots A^{[\sigma_n']} \dots A^{[\sigma_N]})_{1G} . \quad (11)
$$

If C represents only the spin- $\mu$  degree of freedom of site n, a similar expression holds, with n replaced by  $n\mu$ . The entropy asso
iated with su
h a density matrix is given by

$$
S^C = -\sum_i w_i^C \ln w_i^C , \qquad (12)
$$

where  $w_i^C$  are the eigenvalues of  $\rho^C$ , with  $\sum_i w_i^C = 1$ . Now, consider the case that  $C = AB$  is a combination of the degrees of freedom of two distinct subsets  $A$  and  $B$ , represented by states of the form  $|\sigma^C\rangle = |\sigma^A\rangle |\sigma^B\rangle$ . Then the mutual information of  $A$  and  $B$ , defined by

<span id="page-4-1"></span>
$$
M^{AB} = S^A + S^B - S^{AB} , \t\t(13)
$$

characterizes the information contained in  $\rho^{AB}$  beyond that contained in  $\rho^A \otimes \rho^B$ . The mutual information

<span id="page-5-0"></span>Figure 3: NRG result for the mutual information  $M_n^{\downarrow\uparrow}$  between spin-down and -up degrees of freedom of site  $n$  of a folded Wilson chain of lenght  $N = 50$ . The Anderson model parameters are fixed at  $U = \frac{1}{2}$ ,  $U/\pi\Gamma = 1.013$ ,  $\epsilon_d = -\frac{1}{2}U$ throughout this paper. Lines connecting data points are guides for the eye. The slight differences in behavior observed for even or odd  $n$  are reminiscent of the well-known  $\operatorname{fact}^{\scriptscriptstyle{1}}$  that the ground state degeneracy of a Wilson chain is different for even or odd N.

 $M^{AB}=0$  if there is no entanglement between the degrees of freedom of A and B, since then  $\rho^{AB} = \rho^A \otimes \rho^B$  and its eigenvalues have a product structure,  $w_{ij}^{AB} = w_i^A w_j^B$ .

We define the mutual information between spin-down and -up degrees of freedom of site  $n$  of the folded chain.  $M_n^{\downarrow\uparrow}$ , by Eq. [\(13\)](#page-4-1), taking  $A = n\downarrow$  and  $B = n\uparrow$ . Figure [3](#page-5-0) shows this quantity as function of  $n$  for the symmetric Anderson model. Evidently  $M_n^{\downarrow\uparrow}$  is very small for all but the first few sites, and decreases exponentially with  $n$ . This implies that for most of the folded hain, there is pra
ti
ally no entanglement between the spin-down and matrices occuring in Eq. [\(7\)](#page-3-0) for  $|E_G^N\rangle_f$  in effect have a direct products are not me at reaching, we accomply the many there.  $A^{[\sigma_n]} \simeq B^{[\sigma_{n+1}]} \otimes B^{[\sigma_{n+1}]}$  In the next subsection, we will exploit this fact to achieve a significant reduction in memory cost, by implementing the effective factorization in an alternative matrix product Ansatz [see Eq. [\(15\)](#page-5-2) below]. defined on an *unfolded* Wilson chain which represents  $n\downarrow$ and  $n \uparrow$  of freedom by two separate sites.

# <span id="page-5-1"></span>IV. DMRG TREATMENT OF UNFOLDED WILSON CHAIN

### <span id="page-5-4"></span>Variational matrix product state Ansatz А.

As pointed out by verstraete *et al.*, an alternative approach for finding a numerical approximation for the ground state can be obtained by *variationally minimizing* the ground state energy in the space of all "variational" matrix product states" (VMPS) of fixed norm. Implementing the latter onstraint via a Lagrange multiplier  $\lambda$ , one thus considers the following minimization problem,

<span id="page-5-3"></span>
$$
\min_{|\Psi\rangle \in \{|\Psi^N\rangle_{\mathrm{u}}\}} [\langle \Psi | \mathcal{H}_N | \Psi \rangle - \lambda (\langle \Psi | \Psi \rangle - 1)] . \tag{14}
$$

The minimization is to be performed over the spa
e of all variational matrix product states  $|\Psi^N\rangle$ <sub>u</sub> having a specified structure (see below), with specified dimensions  $D_n^{\prime}$ for the matrices, whose matrix elements are now treated as variational parameters. This minimization an be performed by a "sweeping procedure", which optimizes one matrix at a time while keeping all others fixed, then optimizing the neighboring matrix, and so forth, until convergen
e is a
hieved. The resulting algorithm is equivalent to a single-site DMRG treatment of the Wilson hain. Our main goal is to analyse how the energies and eigenstates so obtained ompare to those produ
ed by NRG.

Having de
ided to use a variational approa
h, it be omes possible to explore matrix produ
t states having different, possibly more memory-efficient structures than those of Eq.  $(7)$  and Fig. [2\(](#page-4-0)a). In particular, we can exploit<sup>17</sup> the fact that the Anderson model Hamiltonian [\(2\)](#page-2-2) ouples spin-down and -up ele
trons only at the impurity site, as emphasized in Eq. [\(2\)](#page-2-2) and Fig. [1\(](#page-3-1)b). For such a geometry, it is natural to consider matrix product states defined on the *unfolded* Wilson chain (subscript u) and having the following form, depicted schematically in Fig.  $2(c)$  $2(c)$ 

<span id="page-5-2"></span>
$$
|\Psi^N\rangle_{\mathbf{u}} = \sum_{\{\boldsymbol{\sigma}^N\}} |\boldsymbol{\sigma}^N\rangle (B^{[\sigma_{N\downarrow}]} \dots B^{[\sigma_{0\downarrow}]} B^{[\sigma_{0\uparrow}]} \dots B^{[\sigma_{N\uparrow}]})_{11}.
$$
\n(15)

The order in which the  $B^{[\sigma_{n\mu}]}$  matrices occur in the produ
t mimi
s the order in whi
h the sites are onne
ted in the unfolded Wilson chain. (The fact that this order differs from the order in which the basis states  $|\sigma_{n\mu}\rangle$  for each site are arranged in the many-body basis state  $|\sigma^N\rangle$ , see Eq. [\(4b\)](#page-2-3), does not cause minus signs complications, because we work with Jordan-Wigner-transformed effective spin chains.) Each  $B^{[\sigma_{n\mu}]}$  stands for a set of  $d'=2$ matrices with matrix elements  $B_{\nu\eta}^{[\sigma_{n\mu}]}$ , with dimensions  $D'_n \times D'_{n-1}$  for  $B^{[\sigma_{n\mu}]}$  and  $D'_{n-1} \times D'_{n}$  for  $B^{[\sigma_{n\tau}]}$ , where

<span id="page-5-5"></span>
$$
D'_n = \min(d'^{N-n}, D'),\tag{16}
$$

as indi
ated on the links onne
ting the squares in Fig.  $2(c)$  $2(c)$ . This choice of matrix dimension allows the outermost few sites at both ends of the unfolded hain to be described exactly (similarly to the first few sites of the folded Wilson chain for NRG), while introducing truncation, governed by  $D'$ , for the matrices in the central part of the chain. The first index on  $B_{1\nu}^{[\sigma_{N\downarrow}]}$  and the second<br>index on  $B_{\nu_1}^{[\sigma_{N\uparrow}]}$  are dummy indices taking on just a single value, namely 1, sin
e they represent the ends of the chain. The triangles in Fig.  $2(c)$  $2(c)$  are meant to represent this fa
t. As a result, Eq. [\(15\)](#page-5-2) represents just a single state, namely the ground state, in contrast to Eq.  $(7)$ , which represents a set of states, labeled by the index  $\beta$ . Moving inward from the endpoints by decreasing  $n$ , the matrix dimension parameter  $D'_n$  increases by one factor of d' for each site, in such a way that the resulting matries are of just the right size to des
ribe the outside ends of the chain (from  $n$  to  $N$ ) exactly, i.e. without truncation. After a few sites, however, truncation sets in and the matrix dimensions saturate at  $D' \times D'$  for the central part of the hain.

To initialize the variational sear
h for optimal Bmatrices, it turns out to be sufficient to start with a set of random matri
es with normally distributed random matrix elements. Next, singular value de
omposition is used to orthonormalize the B-matrices in such a way [see Eq.  $(A1)$ ] that the matrix product state Eq.  $(15)$ has norm 1 (see App. [A 1](#page-16-2) for details). Thereafter, variational optimization sweeps are performed to minimize Eq. [\(14\)](#page-5-3) one *B*-matrix at a time<sup>15</sup>. (The technical details of this procedure will be published separately<sup>20</sup>.) After a sweeping back and forth through the entire chain a few times, the variational state typi
ally onverges (as illustrated by Fig. [13](#page-14-1) in Se
. [VI B](#page-14-1) below), provided that  $D'$  is sufficiently large. We shall denote the resulting converged variational ground state by  $|E_{\text{G}}^{N}\rangle_{\text{u}}$ . Its variational  $\text{energy}, \, (E^N_\text{G})_\text{u}, \, \text{turns}$  out to be essentially independent of the random hoi
e of initial matri
es.

### B. VMPS trun
ation

Since  $D' \times D'$  is the maximal dimension of B-matrices,  $D'$  is the truncation parameter determining the effective size of the variational spa
e to be sear
hed and hen
e the accuracy of the results. Its role can be understood more explicitly using a technique that is exceedingly useful in the VMPS approa
h, namely singular value de
omposition: any rectangular matrix  $\mathcal B$  of dimension  $m \times m'$  can be written as

<span id="page-6-2"></span>
$$
\mathcal{B} = \mathcal{U}\mathcal{S}\mathcal{V}^{\dagger} , \quad \text{with} \quad \mathcal{U}^{\dagger}\mathcal{U} = \mathcal{V}^{\dagger}\mathcal{V} = \mathbb{1} , \qquad (17)
$$

where  $S$  is a diagonal matrix of dimension  $\min(m, m'),$ whose diagonal elements, the so-called "singular values". an always be hosen to be real and non-negative, and  $\mathcal{U}$  and  $\mathcal{V}^{\dagger}$  are column- and row-unitary matrices (with dimensions  $m \times \min(m, m')$  and  $\min(m, m') \times m'$ , respectively). Due to the latter fact, the matrix norm of  $\beta$ is governed by the magnitude of the singular values.

<span id="page-6-1"></span>Figure 4: (Color online) (a) Typical singular value spectrum for site 5↓ of the unfolded Wilson hain, obtained by singular value decomposition of  $B^{[\sigma_{5\downarrow}]}$ . It shows, roughly, power-law decrease for large enough  $\beta$ , modulo steps due to degeneracies in the singular value spectrum. (b)  $D'$ -dependence of the truncation error  $\tau(D')$  [Eq. [\(18\)](#page-6-0)].

For any given site of the unfolded Wilson hain, this de omposition an be applied in one of two ways (depending on the context, see App. [A\)](#page-16-3) to the set of matrices with elements  $B^{[\sigma_{n\mu}]}_{\nu\eta}$ : introduce a composite index  $\bar{\nu}=(\sigma_{n\mu},\nu)$ (or  $\bar{\eta} = (\sigma_{n\mu}, \eta)$ ) to arrange their matrix elements into a elements  $B_{\bar{\nu}\eta} = B_{\nu\eta}^{[\sigma_{n\mu}]}$  (or  $\tilde{B}_{\nu\bar{\eta}} = B_{\nu\eta}^{[\sigma_{n\mu}]}$ ), and decompose this new matrix as  $B = USV^{\dagger}$ .

Now, if this is done for any site for which the set of matrices  $B^{[\sigma_{n\mu}]}$  have maximal dimensions  $D' \times D'$ , the corresponding matrix  $S$  will likewise have dimensions  $D' \times D'$ . Let its diagonal elements, the singular values  $s_{\nu}$  (with  $\nu = 1, \ldots, D'$ , be labelled in order of decreasing size. (Their squares,  $s_{\nu}^2$ , correspond to the eigenvalues of the density matrix constructed in the course of the single-site DMRG algorithm<sup>8</sup>.) If  $D'$  is sufficiently large, the  $s_{\nu}$  are typically found to decrease with increasing  $\nu$  roughly as some negative power of  $\nu$ , as illustrated in Fig. [4\(](#page-6-1)a). The last and smallest of the singular values,  $s_{D'}^2$  (squared, fol-lowing Ref. [8](#page-18-14)), thus indicates the weight of the information that is lost at that site due to the given (finite) choice of D′ : by hoosing D′ larger, less information would be lost sin
e more singular values (though of smaller size) would be retained. Repeating su
h an analysis for all sites of the unfolded Wilson chain, one may define the largest of the  $s_D^2$ , parameters of the entire chain,

<span id="page-6-0"></span>
$$
\tau(D') = \max_{\{n\mu\}} (s_{D'}^2) , \qquad (18)
$$

as "truncation error" characterizing the maximal information loss for a given value of  $D'$ . Typically,  $\tau(D')$ decreases as some negative power of  $D'$ , as illustrated in Fig. [4\(](#page-6-1)b). In this way,  $D'$  assumes the role of a cutoff parameter that directly governs the accuracy of the VMPS approa
h, in a way analogous to the parameter D of NRG.

### C. Refolding

The VMPS approach purposefully focusses on finding an optimal des
ription of the variational ground state  $|E_{\text{G}}^{N}\rangle_{\text{u}}$ . Nevertheless, the *B*-matrices from which the latter is onstru
ted ontain information about all energy scales of the model, due to the logarithmic discretization of the Wilson hain. In parti
ular, information about the scale  $\Lambda^{-n/2}$  is encoded in the set of matrices  $B^{[\sigma_{n\mu}]}$  associated with the two site  $n\downarrow$  and  $n\uparrow$ . From these, it is possible to extract excited-state eigenspectra and energy flow diagrams in complete analogy to those produced by NRG. In this subsection we explain how this can be accomplished by a technique to be called "refolding", which combines the two matrices  $B^{[\sigma_{n\downarrow}]}$  and  $B^{[\sigma_{n\uparrow}]}$  into a single matrix, say  $B^{[\sigma_n]}$ , and thereby recasts unfolded matrix produ
t states into folded ones. It should be emphasized that this pro
edure simply amounts to an internal reorganization of the representation of the VMPS ground state.

Consider a given matrix product state  $|\Psi^N\rangle_u$  of the form [\(15\)](#page-5-2), defined on an unfolded Wilson chain of length N (e.g. the converged ground state  $|E_{\text{G}}^{N}\rangle_{\text{u}}$ ). To refold it (subs
ript r) , it is expressed as a state of the following form [same as Eq.  $(7)$ ]

<span id="page-7-1"></span>
$$
|\Psi^N\rangle_{\rm r} = \sum_{\{\boldsymbol{\sigma}^N\}} |\boldsymbol{\sigma}^N\rangle (B^{[\sigma_0]} B^{[\sigma_1]} \dots B^{[\sigma_N]})_{11} , \qquad (19)
$$

defined on a folded Wilson chain of length  $N$  and normalized to unity,  $\chi_{\mathbf{r}}(\Psi^n|\Psi^n)_r = 1$ . Graphically speaking, this orresponds to rewriting a state of the form shown in Fig.  $2(c)$  $2(c)$  in terms of states of the form of Fig.  $2(a)$ . To ob-tain the matrices needed for Eq. [\(19\)](#page-7-1), one constructs, for every site *n* of the refolded chain, a set of d matrices  $B^{[\sigma_n]}$ from a ombination of the two sets of spin-resolved matrices  $B^{[\sigma_{n\downarrow}]}$  and  $B^{[\sigma_{n\uparrow}]}$  of the unfolded chain (App. [A 2](#page-16-0)) gives the details of this onstru
tion). This is done in such a way, using singular value decomposition, that (i) the resulting matrices  $B^{[\sigma_n]}$  satisfy the orthonormality conditions [\(6\)](#page-3-3) (with  $A \rightarrow B$ ), thereby guaranteeing the unit normalization of the the refolded state  $|\Psi^N\rangle_r$ ; and (ii) the  $B^{[\sigma_n]}$  matrices have a structure similar to that of the matrices  $A^{[\sigma_n]}$  generated by NRG, except that their dimensions,  $D_n^r \times D_{n+1}^r$ , are governed by

<span id="page-7-3"></span>
$$
D_n^{\mathbf{r}} = \min(d^n, d^{N+1-n}, D'^2) \tag{20}
$$

[instead of Eq.  $(8)$ ], for reasons explained in App. [A 2.](#page-16-0) Thus, their dimensions have the maximal value  $D^r \times D^r$ , with  $D^{\rm r} = D^{\prime 2}$ , in the central part of the refolded chain, while decreasing at its ends towards  $1 \times d$  or  $d \times 1$  for  $n = 0$  or N, respectively.

Now, suppose that a onverged variational ground state  $|E_{\text{G}}^{N}\rangle_{\text{u}}$  has been obtained and refolded into the form  $|\Psi^N\rangle_r$ , so that the corresponding orthonormalized matri- $\cos B^{[\sigma_n]}$  for the refolded Wilson chain of length  $N$  are the building blo
ks of the ground state of the system. Then

it is possible to extra
t from them information about the many-body excitation spectrum at energy scale  $\Lambda^{-n/2}$ that is analogous to the information produ
ed by NRG. To this end, consider a *subchain* of length  $n$  of the full refolded Wilson chain, and use the definition

<span id="page-7-4"></span>
$$
|\Psi_{\beta}^{n}\rangle_{\rm r} = \sum_{\{\boldsymbol{\sigma}^{n}\}} |\boldsymbol{\sigma}^{n}\rangle (B^{[\sigma_{0}]}B^{[\sigma_{1}]} \dots B^{[\sigma_{n}]})_{1\beta} , \qquad (21)
$$

[as in Eq. [\(19\)](#page-7-1), but with N replaced by  $n \mid$  to construct a set of states  $|\Psi^{n}_{\beta}\rangle_{\rm r}$  on this subchain. These states, shown schematically by sites 0 to n of Fig. [2\(](#page-4-0)a), form an orthonormal set,  $\mathbf{r} \langle \Psi_{\alpha}^{n} | \Psi_{\beta}^{n} \rangle_{\mathbf{r}} = \delta_{\alpha\beta}$ , due to the orthonormality  $[Eq. (6)]$  $[Eq. (6)]$  $[Eq. (6)]$  of their constituent matrices. They can thus be viewed as a basis for that *subspace* of the manybody Hilbert spa
e for the length-n Wilson hain, i.e. of that subspace of span $\{|\sigma^n\rangle\}$ , which VMPS sweeping has singled out to be most relevant for describing the ground state  $|E_{\text{G}}^{N}\rangle_{\text{u}}$  of the full chain of length N. Therefore we shall henceforth call the  $|\Psi_{\beta}^{n}\rangle_{r}$  "(refolded) VMPS basis states" for this subchain.

This basis can be used to define an effective "refolded Hamiltonian"  $\mathcal{H}^n_\mathrm{r}$  for this subchain, with matrix elements

<span id="page-7-2"></span>
$$
(\mathcal{H}_r^n)_{\alpha\beta} = {}_r\langle \Psi_\alpha^n | \mathcal{H}_n | \Psi_\beta^n \rangle_r . \tag{22}
$$

Its eigenvalues and eigenstates, say  $(E_{\beta}^{n})_{r}$  and  $|E_{\beta}^{n}\rangle_{r}$ , are the VMPS analogues of the NRG eigenvalues and eigenstates,  $(E_{\beta}^{n})_f$  and  $|E_{\beta}^{n}\rangle_f$ , respectively. They differ, in general, because VMPS and NRG use different truncation criteria, but are expected to agree well for sufficiently large choices of  $D'$  and D. This is indeed found to be the ase, as will be shown in detail in the next se
tion.

# <span id="page-7-0"></span>V. COMPARISON OF NRG AND VMPS RESULTS

Having outlined the NRG and VMPS strategies in the previous se
tion, we now turn to a omparison of their results. This will be done, in successive subsections, by omparing their ground state energies and the overlaps of the orresponding ground states; the eigenspe
tra and density of states obtained from both approaches; and finally, the energy eigenstates used in the two approa
hes. We will thereby gain more insights into the differences between NRG and VMPS truncation criteria. Before embarking on a detailed omparison, though, some remarks on the choices to be made for  $D$  and  $D'$  are in order.

Since the structure of the matrix products occurring in Eqs.  $(7)$  and  $(15)$  differ, the spaces consisting of all states of the type  $|E_{\beta}^{n}\rangle_{f}$  or  $|E_{\beta}^{n}\rangle_{r}$ , to be called the "NRGsubspace" or "VMPS-subspace" for a length-n chain, re- ${\rm spectively,~constitute~nonidentical~subspaces~of~the}~d^{n+1}.$ dimensional Hilbert spa
e spanned by the basis states  $|\sigma^n\rangle$ . The extent to which they describe the energy eigenstates of  $\mathcal{H}_N$  with comparable accuracy will depend very strongly on the choices made for  $D$  and  $D'$ . It turns out

(numeri
al eviden
e will be presented below) that with the choice

<span id="page-8-2"></span>
$$
D' = d'^m \sqrt{D} , \qquad (23)
$$

the VMPS-subspace is sufficiently large to give highly accurate representations of all kept states of NRG (including, in particular, the ground state) for the choice  $m = 1$ , or of all kept and discarded states of NRG for the choice  $m = 2$ . The fact that D' should be proportional to  $\sqrt{D}$  can be made plausible by considering the following question: given a folded Wilson subchain of length  $n$ (i.e. consisting of sites  $0$  to  $n$ ) and its equivalent unfolded version, what are the smallest values for the dimensions D and D' for which both approaches describe the ground state exactly, i.e. without any truncation? Answer: On the one hand, the folded subchain has  $n + 1$  sites of dimension  $d$ , and hence a total dimension  $d^{n+1}$ ; to ensure that the ground state in this space is described exactly, the kept spa
e of the previous iteration must not involve any truncation, implying  $D = d^n$ . On the other hand, for the equivalent unfolded subchain, the spin  $\downarrow$  and  $\uparrow$  parts each have  $n+1$  sites of dimension  $d'$ , hence each have a Hilbert space of total dimension  $d^{(n+1)}$ ; to ensure that this spa
e is des
ribed without trun
ation, its dimension should equal the maximal dimension of the B-matri
es at sites  $0\mu$ , implying  $D' = d^{n+1}$ . Using  $d' = \sqrt{d}$  we readily find  $D' = d' \sqrt{D}$ , establishing the proportionality between D' and  $\sqrt{D}$  and suggesting the choice  $m = 1$  to achieve an accurate VMPS-representation of the ground state. Actually, we find numerically that already  $m = 0$ yields good qualitative agreement between the VMPS and NRG ground states, while  $m = 1$  yields a quantitatively accurate VMPS-representation of the NRG ground state also for larger hain lengths, that do involve trun ation. Sin
e su
h ground states are built from the kept spaces of previous iterations, this implies that for  $m = 1$ , all kept states in NRG (not only the ground state) are likewise well represented by VMPS. Indeed, we will find this to be the case. Moreover, it turns out numerically that with  $m = 2$ , it is also possible to achieve an accurate VMPS-representation of all kept and discarded NRG-type states, as will be extensively illustrated be $low.$ 

For the results reported below, we show data only for even iteration number  $n$ , to avoid even/odd oscillation effects that are typical and well-understood for Wilsonian logarithmic discretization, but not of particular interest here. We set  $D' = d'^m \sqrt{D}$  throughout and specify the choices made for  $m$ . All VMPS results shown in this section are extracted from randomly initialized, fully converged variational ground states  $|E_{\text{G}}^{N}\rangle_{\text{u}}$  of the form [\(15\)](#page-5-2).

### <span id="page-8-0"></span>A. Ground state energies and overlaps

Figures [5\(](#page-9-0)a) and [5\(](#page-9-0)b) ompare the NRG and VMPS ground state energies,  $(E_{\mathrm{G}}^N)_{\mathrm{f}}$  and  $(E_{\mathrm{G}}^N)_{\mathrm{u}},$  for three values of  $\Lambda$  and, in (a), two values of m. They illustrate three points. Firstly, for a given  $\Lambda$  the VMPS ground state energies are smaller than those of NRG,  $(E_{\mathrm{G}}^{N})_{\mathrm{u}} < (E_{\mathrm{G}}^{N})_{\mathrm{f}},$ as expe
ted, sin
e VMPS is a variational method and NRG is not. Secondly, Fig.  $5(a)$  $5(a)$  shows that larger values of m yield lower VMPS ground state energies, as expe
ted, sin
e their variational spa
e is larger. Thirdly, the improvement of VMPS over NRG, as measured by the energy difference  $(E_{\mathbf{G}}^{N})_{\text{f}} - (E_{\mathbf{G}}^{N})_{\text{u}}$  shown in Fig. [5\(](#page-9-0)b), becomes more significant for smaller  $\Lambda,$  as expected, since the trun
ation s
heme of NRG relies heavily on energy scale separation, and hence becomes less efficient for smaller Λ.

Figure [5\(](#page-9-0)c) compares the overlap between NRG and VMPS ground states, hara
terized by the deviation from 1 of the overlap  $|{}_{\mathrm{f}}\langle E_{\mathrm{G}}^N|E_{\mathrm{G}}^N\rangle_{\mathrm{u}}|$ . The latter can be calculated straightforwardly from

<span id="page-8-3"></span>
$$
{}_{f}\langle E_{\mathcal{G}}^{N}|E_{\mathcal{G}}^{N}\rangle_{\mathbf{u}} = \sum_{\{\boldsymbol{\sigma}^{N}\}} (A^{[\sigma_{N}]^{\dagger}} \dots A^{[\sigma_{0}]^{\dagger}})_{\mathcal{G}1} \qquad (24)
$$

$$
\times (B^{[\sigma_{N\downarrow}]} \dots B^{[\sigma_{0\downarrow}]} B^{[\sigma_{0\uparrow}]} \dots B^{[\sigma_{N\uparrow}]})_{11}
$$

where the index contractions associated with the summation over repeated indi
es are illustrated in Fig. [6\(](#page-9-1)a). Fig. [5\(](#page-9-0)) shows that the deviation of the overlap from 1 becomes larger the smaller  $\Lambda$ , again illustrating that then the NRG trun
ation s
heme be
omes less reliable.

### <span id="page-8-1"></span>Comparison of eigenspectra and density of В. states

Figure [7](#page-10-1) compares the energy flow diagrams obtained from NRG and refolded VMPS data, the latter obtained by diagonalizing the effective Hamiltonian of Eq.  $(22)$ . It shows the rescaled energies  $(\varepsilon_{\beta}^{n})_{f,r}$  of Eq. [\(9\)](#page-3-5) as functions of n, for four combinations of m and  $\Lambda$ , and illustrates the same trends as found in the previous subse
 tion: Firstly, the NRG and VMPS flow diagrams clearly agree not only for the ground state but also for a significant number of excited states. Evidently, the variational space searched by VMPS is large enough to capture considerable information about excited states, too, although the VMPS method was designed to optimize only the ground state. Moreover, for a given choice of  $\Lambda$ , NRG and VMPS eigenenergies oin
ide for a larger number of states for  $m = 2$  than for  $m = 0$  [compare (b) to (a) and (d) to (c), because the variational space is larger. Secondly, for a given choice of  $m$ , NRG and VMPS eigenenergies agree better for  $\Lambda = 2.5$  than for  $\Lambda = 1.5$  [compare  $(c)$  to  $(a)$  and  $(d)$  to  $(b)$ , as expected, because larger Λ leads to better energy s
ale separation and redu
es the inaccuracies inherent in NRG's Wilsonian truncation s
heme.

As a complementary way of analysing spectral information we also consider the "density of states", for a given

<span id="page-9-0"></span>Figure 5: (Color online) Comparison of NRG and VMPS results for  $(a,b)$  the ground state energies and  $(c)$  the ground state overlaps, plotted as a functions of D with  $D' = d^{\prime m} \sqrt{D}$ , for three values of  $\Lambda$  and, in (a), for two values of m. In (a) the reference energies  $E_{\mathrm{ref}}^{N}$  for each  $\Lambda$  were obtained by extrapolating the VMPS data points for  $m = 2$  to  $D' \to \infty$ , which represents the best estimate of the true ground state energy available within the present set of methods. The power law fits to the numerical data in  $(b)$  and  $(c)$ , shown as dashed lines, were made for the three data points with largest D, for whi
h the dimensions are large enough to have reliable NRG data.

iteration number  $n$ ,

$$
\rho_n(\varepsilon) = \sum_{\alpha=1}^{D_{\text{max}}} \delta_\sigma(\varepsilon - \varepsilon_\alpha^n) , \qquad (25)
$$

using the rescaled eigenenergies  $\varepsilon_{\beta}^{n}$  of Eq. [\(9\)](#page-3-5). Here

<span id="page-9-1"></span>Figure 6: (Color online) Contraction patterns used to calculate (a) the overlap  $_{f} \langle E_{\rm G}^N | E_{\rm G}^N \rangle$ <sub>u</sub> [Eq. [\(24\)](#page-8-3)] between folded NRG and unfolded VMPS ground states, and (b) the overlap matrix  $\tilde{S}^n_{\alpha\beta} = {}_{\rm r}\langle \Psi^n_\alpha|E^n_\beta\rangle_{\rm f}$  [Eq. [\(27b\)](#page-10-2)] between refolded VMPS basis states and folded NRG eigenstates. Boxes represent A or B matri
es in the graphi
al representation of Fig. [2,](#page-4-0) and links onne
ting them represent indi
es that are being summed over.

 $\delta_{\sigma}(\varepsilon) = e^{-\varepsilon^2/\sigma^2}/(\sigma\sqrt{\pi})$  is a Gaussian peak of width  $\sigma$ and unit weight, used to broaden the discrete spectrum in order to be able to plot it, and the number of states included in the sum is taken as  $D_{\text{max}} = dD$  or  $d^m D$  for NRG or VMPS results, respe
tively. Figure [8](#page-11-0) shows su
h a density of states for several choices of m and iteration number  $n$ . It illustrates three points:

Firstly, although for small energies  $\rho_n(\varepsilon)$  grows rapidly with  $\varepsilon$ , as expected for a many-body density of states, it does not continue to do so for larger  $\varepsilon$  (the exact density of states would), due to the trun
ation inherent in both NRG and VMPS strategies. For NRG,  $\rho_n(\varepsilon)$  drops to 0 very abruptly, because by construction Wilsonian trunation is sharp in energy spa
e (at ea
h iteration only the lowest  $dD$  eigenstates are calculated). In contrast, for VMPS  $\rho_n(\varepsilon)$  decreases more gradually for large  $\varepsilon$ . because VMPS truncation for states at site  $n$  is based not on their energy, but on the variationally determined weight of their ontribution to the ground state of the full Wilson chain of length  $N$ . Evidently, these weights decrease with increasing  $\varepsilon$  less rapidly than assumed by NRG.

Secondly, the agreement of the VMPS curve for  $\rho_n(\varepsilon)$ with that of NRG is rather poor for  $m = 0$  (disagreement sets in already within the range of kept states of NRG, indicated by the shaded region), better for  $m = 1$  (the

<span id="page-10-1"></span>Figure 7: (Color online) Comparison of energy flow diagrams from NRG (dashed red lines) and refolded VMPS data (solid black lines), showing the rescaled energies  $(\varepsilon_{\beta}^n)_{\rm f,r}$  [Eq. [\(9\)](#page-3-5)] versus  $n,$  calculated for even iteration numbers and four combinations of  $m (= 0$  or 2) and  $\Lambda (= 1.5$  or 2.5). The number of NRG states shown (kept and discarded) is  $Dd$ ; the number of refolded VMPS states shown is  $D^{\rm r}=D'^2=d^mD,$  this being the maximal dimension of refolded matrices  $B^{[\sigma_n]}$ . For  $m=2$  and  $\Lambda=2.5,$ the NRG and DMRG flow diagrams agree very well, see (d).

range of kept states is fully reprodu
ed), and very good for  $m = 2$  (disagreement sets in only close to the upper end of range of dis
arded states).

Thirdly, for large n,  $\rho_n(\varepsilon)$  becomes increasingly spiky. This reflects the fact that the spectrum approaches a xed point with regularly-spa
ed eigenenergies, as is ev-ident in the energy flow diagrams of Fig. [7.](#page-10-1)

### <span id="page-10-0"></span>C. Comparison of energy eigenstates

To compare the energy *eigenstates* produced by NRG and refolded VMPS for a chain of length  $n$ , we analyse the overlap matrix

<span id="page-10-3"></span>
$$
S^n_{\alpha\beta} = {}_{\rm r} \langle E^n_{\alpha} | E^n_{\beta} \rangle_{\rm f} \ . \tag{26}
$$

It can be conveniently calculated from  $S^n\;=\;U^n\tilde{S}^n,$ where  $U_{\alpha\beta}^n = {}_{\rm r}\langle E_{\alpha}^n | \Psi_{\beta}^n \rangle_{\rm r}$  is the matrix that diagonalizes the effective Hamiltonian matrix  $\mathcal{H}_{\alpha\beta}^n$  of Eq. [\(22\)](#page-7-2), and the matrix

<span id="page-10-2"></span>
$$
\tilde{S}^{n}_{\alpha\beta} = {}_{\rm r}\langle \Psi^{n}_{\alpha} | E^{n}_{\beta} \rangle_{\rm f} ,
$$
\n
$$
= \sum_{\{\sigma^{N}\}} (B^{[\sigma_{n}] \dagger} \dots B^{[\sigma_{0}] \dagger})_{\alpha 1} (A^{[\sigma_{0}]} \dots A^{[\sigma_{n}]})_{1\beta} (27b)
$$

hara
terizes how mu
h weight the NRG eigenstates have in the spa
e spanned by the refolded VMPS basis states, and vice versa. The contractions implicit in Eq. [\(27b\)](#page-10-2) are illustrated in Fig. [6\(](#page-9-1)b).

Figure [9](#page-11-1) shows the overlap matrix  $S^n_{\alpha\beta}$  on a color scale ranging from 0 to 1, for  $m = 1$  and several values of n. For the region of low excitation energies (about the first

<span id="page-11-0"></span>Figure 8: (Color online) Results for the density of states,  $\rho_n(\varepsilon)$  $|Eq. (25)|$  $|Eq. (25)|$  $|Eq. (25)|$ , broadened with a Gaussian broadening function. In each panel, the red vertical dashed and solid lines which coincide in (a) indicate the energies of the highest-lying kept and dis
arded NRG states of that iteration, while the shaded area indi
ates the range of kept NRG states.

hundred or so states) its structure is evidently close to block-diagonal, indicating that both sets of states from which it is built are reasonably good energy eigenstates. Had both sets been perfe
t energy eigenstates, as would be the case for  $D'$  and  $D$  large enough to avoid all trunation, the blo
ks would be ompletely sharp, with sizes determined by the degeneracies of the corresponding energies. Sharp blocks are indeed observed for  $n = 2$ [Fig.  $9(a)$  $9(a)$ ], because no truncation has occurred yet. The "fuzziness" shown by the blocks in Fig.  $9(b)$  $9(b)$  to  $9(d)$  for larger  $n$  implies that truncation is beginning to make itself felt, ausing NRG and VMPS to in
reasingly disagree on how to onstru
t the eigenstates orresponding to a given range of eigenenergies. Note that the fuzziness be comes markedly more pronounced for  $\alpha, \beta > 256$ . The reason is that whenever  $S^n_{\alpha\beta}$  is nonzero for  $\beta > D$ , the associated VMPS states have weight among the discarded states of NRG, implying that NRG dis
ards some states relevant for building the VMPS ground state. Thus,  $S^{n}_{\alpha\beta}$ quite literally measures to what extent the truncation criteria of NRG and VMPS are ompatible. Near the end of the chain, for  $n = 18$  [Fig. [9\(](#page-11-1)d)], the off-diagonal spread is significantly reduced compared to the middle of the chain  $(n = 6, 12)$  [Fig. [9\(](#page-11-1)b,c)], for two reasons. Firstly, the dimensions of the refolded B-matrices become small for *n* near N, see Eq.  $(20)$ , so that the amount of truncation is mu
h less severe near the end of the hain than in its middle. Se
ondly, the eigenspe
tra have onverged to their fixed point values, so that the number of different eigenenergies in a given energy interval is reduced, thus redu
ing the fuzziness in Fig. [9\(](#page-11-1)d).

Next onsider the total weight whi
h a given NRGstate  $|E_{\beta}^n\rangle_{\rm f}$  has within the refolded VMPS-subspace for

<span id="page-11-1"></span>Figure 9: (Color online) Plot of the overlap matrix  $S^n_{\alpha\beta}$  =  $\mathbf{E}_{\alpha}[E_{\alpha}^{n}]E_{\beta}^{n}\rangle_{\mathrm{f}}$  [Eq. [\(26\)](#page-10-3)] between refolded VMPS and NRG energy eigenstates, with a olor s
ale ranging between 0 and 1. In (a), with  $n = 2$ , no truncation occurs at all, and both state labels  $\alpha$  and  $\beta$  run from 1 to  $d^{n+1} = 64$ . In (b) to (d), truncation does occur: For the folded NRG eigenstates  $|E_{\beta}^{n}\rangle_{\text{f}}$ , the label  $\alpha$  runs from 1 to  $Dd = 1024$ , i.e. it includes all kept and dis
arded NRG states, while for the refolded VMPS eigenstates  $|E_{\beta}^n\rangle_r$  $|E_{\beta}^n\rangle_r$ , the label  $\beta$  runs from 1 to  $D_n^r = D'^2 = 1024$  $[Eq. (20)].$ 

that n,

<span id="page-11-2"></span>
$$
w_{\beta}^{(n)} = \sum_{\alpha=1}^{D_n^r} |S_{\alpha\beta}|^2 = \sum_{\alpha=1}^{D_n^r} |\tilde{S}_{\alpha\beta}|^2.
$$
 (28)

It satisfies  $0 \leq w_{\beta}^{(n)} \leq 1$ . Weights less than 1 imply that the VMPS-subspa
e is too small to adequately represent the corresponding NRG state. The second equality in Eq. [\(28\)](#page-11-2), whi
h follows from the unitarity of  $U$ , is useful since it implies that these weights can also be calculated directly from the refolded states  $|\Psi_{\beta}^{n}\rangle_{\rm r}$ [Eq.  $(21)$ ], without the need for diagonalizing the large  $(D^2 \times D^2$ -dimensional) effective refolded Hamiltonian  $\mathcal{H}_r^n$  [Eq. [\(22\)](#page-7-2)].

Figure [10](#page-12-0) shows such weights  $w_\beta^{(n)}$  $\beta$  for various choices of  $n, \Lambda$  and  $m$ . Their dependence on  $m$  reinforces the conclusions of the previous subsection: For  $m = 0$  (blue + symbols), the weights are equal to 1 for the lowest state of ea
h iteration, but less than 1 for many of the kept states. This shows that the VMPS subspa
e is large enough to accurately represents the NRG ground state, but significantly too small to accurately represent all kept states. For  $m = 1$  (green  $\times$  symbols), the weights are close to 1 only for the kept states, while smoothly de
reasing towards 0 for higher-lying dis
arded states. Finally, for  $m = 2$  (orange  $\circ$  symbols), the weights of both kept and dis
arded NRG states are all lose to 1, implying that the VMPS subspace is large enough to accurately represent

<span id="page-12-0"></span>Figure 10: (Color online) For several NRG iteration numbers n and two values of  $\Lambda$  (different panels), this figure shows the weights  $w_{\beta}^{(n)}$  [Eq. [\(28\)](#page-11-2)] with which NRG states  $|E_{\beta}^{n}\rangle_{\mathrm{f}}$  with rescaled NRG eigenenergies  $(\varepsilon_{\beta}^n)_\mathrm{f}$  [Eq. [\(9\)](#page-3-5)] are found to lie in the VMPS-subspace of dimension  $D' = d'^m \sqrt{D}$ , with  $m = 0$ , 1 or 2 (indicated by  $+$ ,  $\times$  or  $\circ$ , respectively). In each panel, the red verti
al dashed and solid lines indi
ate the energies of the highest-lying kept and dis
arded NRG states of that iteration. For  $n = 3$ , both of these lines are missing, since truncation has not yet set in. The choices for  $n$  in the left and right panels of each row are related by  $\Lambda_1^{-n_1/2} = \Lambda_2^{-n_2/2}$ , to ensure that both panels show a omparable energy s
ale.

essentially *all* states kept track of by NRG. Note that for  $m=0$  and 1, the decrease of the weights  $w_\beta^{(n)}$  $\beta$  with increasing energy occurs in a smooth and gradual fashion, illustrating yet again the smooth nature of VMPS trun ation when viewed in energy spa
e. When a smaller value of  $\Lambda$  is used [compare panels (a-d) to (e-h)] the weights of the higher-lying states of a given iteration tend to spread out over a larger range of values, sin
e NRG has a weaker energy scale separation for smaller  $\Lambda$ . Finally, the increasing spikyness of the eigenspectrum with increasing n, see Fig.  $10(d,h)$  $10(d,h)$ , is due to the approach to a fixed point spectrum with regularly-spaced eigenenergies, as mentioned above.

<span id="page-12-2"></span>Figure 11: (Color online) Integrated weights  $W_{\rm X}^{(n)}$  (see Eq. [\(29\)](#page-12-1)) for two different  $\Lambda$  and three values of m. Dashed lines depi
t the maximum possible values of the kept and dis carded weights,  $\frac{1}{4}$  and  $\frac{3}{4}$  for  $W_{\rm K}^n$  and  $W_{\rm D}^n$ , respectively.

The results just discussed may be represented more compactly by considering, for a given iteration  $n$ , the integrated weights obtained by summing up the weights of all NRG states of type  $X$ ,

<span id="page-12-1"></span>
$$
W_{\mathbf{X}}^{(n)} = \frac{1}{dD} \sum_{\beta \in \mathbf{X}} w_{\beta}^{(n)} , \qquad (29)
$$

where  $X = K, D, A$  stands for kept, discarded or all, respe
tively. All three types of integrated weights are normalized to the total number  $dD$  of all NRG states calculated at a given iteration (with  $d = 4$  here), and reach their maximal values  $(\frac{1}{4}, \frac{3}{4}$  and 1, respectively) when all the individual weights for that iterations for  $\mathcal{L}_1$ ure [11](#page-12-2) shows su
h integrated weights for several values of m and  $\Lambda$ . Upon increasing m from 0 to 2, the integrated weights tend toward their maximal values, doing so more rapidly for larger  $\Lambda$ . For  $m = 2$ , they essentially saturate their maximal values, indicating yet again that the VMPS variational spa
e is now large enough to fully retain all information kept tra
k of by NRG.

To summarize the result of this section: The VMPS approa
h reprodu
es NRG ground state properties mu
h more cheaply, requiring only  $D' = \sqrt{D}$  for qualitative agreement, and  $D' = d' \sqrt{D}$  for quantitative agreement. Moreover, it can also reproduce all kept and discarded NRG eigenstates if  $D' = d'^2 \sqrt{D}$  is used. However, to obtain excited energy eigenstates, we have to refold, requiring the diagonalization of matri
es of dimension  $D^2 \times D^2$ . The numerical cost of doing so is comparable to that of NRG.

The fact that VMPS gives access to the same information on eigenstates and eigenvalues as NRG has a very significant and reassuring consequence: all physical properties of the model that can be calculated by NRG can also be calculated by VMPS, in combination with refolding.

# <span id="page-13-0"></span>IMPROVEMENT OF NRG GROUND STATE

Viewed in MPS language, the NRG method onstru
ts the ground state in a single sweep along the chain: each A is calculated only once, without allowing for possible feedba
k of information from A's des
ribing lower energies to those of higher energies al
ulated earlier. Thus, the resulting NRG ground state  $|E_G^N\rangle_f$ , to be denoted simply by  $|G\rangle_f$  below, is not optimal in a variational sense. In this section we investigate to what extent the ground state energy an be lowered further by performing variational energy optimization sweeps on  $|G\rangle_f$  that serve to account for feedback of information from low to high energy scales. This feedback turns out to be small in practice, as will be seen below, but it is not strictly zero and its importance increases as the logarithmic discretization is refined by taking  $\Lambda \rightarrow 1$ .

### <span id="page-13-4"></span>A. Mapping folded to unfolded states by loning

Our first step is to rewrite a given NRG ground state  $|G\rangle_f$  in a form amenable to subsequent energy minimization sweeps. To this end, we use a variational *cloning* pro
edure (subs
ript ),

$$
|G\rangle_f \stackrel{\text{cloning}}{\longrightarrow} |G\rangle_c \in \{|\Psi^N\rangle_u\},\tag{30}
$$

which maps  $|G\rangle_f$  of the form of Eq. [\(7\)](#page-3-0)  $[Fig. 2(a)]$  $[Fig. 2(a)]$  $[Fig. 2(a)]$  onto an unfolded state  $|G\rangle_c$  of the form  $|\Psi^N\rangle_u$  of Eq. [\(15\)](#page-5-2) [Fig. [2\(](#page-4-0)c)]. Since their matrix product structures differ, this mapping will, for general values of  $D$  and  $D'$ , not be exact, though its accuracy should improve systematically with increasing  $D'$  and hence increasing dimensions of the variational spa
e. To be expli
it, we seek the best possible approximation to  $|G\rangle_f$  in the space of all unfolded states of the form [\(15\)](#page-5-2), by solving the minimization problem

<span id="page-13-1"></span>
$$
\min_{|G\rangle_c \in \{|\Psi^N\rangle_u\}} \left[ \|\ |G\rangle_f - |G\rangle_c\|^2 + \lambda (\|\ |G\rangle_c\|^2 - 1) \right] \ , \ (31)
$$

which minimizes the "distance" between  $|G\rangle_c$  and  $|G\rangle_f$ under the onstraint, implemented using a Lagrange mul-

<span id="page-13-3"></span>Figure 12: (Color online) The deviation of the overlap  $|c\langle G|G\rangle_f|$  from 1 (red circles) and the cloning truncation error  $\tau(D')$  (blue squares), as functions of the number  $D'$  of kept states in the cloning procedure. Both approach 0 in power-law fashion, as indicated by the dashed line fits. The inset shows how the overlap deviation from 1 decreases and converges to a small but finite constant in the course of sequential cloning sweeps.

tiplier  $\lambda$ , that the norm  $_{\rm c}\langle G|G\rangle_{\rm c} = 1$  remains constant. Varying Eq.  $(31)$  with respect to the matrices defining  $|G\rangle_c$  leads to a set of equations, one for each  $k\mu$ , of the form

<span id="page-13-2"></span>
$$
\frac{\partial}{\partial B^{[\sigma_{k\mu}]}} \Big[ (1+\lambda) \, {}_{c}\langle G|G\rangle_c - 2\text{Re}\big({}_{f}\langle G|G\rangle_c\big) \Big] = 0, \quad (32)
$$

which determine the B-matrices of the desired "cloned" state  $|G\rangle_c$ . These equations can be solved in a fashion entirely analogous to energy optimization: Pick a particular site of the unfolded chain, say  $k\mu$ , and solve the corre-sponding Eq. [\(32\)](#page-13-2) for the matrix  $B^{[\sigma_{k\mu}]}$  while regarding the matrices of all other sites as fixed. Then move on to the neighboring site and in this fashion sweep ba
k and forth through the chain until convergence is achieved. Appendix [A 3](#page-17-1) des
ribes some details of this pro
edure.

A figure of merit for the success of cloning is the deviation of the overlap  $|c \langle G | G \rangle_f |$  from 1. This deviation decreases monotonically with successive cloning sweeps and converges to a small but finite  $(D^\prime\text{-dependent})$  value when the cloning process converges, as illustrated in the inset of Fig. [12.](#page-13-3) The main part of Fig. [12](#page-13-3) shows that when the number  $D'$  of VMPS states is increased, the onverged value of the overlap deviation approa
hes 0 as a power law in  $D'$  (red circles). It also shows that the cor- $\mathop{\mathsf{resp}}\nolimits$  onding VMPS truncation error  $\tau(D')$  incurred during cloning (blue squares), calculated according to Eq.  $(18)$ , likewise decreases in power-law fashion with  $D'$ . All in all, Fig. [12](#page-13-3) confirms that cloning works very well if  $D'$  is sufficiently large.

<span id="page-14-1"></span>Figure 13: (Color online) Comparison of (a) energies and (b) wave function overlaps for random initialization (squares) vs. NRG-cloned initialization (circles), as functions of the number  $k_{\text{em}}$  of variational energy minimization sweeps. Results are shown for  $\Lambda = 1.5$  (green, open symbols, dashed lines) and  $\Lambda = 2.5$ , (blue, filled symbols, solid lines). The energies in (a) and overlaps in (b) are calculated with respect to a reference ground state  $|G\rangle_{ref}$  with  $D' = 64$ , obtained by performing 50 energy minimization sweeps starting from random initialization. The red horizontal straight lines in (a) (dashed or solid for  $\Lambda = 1.5$  or 2.5, respectively), show the energy difference  $E_{\text{NRG}} - E_{\text{ref}}$ , where  $E_{\text{NRG}}$  is the energy of the NRG ground state  $|G\rangle_f$  used as input into cloning. The fact that  $E_{\rm NRG}$ does not completely coincide with the energy  $E_c = E_{k_{\text{em}}=0}$  of the cloned state (horizontal straight lines do not meet circles at  $k_{\text{em}} = 0$ ) is due to the fact that the deviation of the overlap  $|c\langle G|G\rangle_f|$  from 1 is not strictly equal to 0 (see Fig. [12\)](#page-13-3).

### B. Variational energy minimization of  $|G\rangle_c$

Having used cloning to find the optimal unfolded representation  $|G\rangle_c$  of the NRG ground state  $|G\rangle_f$ , we now variationally minimize its energy by sweeping. We thereby obtain a sequence of states  $|G\rangle_c^{k_{\text{em}}}$  of ever lower energy,  $E_{k_{em}}$ , where the index  $k_{em} = 0, 1, 2, \dots$  gives the number of energy minimization sweeps that have been performed. The pro
edure is pre
isely analogous to that described in Section IVA, the only difference being that the random initial state used there is here repla
ed by the cloned state  $|G\rangle_c^0 = |G\rangle_c$  as initial state.

Figure  $13(a)$  $13(a)$  shows the evolution of the ground state

energy  $E_{k_{em}}$  as function of the number  $k_{em}$  of energy minimization sweeps, for both random (squares) and cloned (circles) initial states.  $E_{k_{\text{em}}}$  is displayed with respect to the energy  $E_{\text{ref}}$  of a reference state  $|G\rangle_{\text{ref}}$ , defined in the figure caption, which represents our best approximation to the true ground state. Figure [13\(](#page-14-1)b) shows how  $1 - \vert_{ref} \langle G | G \rangle_c$  decreases as sweeping procedes, converging to a small but finite value. For a given value of  $\Lambda$  (1.5, shown in green, open symbols onne
ted by dashed lines, or 2.5, shown in blue, filled symbols connected by solid lines), the energies for random and cloned initialization shown in Fig.  $13(a)$  $13(a)$  converge to the same value within just a few sweeps. However, the convergence is quicker for the cloned (circles) than the random (squares) input state, sin
e the former represents an already rather good initial approximation (namely that of NRG) to the true ground state, whereas the latter is simply a random state. Nevertheless, the circles show strikingly that the NRG ground energy is not optimal, in that the energy an be lowered still further by sweeping. Moreover, this improvement is more significant for small than large  $\Lambda$ (for ir
led data points, ompare dashed green to solid blue lines for  $\Lambda = 1.5$  or 2.5, respectively). The reason is that the NRG truncation scheme becomes less accurate the smaller  $\Lambda$  is, implying that the NRG result can be improved more significantly by further sweeping. This is again a reminder that the systematic error of NRG increases as  $\Lambda$  approaches 1, as already observed in Fig. [5.](#page-9-0)

### <span id="page-14-0"></span>VII. CONCLUSIONS

In this paper we presented a systematic comparison between NRG and DMRG, whi
h we mainly referred to as VMPS, for the single-impurity Anderson model within the framework of matrix product states. We first reformulated both NRG and DMRG in the language of MPS, using a folded Wilson hain for NRG and an unfolded one for DMRG. Then we quantitatively ompared the results of NRG and the VMPS approa
h for energy eigenvalues and eigenstates and explicitly analysed the difference in their truncation criteria, which are sharp or smooth in energy spa
e, respe
tively.

The most important on
lusion of our study is this: For the purpose of obtaining the ground state of this model, the VMPS approach applied to the unfolded Wilson chain yields a very significant increase in numerical efficiency compared to NRG  $(D' = d' \sqrt{D})$ , essentially without loss of relevant information. The physi
al reason is that the spin-down and -up hains are only weakly entangled for this model, so that the NRG matrices  $A^{[\sigma_n]}$  of dimension D that describe site  $n$  of the Wilson chain, can, in effect, be factorized as a direct product  $B^{[\sigma_{n\downarrow}]} \otimes B^{[\sigma_{n\uparrow}]}$  of two matrices, each having dimension  $d' \sqrt{D}$ . It should be emphasized, though, that this property relies on the physi
s of the model, namely the weak entanglement of the spin down and up hains. To what extent this property survives for other impurity models should be a subject for further resear
h, the twohannel Kondo model being a parti
ularly interesting andidate in this respe
t.

Nevertheless, the possibility of using unfolded Wilson chains to reduce numerical costs for ground state calulations is very attra
tive for possible appli
ations of the VMPS method to more ompli
ated models involving more than one conduction band.<sup>21</sup> For example, the ondu
tan
e through a quantum dot oupled to two leads an under ertain onditions (linear response, zero temperature, Fermi liquid behavior, et
.) be expressed in terms a set of phase shifts that are uniquely determined by the ground state occupation of the dot energy levels.<sup>23</sup> Thus, in su
h situations reliable knowledge of the ground state is sufficient to calculate transport properties.

Going beyond ground state properties, we showed that the entire excited state eigenspectrum of both kept and dis
arded NRG states an be re
overed within the VMPS approach with at least the same accuracy as NRG, by using  $D' = d'^2 \times$  $\sqrt{D}$  and refolding. However, the latter step requires a subsequent additional diagonalization of matrices of dimensions  $D^2$ , giving rise to a significant inrease in numeri
al resour
es ompared to the ase that only ground state information is required. A quantitative omparison between NRG and VMPS for the eigenspe
trum's energies and eigenstates showed better agreement for  $\Lambda = 2.5$  than 1.5, due to the fact that the NRG truncation scheme becomes increasingly less accurate the closer  $\Lambda$  approaches 1.

Finally, we used a cloning procedure to recast a given folded NRG ground state into an unfolded form, and showed that its energy could be lowered further by subsequent energy minimization sweeps. As expected, we found that sweeping improves the relative accuracy with which the ground state energy can be determined, the more so the smaller the value of  $\Lambda$ . For example, for  $\Lambda = 1.5$  the accuracy changed from  $\mathcal{O}(10^{-4})$  $\mathcal{O}(10^{-4})$  $\mathcal{O}(10^{-4})$  before sweeping to  $\mathcal{O}(10^{-7})$  thereafter [see Fig. 13(a)]. The fact that su
h a further variational improvement of the NRG ground state is possible, however, is of significance mainly as a matter of principle, not of practice: for the numerous situations where NRG works well (in particular, for  $\Lambda$  not too close to 1), we expect that such further variational improvement of the NRG ground state will not noticeably affect any physical observables.

Let us conclude with some comments about the pros and ons of NRG and VMPS. For quantum impurity models with a comparatively low degree of complexity, su
h as the single-lead Anderson and Kondo models, NRG works exceedingly well and for practical purposes nothing is to be gained from switching to the VMPS approa
h. The latter is a potentially attra
tive alternative to NRG only for two types of situations, namely (i) more complex quantum impurity models, and (ii) nonlogarithmic discretization of the leads. We briefly discuss these in turn.

(i) For omplex quantum impurity models, in parti
-

ular ones involving several leads, VMPS a
hieves a very significant reduction in memory cost, relative to NRG, for des
ribing ground state properties via unfolding the Wilson chain. There are several caveats, though. Firstly, this reduction in memory cost applies only when only ground state properties are of interest. To obtain ex cited state eigenspectra, the memory costs of NRG and VMPS are omparable. Se
ondly, unfolding is expe
ted to work well only for models for whi
h the sub
hains that are being unfolded are only weakly entangled, whi
h will not be the ase for all impurity models. For example, the twohannel model might be an example where unfolding works less well. In general, one needs to check the extent to which degrees of freedom on different subchains are entangled with each other, by calculating the mutual information of two sites on different subchains. If this does not de
rease rather rapidly with their separation from the impurity site, then unfolding will be a poor strategy. Appealingly, though, such a check can be done purely using NRG data, as illustrated in Section [III C.](#page-4-2) Thirdly, the fa
t that VMPS relies on variationally optimizing the ground state might ause onvergen
e problems for models whi
h have degenerate ground states. Con
eivably this problem an be redu
ed by systemati
ally exploiting all relevant symmetries of the Hamiltonian, in
luding non-Abelian symmetries,24,25 . However, if states in the lo
al state spa
e of a folded Wilson hain are related by a non-Abelian symmetry, then this symmetry would not be manifest in the unfolded representation. Thus, the two possible strategies for achieving significant memory reduction, namely unfolding and exploitation of symmetries might not always be mutually ompatible; whi
h one is more favorable will depend on the details of the model, and is an interesting subject for further study.

(ii) The VMPS approach offers clear advantages over NRG in situations where Wilson's logarithmic discretization of the ondu
tion band annot be applied. In the present paper, we found clear indications for this fact in the observation that the improvement of VMPS relative to NRG becomes more significant as  $\Lambda$  is chosen closer to 1. More importantly, VMPS offers the possibility, inaccessible to NRG, to improve the frequency resolution of spectral functions at high frequencies, by using a flexible (non-logarithmic) discretization scheme which reduces the level spacing of effective lead states in the energy regimes where higher frequency resolution is desired. For su
h a dis
retization s
heme Wilsonian energy scale separation is lost and NRG truncation cannot be applied. However, the ground state an still be found variationally, and spectral functions can be computed using projection operator techniques. In this fashion, it has recently been possible to calculate the spectral function for the Anderson model at large magnetic fields,  $B > T<sub>K</sub>$ , and to resolve the split Kondo resonance with sufficient accuracy to reproduce the widths expected from perturbation theory in this regime. These developments, though, go beyond the s
ope of the present paper and will be published separately.15,20

### <span id="page-16-3"></span>Appendix A: TECHNICAL DETAILS

In this appendix, we collect some technical details on various manipulations involving matrix produ
t states.

# <span id="page-16-2"></span>1. Orthonormalization of B-matri
es of unfolded Wilson hain

To keep the notation simple, in this subse
tion we shall imagine the sites of the unfolded Wilson hain to be stret
hed along a line running from left to right, enumerated by an index k running from 1 for site  $N\downarrow$ to  $K = 2(N + 1)$  for site  $N \uparrow$ . Correspondingly, matrix product states will generically be written as  $|\Psi\rangle$  =  $\sum_{\{\sigma^K\}} |\sigma^K\rangle \left(\prod_{k=1}^K B^{[\sigma_k]}\right)$ , with matrix elements  $B^{[\sigma_k]}_{\nu\eta}$ .

It is onvenient to ensure that every B-matrix in <sup>a</sup> matrix product state satisfies one of the following two orthonormality onditions:

<span id="page-16-4"></span><span id="page-16-1"></span>
$$
\sum_{\sigma_k} B^{[\sigma_k] \dagger} B^{[\sigma_k]} = 1 , \qquad (A1a)
$$

$$
\sum_{\sigma_k} B^{[\sigma_k]} B^{[\sigma_k]\dagger} = 1. \tag{A1b}
$$

In particular, if all B-matrices satisfy either the first or the se
ond of these onditions, the orresponding matrix produ
t state is automati
ally normalized:

$$
\langle \Psi | \Psi \rangle = \sum_{\{\sigma^K\}} (B_{1\nu'}^{[\sigma_K] \dagger} \dots B_{\eta' 1}^{[\sigma_1] \dagger}) (B_{1\eta}^{[\sigma_1]} \dots B_{\nu 1}^{[\sigma_K]}) = 1.
$$
\n(A2)

This follows by iteratively applying Eq. [\(A1\)](#page-16-1). To start the iteration, note that for matri
es at the beginning or end of the hain, where one of the matrix Eqs. [\(A1a\)](#page-16-4) or [\(A1b\)](#page-16-4) imply  $\sum_{\sigma_1} B_{\eta'1}^{[\sigma_1]\dagger} B_{1\eta}^{[\sigma_1]} = \delta_{\eta'\eta}$  or  $\sum_{\sigma_K} B_{\nu 1}^{[\sigma_K]} B_{1\nu'}^{[\sigma_K]\dagger} = \delta_{\nu \nu'}$ , respectively. In the NRG approa
h, all A-matri
es naturally satisfy Eq. [\(A1a\)](#page-16-4) [
f. Eq.  $(6)$ .

In the VMPS approach, it is convenient to ensure that during variational optimization sweeps, Eq. [\(A1a\)](#page-16-4) holds for all matrices to the left of the site, say  $k$ , currently being updated, and Eq. [\(A1b\)](#page-16-4) for all matri
es to its right. Thus, after optimizing the set of matrices  $B^{[\sigma_k]}$  at site  $k$ , this set should be orthonormalized before moving on to the next site, such that it satisfies Eq.  $(A1a)$  when sweeping from left to right (or Eq. [\(A1b\)](#page-16-4) when sweeping from right to left). This can be achieved using singular value decomposition [cf. Eq.  $(17)$ ]: Arrange the matrix elements of the set of matrices  $B^{[\sigma_k]}$  into a rectangular into a re
tangular matrix arrying only two labels, with matrix elements  $\mathcal{B}_{\bar{\nu}\eta} = B_{\nu\eta}^{[\sigma_k]}$  (or  $\mathcal{B}_{\nu\bar{\eta}} = B_{\nu\eta}^{[\sigma_k]}$ ), by introducing a composite index  $\bar{\nu} = (\sigma_k, \nu)$  (or  $\bar{\eta} = (\sigma_k, \eta)$ ). Using singular value decomposition  $[Eq. (17)],$  $[Eq. (17)],$  $[Eq. (17)],$  write this new matrix as  $\mathcal{B} = \mathcal{U} \mathcal{S} \mathcal{V}^{\dagger}$ . Then rewrite the matrix product of two neighboring B-matrices as  $B^{[\sigma_k]}B^{[\sigma_{k+1}]} = \tilde{B}^{[\sigma_k]} \tilde{B}^{[\sigma_{k+1}]}$  $(\text{or } B^{[\sigma_{k-1}]}B^{[\sigma_k]} = \tilde{B}^{[\sigma_{k-1}]}\tilde{B}^{[\sigma_k]}),$  where the new matrices  $\ddot{B}$  are defined by

<span id="page-16-8"></span>
$$
\tilde{B}_{\nu\gamma}^{[\sigma_k]} = \mathcal{U}_{\bar{\nu}\gamma} , \quad \tilde{B}_{\gamma\delta}^{[\sigma_{k+1}]} = (\mathcal{S}\mathcal{V}^{\dagger}B^{[\sigma_{k+1}]})_{\gamma\delta} , \quad (A3)
$$

$$
(\text{or } \tilde{B}_{\delta\eta}^{[\sigma_k]} = \mathcal{V}_{\delta\bar{\eta}}^{\dagger}, \quad \tilde{B}_{\gamma\delta}^{[\sigma_{k-1}]} = (B^{[\sigma_{k-1}]} \mathcal{U} \mathcal{S})_{\gamma\delta}). \quad (A4)
$$

The property  $\mathcal{U}^{\dagger} \mathcal{U} = \mathbb{1}$  (or  $\mathcal{V}^{\dagger} \mathcal{V} = \mathbb{1}$ ) ensures that the new set of matrices  $\tilde{B}^{[\sigma_k]}$  at site k is orthonormal according to Eq.  $(A1a)$  (or Eq.  $(A1b)$ ), as desired. Now proceed to the next site to the right (or left) and orthonormalize  $\tilde{B}^{[\sigma_{k+1}]}$  (or  $\tilde{B}^{[\sigma_{k-1}]})$  in the same manner, etc.

The above pro
edure an be used to orthonormalize the matri
es of a randomly generated matrix produ
t state before starting VMPS sweeping. Likewise, during VMPS sweeping, ea
h newly optimized matrix an be orthonormalized in the above fashion before moving on to optimize the matrix of the next site.

### <span id="page-16-0"></span>2. Refolding

This subse
tion des
ribes how to refold an unfolded matrix produ
t state of the form

<span id="page-16-5"></span>
$$
|\Psi_{\nu\eta}^{n}\rangle_{\mathfrak{u}} = \sum_{\{\sigma^{N}\}} |\sigma^{n}\rangle (B^{[\sigma_{n\downarrow}]} \dots B^{[\sigma_{0\downarrow}]} B^{[\sigma_{0\uparrow}]} \dots B^{[\sigma_{n\uparrow}]})_{\nu\eta},
$$
\n(A5)

shown schematically by sites  $n\downarrow$  to  $n\uparrow$  of Fig. [2\(](#page-4-0)c). Its two indices will be treated as a composite index  $\beta = (\nu, \eta)$ below. The variational matrix product state  $|\Psi^N\rangle_u$  of Eq. [\(15\)](#page-5-2) discussed in the main text is a special case of Eq. [\(A5\)](#page-16-5), with  $n = N$  and  $\nu = \eta = 1$ . The goal is to express Eq. [\(A5\)](#page-16-5) as a linear ombination,

<span id="page-16-7"></span>
$$
|\Psi_{\nu\eta}^{n}\rangle_{\mathbf{u}} = \sum_{\alpha} |\Psi_{\alpha}^{n}\rangle_{\mathbf{r}} C_{\alpha\beta}^{n}, \qquad (A6)
$$

 $(\beta = (\nu, \eta)$  is a composite index) of an orthonormal set of "refolded basis states" of the form of Eq.  $(21)$ ,

<span id="page-16-6"></span>
$$
|\Psi_{\alpha}^{n}\rangle_{\rm r} = \sum_{\{\sigma^{n}\}} |\sigma^{n}\rangle (B^{[\sigma_{0}]}B^{[\sigma_{1}]} \dots B^{[\sigma_{n}]})_{1\alpha} ,\qquad (A7)
$$

shown schematically by sites 0 to n of Fig. [2\(](#page-4-0)a). To this end, we procede iteratively in  $n$ . We use singular value de
omposition to iteratively merge, for every pair of sites  $n\downarrow$  and  $n\uparrow$  of the unfolded chain, the matrices  $B_{\nu\nu'}^{[\sigma_{n\downarrow}]}$  and  $B_{\eta'\eta}^{[\sigma_{n}]}$  into a new set of matrices  $B_{\alpha'\alpha}^{[\sigma_{n}]}$  for site n of the refolded chain, thereby trading the indices  $\sigma_{n\downarrow},\sigma_{n\uparrow}$  and  $\nu\eta$  of Fig. [2\(](#page-4-0)c) for the indices  $\sigma_n$  and  $\alpha$  of Fig. 2(a). This is to be done in such a way that the matrices  $B^{[\sigma_n]}$  are orthonormal in the sense of Eq.  $(6)$ , and that for the first few sites their dimensions increase in a way analogous to those of the  $A^{[\sigma_n]}$  matrices of NRG, starting from  $1 \times d$ at site  $n = 0$ .

For the first iteration step, start with  $n = 0$ , make a singular value de
omposition of the matrix produ
t

<span id="page-17-2"></span>
$$
(B^{[\sigma_{0\downarrow}]}B^{[\sigma_{0\uparrow}]})_{\nu'\eta'} = (\mathcal{U}^0\mathcal{S}^0\mathcal{V}^{0\dagger})_{\sigma_0\beta'},\tag{A8}
$$

with  $\beta' = (\nu', \eta')$ , and use  $\mathcal{U}^0$  to define a new set of d matrices  $B^{[\sigma_0]}$  for site 0 of the refolded chain, with matrix elements  $B_{1\alpha'}^{[\sigma_0]} = \mathcal{U}_{\sigma_0\alpha'}^0$ . The  $B^{[\sigma_0]}$  have dimensions  $1 \times d$ (the dummy first index has just one value), and are by construction orthonormal in the sense of Eq.  $(6)$ , since  $\mathcal{U}^{0\dagger}\mathcal{U}^{0} = \mathbb{1}$ . Upon inserting Eq. [\(A8\)](#page-17-2) into Eq. [\(A5\)](#page-16-5), the factor  $\mathcal{U}^0$  produces the first matrix factor  $B^{[\sigma_0]}$  in the refolded state  $(A7)$ , thus completing the first iteration step. For the second iteration step, contract the factors  $S^0\mathcal{V}^{0\dagger}$  with the factors  $B^{[\sigma_{1\downarrow}]}$  and  $B^{[\sigma_{1\uparrow}]}$  in Eq. [\(A5\)](#page-16-5), factorize the result as  $\mathcal{U}^1 \mathcal{S}^1 \mathcal{V}^{1\dagger}$  and use  $\mathcal{U}^1$  to construct new matrices  $B^{[\sigma_1]}$  for site 1 of the refolded chain, etc. To be explicit, for general  $n$ , make a singular value decomposition of the matrix produ
t

<span id="page-17-0"></span>
$$
\sum_{\nu'\eta'} B_{\nu\nu'}^{[\sigma_{n+1}]}(\mathcal{S}^{(n-1)}\mathcal{V}^{(n-1)\dagger})_{\alpha'\beta'} B_{\eta'\eta}^{[\sigma_{n+1}]} = (\mathcal{U}^n \mathcal{S}^n \mathcal{V}^{n\dagger})_{\bar{\alpha}\beta},
$$
\n
$$
(A\alpha)\tag{4.9}
$$

 $\sqrt{2}$ 

with composite indices  $\bar{\alpha} = (\sigma_n, \alpha')$ ,  $\sigma_n = (\sigma_{n\downarrow}, \sigma_{n\uparrow})$ ,  $\beta = (\nu, \eta)$  and  $\beta' = (\nu', \eta')$ . Then use  $\mathcal{U}^n$  to define a new set of orthonormal matrices  $B^{[\sigma_n]}$  for site *n* of the refolded chain, with matrix elements  $B_{\alpha'\alpha}^{[\sigma_n]} = \mathcal{U}_{\alpha\alpha}^n$ . In this way one readily establishes that  $|\Psi_{\nu\eta}^n\rangle$ <sub>u</sub> can be written in the form of Eq. [\(A6\)](#page-16-7), with  $C_{\alpha\beta}^n = (\mathcal{S}^n \mathcal{V}^{n\dagger})_{\alpha\beta}$ .

The dimensions of the matrices  $B^{[\sigma_n]}$  initially grow by a factor of d with each iteration step, until their dimensions are restri
ted by the number of possible values of the composite index  $\beta$ , namely  $D_n^2$ , with  $D_n^{\prime}$  given by Eq. [\(16\)](#page-5-5). Thus, the  $B^{[\sigma_n]}$  have dimensions  $D_{n}^{\rm r} \times D_{n+1}^{\rm r}$ , with  $D_n^{\rm r} = \min(d^n, D_{n-1}^{\prime 2})$ , which leads to Eq. (20).

### <span id="page-17-1"></span>3. Cloning

This subse
tion gives some details of the loning pro edure of Se
tion [VI A.](#page-13-4) The goal is to solve the variational Eq.  $(32)$ , which determines the B-matrices of the cloned state  $|G\rangle_c$ . As described in the main text, this can be done by sweeping ba
k and forth along the unfolded Wilson hain, and updating one matrix at a time.

Figure 14: (Color online) Graphi
al representation of the variational equation used for loning, Eqs. [\(32\)](#page-13-2) or [\(A14\)](#page-18-16), drawn for the case  $\mu = \uparrow$ , and assuming all matrix elements to be real. The upper part of the figure represents  $\frac{1}{2} \frac{\partial}{\partial B^{[k\uparrow]}} c \langle G | G \rangle_c$ ; it simplifies to  $B^{[k\uparrow]}$  [left hand side of Eq. [\(A14\)](#page-18-16)] upon realizing that the parts in dashed boxes represent the left hand sides of Eqs. [\(A12a\)](#page-18-17) and [\(A12b\)](#page-18-17), and hence reduce to unity.

Let  $k\mu$  label the site to be updated and write the cloned state, whi
h is assumed to be of the form [\(15\)](#page-5-2), as

$$
|G\rangle_{\rm c} = \left(X_l^{k\mu}\right)_{1\nu} B_{\nu\nu'}^{[\sigma_{k\mu}]} \left(X_r^{k\mu}\right)_{\nu'1}.
$$
 (A10)

Here we introdu
ed the shorthands

ν1

$$
\begin{aligned}\n\left(X_l^{k\mu}\right)_{1\nu} &= \left(B^{[\sigma_{N\downarrow}]} \dots B^{[\sigma_{k_l\mu_l]}}\right)_{1\nu}, \quad \text{(A11a)}\\
\left(X_r^{k\mu}\right)_{\nu 1} &= \left(B^{[\sigma_{k_r\mu_r}]} \dots B^{[\sigma_{N\uparrow}]}\right)_{\nu 1}, \quad \text{(A11b)}\n\end{aligned}
$$

for the products of matrices standing before or after the one of present interest in the unfolded Wilson hain, and the labels  $k_l\mu_l$  or  $k_r\mu_r$  label the sites just before or after this site. Moreover, assume that all the B-matri
es in  $X_l$  and  $X_r$  have been orthonormalized according to Eq.  $(A1a)$  or  $(A1b)$ , respectively. (This can always be ensured by suitably orthonormalizing ea
h B-matrix after updating it, see below.) These orthonormality relations immediately imply similar ones for the matrix products

just introdu
ed:

<span id="page-18-17"></span>
$$
\sum_{\sigma_{N+},...,\sigma_{k_l\mu_l}} \left(X_l^{k\mu}\right)_{\nu 1}^\dagger \left(X_l^{k\mu}\right)_{1\nu'} = \delta_{\nu\nu'}, \quad \text{(A12a)}
$$

$$
\sum_{\sigma_{k_r\mu_r},...,\sigma_{N\uparrow}} \left( X_r^{k\mu} \right)_{\nu 1} \left( X_r^{k\mu} \right)_{1\nu'}^{\dagger} = \delta_{\nu\nu'} \ . \tag{A12b}
$$

Thus, the norm of  $|G\rangle_c$  can be written as

<span id="page-18-18"></span>
$$
{}_{c}\langle G|G\rangle_{c} = \frac{1}{\mathcal{N}} \sum_{\nu\nu'} B_{\nu'\nu}^{[\sigma_{k\mu}]^{\dagger}} B_{\nu\nu'}^{[\sigma_{k\mu}]} , \qquad (A13)
$$

where  $\mathcal N$  is a normalization constant ensuring that the norm equals unity.

Using Eq.  $(A13)$ , the variational Eq.  $(32)$  readily reduces to

<span id="page-18-16"></span>
$$
B_{\nu\nu'}^{[\sigma_{k\mu}]} = \sum_{\{\sigma'^N\}} \frac{(A^{[\sigma_N] \dagger} \dots A^{[\sigma_0] \dagger})_{G1}}{1+\lambda} \Big(X_l^{k\mu}\Big)_{1\nu} \Big(X_r^{k\mu}\Big)_{\nu'1},
$$

where  $\{\boldsymbol{\sigma}^{\prime N}\}$  denotes the local indices of all sites except the index  $\sigma_{ku}$  of site  $k\mu$ , and we have assumed all Aand B-matri
es to be purely real (exploiting the timereversal invarian
e of the present model). This equation completely determines the new matrix  $B^{[\sigma_{k\mu}]}$  in terms of the A-matrices specifying the NRG input state  $|G\rangle_f$  and the B-matrices of sites other than the present one, which had been kept fixed during this variational step.

Having calculated  $B^{[\sigma_{k\mu}]}$ , it should be properly orthonormalized, following the pro
edure of Eq. [\(A3\)](#page-16-8) or Eq. [\(A4\)](#page-16-8), depending on whether we are sweeping from left to right or vice versa. In other words, use the singular value decomposition  $USV^{\dagger}$  of the new-found matrix  $B^{[\sigma_{k\mu}]}$ , to transfer a factor  ${\cal SV}^\dagger$  or  ${\cal US}$  onto its right or left neighbor, respectively, and rescale this neighbor by an overall constant to ensure that the new state  $|G\rangle_c$ is still normalized to unity. This on
ludes the update of site  $k\mu$ . Now move on to its neighbor, etc., and thus sweep ba
k and forth through the unfolded Wilson hain, until onvergen
e is rea
hed.
