OMCat: Catalogue of Serendipitous Sources Detected with the XMM-Newton Optical Monitor

K. D. Kuntz^{1,2}, Ilana Harrus^{1,2}, Thomas A. McGlynn², Richard F. Mushotzky², & Steven L. Snowden²

ABSTRACT

The Optical Monitor Catalogue of serendipitous sources (OMCat) contains entries for every source detected in the publicly available *XMM-Newton* Optical Monitor (OM) images taken in either the imaging or "fast" modes. Since the OM is coaligned and records data simultaneously with the X-ray telescopes on *XMM-Newton*, it typically produces images in one or more near-UV/optical bands for every pointing of the observatory. As of the beginning of 2006, the public archive had covered roughly 0.5% of the sky in 2950 fields.

The OMCat is not dominated by sources previously undetected at other wavelengths; the bulk of objects have optical counterparts. However, the OMCat can be used to extend optical or X-ray spectral energy distributions for known objects into the ultraviolet, to study at higher angular resolution objects detected with *GALEX*, or to find high-Galactic-latitude objects of interest for UV spectroscopy.

Subject headings: catalogues

1. Overview

The Optical Monitor (OM) Catalogue (OM-Cat) contains entries for every point-like source detected in imaging or fast mode OM data. The OMCat was constructed from a complete reprocessing of the OM data using the standard omichain/omfchain pipelines in SAS 6.5.0¹. For each observation (ObsID) the reprocessing created a source list; the OMCat is a concatenation of these source lists. Thus, if the same region of sky was observed by multiple ObsIDs, then some sources will be listed multiple times. Each listing should have the same coordinates (to the limit of the astrometric accuracy) and thus it should be reasonably obvious which listings refer to the same source. We have opted to retain multiple list-

ings (rather than to combine them into a "mean" entry) to retain any useful information of temporal variability in an easily accessible manner. An overview of the catalogue statistics is given in Table 1.

In this paper §2 provides a brief description of the OM and its primary observation modes, §3 describes the standard pipeline processing, the further processing done to produce the source lists, and the output products that are unique to our processing. §4 contains some useful statistics describing the catalogue. In §5 we demonstrate the extent to which the OM filter set allows photometric classification of point-like sources, and in §6 we explore some of the scientific uses of the OM-specific bands.

2. Brief Description of the OM

The telescope and detector: The OM (Mason et al. 2001) is a 30 cm f/12.7 Ritchey Chretien telescope coaligned with the X-ray telescopes and operating simultaneously with them. The detector is a micro-channel plate intensified

charge-coupled device (CCD). Photons striking a photocathode produce electrons that are amplified by two successive micro-channel plates. The electron clouds then strike a phosphor, and the resulting photon splashes are recorded by a CCD; the location of the photon splash is centroided on board. The centroids are stored in units of 1/8 of a CCD pixel. Since it is these photon splashes that are recorded by the CCD, rather than individual photons, the CCD is read out very rapidly (every 11μ s), and the centroids of the photon splashes determined and stored. Thus, the CCD is used more like a photon-counting device than an accumulator, although it is an image, rather than an event list, that is produced. The photocathode is optimized for the blue and ultraviolet. The "native" pixel size is 0".476513 and the point spread function (PSF) FWHM is 1".4-2".0 depending upon filter. The largest possible field of view (FOV) is roughly $17' \times 17'$.

The OM has a smaller FOV than GALEX (a 1.2° circle) but better angular resolution (GALEX has a 4.75 FWHM PSF in its FUV filter (1350-1750 Å, and a 6.70 FWHM PSF in its NUV filter (1750-2800 Å) Morrissey et al. 2005). The effective areas of the OM and GALEX filters are shown in Figure 1 while the OM filter particulars are given in Table 2. Thus, the OMCat data in the UVW2 and UVM2 filters provide an excellent higher resolution complement to the GALEX NUV data, while UVW1 data is somewhat redder than the GALEX band. The Swift UVOT is, essentially, an improved OM, with similar filters, so comparison of data in this catalogue with UVOT data should

Fig. 1.— The OM and GALEX filter sets. The two lowest wavelength filters are the GALEX FUV and NUV filters. The next three are the OM UVW2, UVM2, and UVW1 filters. The three highest wavelength filters are the OM U, B, and V filters.

be straightforward.

The observation modes: Due to the onboard centroiding, memory limitations, and telemetry limitations, setting the OM observation mode has to be a balance of temporal resolution and spatial coverage; the higher the temporal resolution the lower the spatial coverage. As a result, the OM allows a large number of observing modes that place different emphases on temporal and spatial optimization. These modes define different "sci-

 $^{^{\}rm b}{\rm As}$ measured by the residual in position between matched OM and USNO sources. 50% of fields have uncertainties smaller than this value. The distribution of uncertainties peaks at $\sim 0\rlap.''3$.

ence windows" covering only portions of the entire FOV; events falling outside of those windows are discarded. There are two primary observation modes at the extremes: the default "imaging" mode and the default "fast" mode.

The default imaging mode consists of five consecutive sub-exposures, each of which employs two science windows; one high-resolution window and one low-resolution window. Note that resolution, in this case, refers to the degree to which the image is sampled, not to an intrinsic change in the PSF size. The FOV of the default imaging mode is shown in the left-hand panel of Figure 2. The high-resolution window (roughly $5' \times 5'$, marked "HR" in the figure) is always located at the center of the FOV. The five low-resolution windows (marked "SW" in the figure) cumulatively cover the entire FOV (roughly $17' \times 17'$) with a center square surrounded by five rectangular regions. For any number of reasons, not all of the sub-exposures of a default image may actually be taken, but, for the default imaging mode, there will always be a high-resolution sub-exposure for each low-resolution sub-exposure. It should be noted that multiple observing modes may be used during the course of a single observation, so not all exposures of a single observation need cover the same region. The use of five different science windows to cover the FOV, with some overlap between the windows, means that the exposure is not uniform across the FOV.

There are two other common full-field low-

resolution modes, "ENG-2" and "ENG-4", which are also included in our processing. The FOV for these modes are shown in the right-hand panel of Figure 2; the two modes cover the same area but with different binning, the "ENG-2" mode having twice the pixel size as the "ENG-4" mode. There is no repeated high-resolution window for these modes.

The default fast mode uses the same windows as the default imaging mode with the addition of a third science window (roughly 10.5×10.5) at an observer-defined location (typically the center of the FOV).

The default modes: If the observer did not specify an OM mode, and there was no bright source in the FOV, the OM took exposures in the default imaging mode. For the first two years of the mission the default filters were B, UVW2, U, and UVW1, in order of priority. The filter priority was then changed to UVM2, UVW1, and U, in order to optimize the use of the unique capabilities of the OM.

Magnitude system: The standard OM processing produces *instrumental* magnitudes. We have opted to continue to work in the instrumental magnitude system. The definition of the instrumental magnitudes and the current conversion to AB magnitudes is given in the *XMM-Newton* User's Handbook² In rough terms, the V and B the instrumental magnitudes are similar to AB mag-

^bWavelength of maximum transmission

Fig. 2.— Left: The FOV for the default mode. The plot has dimension of 2048×2048 unbinned pixels or 16'26 × 16'26. Right: The FOV for the ENG-2 and ENG-4 modes. The plot has the same dimensions as the previous panel.

nitudes, but the UV the instrumental magnitudes are typically smaller than the AB magnitudes by a magnitude to a magnitude and a half.

3. Processing

Image mode processing: For the most part, we have used the standard omichain³ processing with the default settings; exceptions are detailed below. The standard omichain processing (processing for images) handles the images produced by each science window separately. For each science window image omichain applies a flatfield. The photon splash centroiding algorithm calculates the centroid to 1/8 of a pixel, but due to the algorithm, not all values are equally likely. This problem results in "modulo-8" fixed pattern noise. The omichain processing applies a redistribution to correct for this effect.

For every science window image *omichain* runs a source detection algorithm, measures the count rates for the sources, and applies a calibration to convert to instrumental magnitudes. Once all of the science windows are processed, *omichain* produces a "master" source list by combining the source list for each science window, matching sources in common between the lists, and de-

termining the mean (α, δ) for each source. The standard processing has the option to use an external catalogue to correct the coordinates of the master source list; we have used this option with the USNO-B1 catalogue (Monet et al. 2003). It should be noted that the coordinate correction using the USNO-B1 catalogue will fail if there are too few matching sources, in which case no significant solution can be found. The omichain algorithm requires at least ten matches in order to produce a significant coordinate correction. If there are too many sources in the field, coordinate correction will also fail, presumably because some fraction of matches are spurious and the solution will not converge. We have found that the coordinate correction can fail for almost any density of sources, though we did not determine the cause of that failure.

In addition to combining the source lists for all the filters, *omichain* mosaics the low-resolution science window images (but not the high-resolution science window images) for each filter. The world coordinate system (WCS) of the first science window for a given filter sets the co-ordinate system of the entire image mosaic. Note that the standard *omichain* processing can correct the master source list, but not the images. Further, the correction using an external catalogue will be applied only if there are at least ten

 $^{^3}$ SAS routines are documented at http://xmm.vilspa.esa.es/sas/6.5.0/doc/packages.All.html

sources. One does have the option of doing the same correction to the individual science windows, but there are often not enough sources in a single science window to perform such a correction. We have applied the correction derived from the external catalogue to the low-resolution mosaics. Since the mosaic images use the WCS from the first science window in the mosaic, we compared the (α, δ) in the source list for the first science window to the (α, δ) in the USNO corrected master list. We then determined the $(\Delta \alpha, \Delta \delta)$ which must be added to the (α, δ) of the first source list in order to obtain the (α, δ) in the USNO corrected master list. We then applied that correction to the header keywords of the mosaicked image. It must be noted that since the telescope can drift by 1-2 arcseconds between exposures, this correction is done separately for each filter.

The standard omichain processing does not combine the images from the high-resolution science windows. However, we have done so, though not with ommosaic, the standard SAS tool. The ommosaic program uses the WCS keywords to determine the offsets needed to align the WCS frames of the individual science windows before summing. We allow the WCS of the summed image to be set by the first science window. For each successive high resolution image, we compare the source list to the source list from the first image, determine the $(\Delta \alpha, \Delta \delta)$ required to match the source lists, and apply that offset to the image before adding it to the mosaic. Not all sources are used for determining the offsets, only sources appearing in at least half of the images; this selection removes sources with poorly determined positions. The offsets are rounded to the nearest integer pixel; subpixelization did not seem to produce a significant improvement in the resultant PSF, and so was not used for this processing. Compared to the direct sum of the images made by ommosaic, our processing does improve the PSF of the summed image, sometimes improving the FWHM by as much as a pixel (see Figure 3). We compare the source list from the first image with the master source list to correct the summed image in the same manner used for the low-resolution mosaics.

Further coordinate correction: After our initial processing of the public archive we found that the pipeline coordinate correction (done by

omichain) using the USNO catalogue failed for $\sim 38\%$ of the fields. Further, the failure was not limited to extremely high or extremely low source densities (see Figure 4)⁴. We thus found it worthwhile to create our own coordinate correction routine (the "post-pipeline" correction) using the USNO catalogue. Although the bulk of fields need only a small correction, some fields need substantial corrections ($\sim 2''$). Thus, although we attempt to find high precision corrections for all fields, it is still worthwhile to find lower accuracy corrections for those fields that do not have a large enough number of matches with the USNO catalogue to attempt a high precision solution.

We used a fairly simple and robust algorithm for matching the OM sources to the USNO sources. If there were > 10 matches we iteratively solved for the offset in (α, δ) that minimized the offset between the OM source list with the USNO source list. By iterating the solution we could eliminate some portion of the false matches. We have not solved for a rotation for two reasons: 1) adding a rotation to the fit did not significantly improve the solution, and 2) given that there are systematic offsets from one science window to another, the rotation could be strongly biased by the offset of a single science window. If there were 3 < n < 10 matches we merely calculated the mean offset between the OM and USNO sources, and used that offset as the coordinate correction. If there were < 3 sources we did not attempt a correction. We applied the same correction to the individual images that we applied to the source lists.

For each OM source in the source list with the *omichain*-calculated maximum-liklihood significance in any filter > 3, the matching algorithm finds the closest USNO source. It then creates the distribution of the distances between the OM sources and their closest USNO counterparts. If all of the OM sources had USNO counterparts, then this distribution would be a Gaussian whose width is the coordinate uncertainties of the two catalogues and whose peak is the offset between the two catalogues. If there were no true matches

⁴ We have not had the opportunity to trace the root of this problem. However, we note that a disproportionate number of ObsIDs lacking pipeline corrections *seemed* to have a single science window that was strongly discrepant from the others.

Fig. 3.— **Top:** Image created from 25 high-resolution science windows using *ommosaic* (left panel) compared to the same image created with our processing (right panel). Note that the central point source is rounder after our processing. **Bottom:** Comparison of the profile of the central point source *red:* with *ommosaic* alone *black:* with our processing. The FWHM improves by almost a pixel in this case and the peak intensity increases by 15%.

Fig. 4.— Histogram of the number of observations as a function of source density. The thin solid line is the total number of observations. The crosses show the number of observations for which the pipeline coordinate correction (i.e., that done by the SAS *omichain* task) failed as a function of the number of sources. The thick line shows the number of observations for which the post-pipeline coordinate correction (our software) failed as a function of the number of sources.

between the OM sources and the USNO catalogue, then the distribution would be given roughly by the probability distribution for the minimum distance between a given point and a uniform distribution of sources:

$$P(r) = e^{\left[-\rho\pi r^2\right]} \rho\pi [(r+\delta r)^2 - r^2] e^{\left[-\rho\pi [(r+\delta r)^2 - r^2]\right]} \eqno(1)$$

where ρ is the surface density of sources and δr is the binsize of one's histogram of distances. For this distribution both the peak of the distribution and the width of the distribution scale as $\rho^{-0.5}$. We expect that some fraction of the OM sources have true USNO matches and that the remainder will not. As a result, the observed distribution of sources has a sharp peak with a width of $\sim 0.3''$ due to matches and a low, broad distribution for the spurious matches. This algorithm has problems with high density regions; for source densities of 5000 sources/image $(0.005 \text{ sources arcsec}^{-2})$ the distribution of spurious matches peaks at 6.3" with the lower half-maximum at 2". Although the peak of the matching sources typically has $r \lesssim 3''$, the true match rate is likely to be small compared to the spurious match rate, and so it is difficult, if not impossible, to find the true match peak in this distribution. However, at these source densities, source confusion is a serious problem as well,

so even if the matching algorithm worked, the coordinate solution would remain problematic.

For the matching algorithm, we simply fit the distribution with a Gaussian. If the width of the Gaussian is smaller than 0.77, then the algorithm takes all of the sources within 3σ of the peak of the distribution as real matches. An initial solution is determined from those matches, and a fit is made in the image coordinate frame to find the (α, δ) offset that minimizes the distance between the OM sources and their USNO matches. The source matching is redone with the new offset, and the process is iterated until it converges. After application of our coordinate correction routines, only $\sim 14\%$ of the fields remained without any coordinate correction. Besides fields with very few objects, the fields without coordinate corrections were characterized by very broad distribution of the matches suggesting a combination of large pointing error and large source density, and thus a large number of spurious identifications.

For fields where the pipeline processing found a good coordinate solution using the USNO catalogue our coordinate correction was not significantly different. However, our coordinate correction did improve the mean distance between OM and USNO sources for $\sim 44\%$ of fields, and provided the only coordinate corrections for $\sim 23\%$ of fields. (Figure 4)

The RMS residual between the OM sources and the matching USNO sources was calculated for every field. A value of zero indicates that there was no coordinate solution. Coordinate solutions with RMS residuals > 0.6 should be considered to be poor.

Fast mode processing: The bulk of the fast mode processing is concerned with the production of light-curves of the source. The fast mode images consist of 10.5×10.5 regions containing, typically, a single source. We combine all of the images for each filter using the same method applied to the high-resolution images.

Further processing: Further processing is required to provide a more useful source list to be incorporated into the OMCat. To the standard image catalogue (a binary fits table) we add images of each source from each filter. Each "postage stamp" image is 19×19 pixels in size, extracted from the low-resolution image mosaics (the pixel

size is 0.95 and the image is 18.1×18.1 in size). Since the sources were derived from all of the science windows, some sources can fall in high-resolution science windows without low-resolution counterparts. In that case the postage stamp is extracted from the high-resolution image and binned to the same resolution and size as the other postage stamps. Sources that appear only in "fast" science windows are treated similarly. Note that postage stamps are extracted from all of the available filters, not just the filters for which the source was detected; many postage stamps may thus appear to be empty.

Processing summary: For each ObsID our processing produces a coordinate corrected source list, a coordinate corrected low-resolution mosaicked image for each filter, a coordinate corrected high-resolution mosaicked image for each filter (if possible), or a summed fast mode image.

Caveats: 1) Individual science windows may be significantly offset (1-2") from the remainder of the mosaic. In this case the correction by use of the USNO-B1 catalogue will not be wholly satisfactory, and sources will appear to be offset in the postage stamps. The extent of this problem for any individual source can determined by looking at the "RMS_RESID" column which contains the RMS residual from the fit of source list to the USNO-B1 catalogue.

2) The source lists will contain spurious sources, sources due to ghost images, diffraction spikes, readout streaks, saturation around bright sources, and other effects. Some of these sources can be removed by consulting the data quality flag (Q_FLAG parameter) Similarly, confused sources are flagged by the C_FLAG parameter. However, we have found that filtering out sources with signal-to-noise ratios of less than three was a more efficient means of removing spurious sources than reference to the quality flags.

Figure 5 and Figure 6 demonstrate the extent to which the data quality, confusion, and extension flags can be used. Figure 5 shows an image with typical difficulties: ghosts, readout streaks, and diffraction spikes. Figure 6 shows images of some of the individual sources from the image in Figure 5. The first row of images contains UVW1 band images of the first 36 sources in the source list which have Q_FLAG= 0, or good quality sources. The second row of images contains

Fig. 6.— UVW1 filter images of individual sources from obsid 0000110101. The first (top) row of images contains UVW1 band images of the first 36 sources in the source list which have Q_FLAG= 0, or good quality sources. The second row of images contains UVW1 band images of the first 36 sources in the source list which have Q_FLAG= 0, or poor quality sources. The third row of images contains UVW1 band images of the 33 sources with C_FLAG= 0 (unconfused). The fourth row of images contains UVW1 band images of the first 48 sources in the source list which have C_FLAG= 0 (confused). The fifth row of images contains UVW1 band images of the first 48 sources in the source list with E_FLAG= 0 (non-extended). The sixth (bottom) row of images contains UVW1 band images of the 38 sources with E_FLAG= 0 (extended).

Fig. 7.— The top row of images shows the effect of increasing significance, as characterized by the SIGNIF parameter in the UVW1 band. The images are some of the 2143 sources from obsid 0000110101. For this row of images, we sorted the sources by SIGNIF, and sampled every (2143/36)th source to represent the entire range of the SIGNIF parameter. The value of the SIGNIF parameter is given directly to the below the images, and the source signal-to-noise ratio directly below that. Similarly, the bottom row of images samples sources of increasing value of the source signal-to-noise ratio; the values of the SIGNIF parameter and the signal-to-noise ratio are shown below the images.

Fig. 5.— An image displaying typical image problems: the UVW1 image from obsid 0000110101. Note the readout streaks, ghosts, and diffraction spikes. Note also that the individual science windows do not always overlap (or butt) correctly, as shown by the black vertical stripe in the right hand part of the image.

UVW1 band images of the first 36 sources in the source list which have $Q_FLAG \neq 0$, or poor quality sources. It is clear that some of the "good quality sources" are unreliable, while some of the "poor quality sources" are reliable. The third and fourth rows of images contain, respectively, sources with C_FLAG= 0 (unconfused) and C_FLAG \neq 0 (confused); again the sources are taken in the order of the source list (which happens to be from low R.A. to high R.A.) and all images are in the UVW1 band. As can be seen, the confusion flag is not reliable. The fifth and sixth rows of images contain, respectively, sources with E_FLAG= 0 (nonextended) and E_FLAG \neq 0 (extended); this flag does seem to be robust. Figure 7 shows images of some of the individual sources from the image in Figure 5, selected to demonstrate the effect of the SIGNIF parameter. The top row of images shows the effect of increasing significance, as characterized by the SIGNIF parameter in the UVW1 band. For this column of images, we sorted the sources by SIGNIF, and sampled the sequence uniformly to represent the entire range of the SIGNIF parameter. The value of the SIGNIF parameter is given

directly below the images, and the source signal-to-noise ratio directly below that. Similarly, the bottom row of images samples sources of increasing value of the source signal-to-noise ratio; the values of the SIGNIF parameter and the signal-to-noise ratio are shown below the images. Neither the SIGNIF parameter nor the signal-to-noise ratio provides a completely reliable estimator of the reality of a particular source.

- 3) Although we provide the mosaicked low-resolution and mosaicked high-resolution images through the archive, these images, according to the SAS documentation, should not be used for photometry. There are a number of corrections in the photometric reduction which can not be made from the mosaicked images. However, since coincidence-loss and dead-time corrections are small for faint sources and faint extended emission, photometry of faint sources using standard non-SAS tools is possible from the mosaics, as has been demonstrated by D. Hammer (private communication).
- 4) Although there may be substantial exposure for a given mosaic, the detection limit in the current catalogue is not that of the mosaic since the source detection is done on the individual science windows rather than on the mosaicked images. Since the individual science windows have a median exposure of $\sim 1800~\rm s,$ and the bulk of the individual science windows have exposures of 1000 s, the detection limit of the OMCat is more uniform but somewhat lower than one would expect from the mosaic exposure times.

Availability: The bulk of the data in the OM-Cat can be accessed either through the Browse facility at the High Energy Astrophysics Science Archive (HEASARC) or through the Multimission Archive at STScI (MAST). Slightly more information for each source (shape, confusion flags, and quality flags, as a function of filter) are retained in the source lists for individual ObsIDs, and can be downloaded from the HEASARC with the rest of the OM data.

4. OMCat Statistics

Observation Statistics: Of the 4373 observations that were public by 1 September 2006, 2950 observations had OM imaging mode data and 202 had OM fast mode data. About 25% of the fields

imaged were observed more than once, allowing some measure of temporal variability. However, the number of fields with multiple observations is a very strongly declining function of the number of repetitions (see Figure 8).

As can be seen in Figure 9, the Galactic plane has a high density of observations (particularly towards the Galactic center), the region with $|b| < 30^{\circ}$ has a lower density of observations, and the region with $|b| > 30^{\circ}$ is relatively uniform, though Coma and the Magellanic clouds have visible concentrations of observations. The imaging mode observations cover a cumulative $\sim 0.5\%$ of the sky.

Figure 10 shows the distribution of total exposure time per field and the exposure time per science window for the most commonly used filter (UVW1). Most science windows have exposures of a kilosecond, while the total exposure per field is significantly higher. Thus, since the point source detection is done in the individual science windows, the OMCat could be made significantly deeper were point source detection to be executed on mosaicked images. As noted above, since the bulk of individual science window exposures are ~ 1000 seconds, the detection depth of the catalogue is relatively uniform. However, given the multiple coverage of sources by individual science windows, the actual measurment accuracy is significantly better than that obtained from a single 1000 second exposure. Figure 11 shows the distribution of magnitudes for each filter.

Coordinate Statistics: Figure 12 shows the distribution of the residuals between the corrected source catalogues and the USNO-B1 catalogue for those fields for which a coordinate correction was successful. The residuals before the post-pipeline correction are peaked around 0".4 with a secondary peak around 0".7. After correction, the distribution is more symmetrically distributed around 0".4. It should be noted that a portion of the residual for any given image can be due to the offset of individual science windows within the mosaic.

The distribution of the calculated offsets between coordinates before and after the post-pipeline correction by the USNO catalogue is shown in Figure 13. The distribution is a broad skewed Gaussian peaking at $\sim 1\rlap.{''}7$ with a significant tail extending to $\gtrsim 5\rlap.{''}$. Note that this distribution does not reflect the pointing ability of the telescope, but rather the performance of the

Fig. 8.— The histogram of the number of fields as a function of the number of times that the observation was repeated. Observations were considered to be repeated if the pointing directions between two observations were offset by no more than half an arcminute. Zero repeats indicates a field with only one observation. The numbers give the number of fields for each number of repetitions.

Fig. 9.— The distribution of observations over the sky. The Aitoff coordinate system is centered on $(\ell, b) = (0^{\circ}, 0^{\circ})$ with positive longitudes towards the left.

Fig. 10.— Top: The distribution of the exposure times for the UVW1 filter. Other filters have not been used as much as the UVW1 filter, so their values will be lower. The solid line is the distribution of the mean exposure time low-resolution mosaic (since the exposure time will vary over the mosaic) and the dotted line is the distribution of exposure time for the sum of the high resolution image centers. Bottom: The distribution of exposure times for individual science windows.

Fig. 11.— The histogram of the numbers of sources at each magnitude for each of the filters. Only sources with $> 3\sigma$ detections have been counted.

Fig. 12.— The histogram of the resultant R.M.S. residuals between the corrected source catalogue and the USNO-B1 catalogue for those fields for which a coordinate correction was successful. *Solid*: Relative number of fields after the post-pipeline correction. *Dashed*: after the pipeline correction.

tracking corrections in the OM pipeline.

Source Statistics: The OMCat contains roughly 3.7×10^6 entries, of which 82% have detection significance (a maximum likelihood measure calculated within *omichain*) greater than three in at

Fig. 13.— The histogram of the magnitude of the shifts introduced by the correction to USNO-B1 coordinates.

least one band and 72% have a significance greater than three in at least one band. Roughly 71% of all entries have had successful coordinate corrections. Only $\sim 4\%$ of sources are classified as extended; the rest are considered point-like. Approximately 60% of the sources are flagged for data quality in at least one band, and approximately 74% of the sources are flagged for confusion in at least one band. However, if one looks only at individual measurements for which the signal-to-noise ratio is > 3, 49% are flagged for data quality, 3% are flagged for confusion, and 4% are flagged as extended. Given the discussion in the previous section, it is clear that the data quality flag in the current processing is a very poor measure of the true data quality, so these statistics, though they give one pause, are not cause for alarm.

Due to the interests of observers and the changing default filter priorities, the distribution of exposures among the various filters is uneven. When measured in terms of the number of sources with 3σ detections in each filter, the UVW1–U, B–V, and U–Bcolors have the best statistics. Table 3 shows the number of sources with 3σ detections for each filter and filter combination. As one might expect, the distribution for X-ray selected sources (that is, X-ray point sources in the field with OM-Cat counterparts rather than just sources observed because of their X-ray properties) is somewhat

different, with UVW1-U, U-B, UVW1-B, and UVW2-UVW1 having the best statistics.

Photometric Statistics: From the OMCat one can empirically determine the repeatability of flux measurements as a function of source flux as, for example, by Antokhin (2001) to study the sources of systematic errors. If the same source is measured twice for a given filter and produces measurements of M_1 and M_2 , then Figure 14 (left) shows the distribution of the magnitude difference $|M_1 - M_2|$ as a function of the mean magnitude $(M_1 + M_2)/2$. One can see that the bulk of the 199000 pairs measured have $|M_1 - M_2| < 0.5$ magnitudes, though there is a long tail to much higher values, in part due to intrinsic variability and (especially in more crowded fields) source matching errors. Figure 14 (right) shows the distribution of $|M_1-M_2|/\sqrt{\sigma_1^2+\sigma_2^2}$ as a function of $(M_1+M_2)/2$. If the difference in magnitudes were strictly statistical, the contours in this diagram would be strictly horizontal with the 68% contour at the y-axis value of unity. Table 4 shows the fraction of pairs with $|M_1 - M_2| < 0.2, 0.1$, and 0.05 magnitudes as a function of magnitude for each of the filters. As can be seen in Figure 14, excluding the very brightest and very faintest sources, the $|M_1 - M_2|$ is roughly what one would expect from the quoted uncertainties.

Comparison to the GALEX AIS: Perhaps the most comparable UV survey is the GALEX AIS, an "all sky survey" which, when completed, will cover $\sim 50\%$ of the sky in its NUV band to a limiting AB magnitude of 20.8 for a 5σ detection (Martin et al. 2005; Morrissey et al. 2005). The closest OM equivalent to the GALEX NUV filter is the UVM2 filter. The magnitude distribution of GALEX NUV sources with signal-to-noise ratios > 5 is sharply peaked at 20.8 and drops to 10% of the peak value by a magnitude of 21.4. The magnitude distribution of OM sources in the UVM2 filter with signal-to-noise ratios > 5 is more broadly peaked (due to the range of exposure times), with a peak at an instrumental magnitude of ~ 16.75 and declines to 10% of the peak value by an instrumental magnitude of ~ 18.25 . The equivalent AB magnitudes are ~ 18.4 and ~ 19.9 respectively. Thus, the current OMCat has a limiting magnitude in UVM2 between 1.5 and 2.5 magnitudes brighter than the limiting magnitude in the GALEX NUV filter. (However, it should be

^aFor colors, the requirement was that both detections be greater than 3σ , not that the color be measured to a signal-to-noise of 3.

Fig. 14.— Two plots showing the photometric stability as a function of magnitude as determined by pairs of measurements of the same object. Some 199000 pairs of sources (not entirely unique source pairs) were measured in the UVW1 filter. Plots for the other filters show similar patterns. Left: The number of measured pairs having a given mean magnitude and a given difference in magnitude shown as a contour diagram. Right: The distribution of magnitude difference divided by its uncertainty as a function of mean magnitude. The contours represent the fraction of pairs at a given mean magnitude with a difference/uncertainty ratio less than the value shown on the vertical axis.

noted that because of the smaller FOV and different brightness limits, the OMCat has good coverage of the Galactic plane, which *GALEX* is not able to observe.)

Comparison to the SDSS: The SDSS u filter, like the OMCat U filter, is similar to the Johnson U. The magnitude distribution of the SDSS u band sources with signal-to-noise ratios > 5 is sharply peaked at 21.5 and drops to 10% of the peak value by a magnitude of 22.4. The magnitude distribution of OM sources in the U filter with signal-to-noise ratios > 5 is more broadly peaked with a peak at an instrumental magnitude of ~ 18.75 and declines to 10% of the peak value by an instrumental magnitude of ~ 20.5 . The equivalent AB magnitudes are 19.7 and 21.4. Thus the current OMCat has a limiting magnitude in U about 2 magnitudes brighter than the SDSS.

5. Source Identification in the OM Colorcolor Planes

The OM unique filters are UVW1, UVM2, and UVW2, in order of decreasing throughput (see Figure 1). In order to explore the abilities of the OM filters, we created UVW1-U vs. UVM2-UVW1 and UVW1-U vs. UVW2-UVW1 color-color diagrams of the sources in the OMCat (Figure 15). On those diagrams we have plotted the expected locus for main-sequence stars (solar metallicity stars from the 1993 Kurucz atlas⁵), as well as points representative of galaxies (taken from the Kinney & Calzetti atlas at STScI⁶ see Kinney et al. 1996) and AGN (taken from STScI AGN atlas collection of spectra⁷ see Francis et al. 1991). The conversion from spectra to photometric colors was made using the OM spectral response matrices available from the XMM-Newton SOC^8 .

It is immediately apparent that the OM colors are a good match to those expected from the Kurucz atlas, except for the stars later than about G5. This problem appears most clearly in the UVW1-U vs. UVW2-UVW1 diagram, but appears as well in the B-V vs. U-B diagram. The problem region is off the bottom of the UVW1-U

vs. UVM2-UVW1 diagram. The true nature of the problem is not yet clear. For much of the stellar tracks the reddening vectors are roughly parallel to the stellar track.

There is a strong overlap between the early dwarf stars (down to A5) and AGN, as well as somewhat later dwarf stars (A5 to F5) and typical galaxies. There is no way to distinguish early stars from AGN using the UV colors alone, and the UV colors of QSO do not change much with redshift. The AGN seem to be more offset from the early-type stars in the optical color-color diagram. Given the extinction in the UV, it would be unreasonable to expect to find AGN in regions with early type stars, though the converse is not necessarily true, and indeed, finding high latitude O and B stars would be interesting. Division of sources into low ($|b| < 30^{\circ}$) and high $(|b| > 60^{\circ})$ Galactic latitude samples shows that in the UV color-color diagram the early type star region is populated somewhat more strongly at higher Galactic latitudes while the later type star region is populated somewhat more strongly at lower Galactic latitudes. We have cross-correlated the OMCat with the 12^{th} Veron QSO catalogue (Veron-Cetty & Veron 2006) and a SDSS AGN catalogue (Kauffmann et al. 2003) and found that the objects in common lie in the expected locations in the color-color diagram (Figure 16).

As can be seen in Figure 17, the crosscorrelation of the CfA redshift survey (the 1995 version as held by HEASARC, Huchra et al. 1992) with the OMCat suggests that the sources falling within the matching radius will be strongly contaminated by false-matches (at the $\sim 20\%$ level), meaning that many OMCat stellar sources will be falsely matched to the CfA survey. This high false-matching rate is presumably due to the fact that either the CfA redshift survey has a very high density of objects that are much fainter than those detected in the OMCat, or that the CfA redshift survey, being primarily a catalogue of extended objects, have positions that are inherently less precise than those in catalogues of true point sources. However, the matching sources from the CfA redshift survey fall at the expected location in the color-color diagrams, though their scatter may be a bit larger than the other surveys.

Fig. 15.— Color-color diagrams for the OM filters. Only sources with significances greater than 3 and $\sigma_{mag} < 0.15$ in each filter have been plotted. The thick solid line upon which the spectral types are indicated is the track of solar-metallicity dwarfs plotted with representative spectral types. The thin lines are reddening vectors for each spectral type assuming E(B-V)=0.1 and the Fitzpatrick (1999) reddening curve. No reddening corrections have been applied to the data. The other track (without spectral type indicators) is for solar-metallicity giants. Also marked are the locations of white dwarfs (WD), QSOs (Q), Seyfert 1 and 2 (S1 and S2), LINERs (L) typical galaxies (S0, Sa, Sb, Sc, and E) as well as spiral bulges (B). The blue contours are from fields with $|b| < 30^{\circ}$, green contours from fields with $30^{\circ} < |b| < 60^{\circ}$, and red contours from fields with $60^{\circ} < |b|$. The purple points are the sources from which the blue contours were calculated.

Fig. 16.— The contours of the source density of all OMCat sources with detection significance > 3 and $\sigma_{mag} < 0.3$. The contours are logarithmically spaced. The location of QSO from the 12^{th} Veron catalogue (+), the QSO from the SDSS catalogue (\square), and the a mixed sample of QSO and galaxies that is the CfA redshift survey (\times). There is a great deal of overlap between the Veron catalogue and the CfA redshift survey.

^aFrom catalogue documentation accessed through the HEASARC.

^bPrecision of coordinate as the uncertainty was not quoted.

 $^{^{\}mathrm{c}}$ Since the FUSE catalogue is of observed targets, the coordinates are presumably those provided by the observers. The smallest aperture in use has a width of 1".5 while the medium aperture has a width of 4".0, suggesting that the coordinates are at least this good in order to make a successful observation.

Fig. 17.— Each diagram is the distribution of the distance between sources in the OMCat and the nearest source in some other catalogue. **Top Left:** Catalogues dominated by stars and galaxies. **Top Right:** Catalogues dominated by QSO and AGN. **Bottom:** Catalogues of UV sources. Note that since FUSE does not measure source positions (the positions were supplied by the user, typically from catalogues such as the Guide Star Catalogue) the width of the distribution for FUSE does not reflect the intrinsic accuracy of the FUSE pointing. The width of the distribution does still indicate the radius at which spurious matches become important.

6. Uses of the OMCat

The uses of the OMCat detailed here involve the cross-correlation of the OMCat with other catalogues. All the catalogues were extracted from the HEASARC Catalogue Resources using the HEASARC Browse tool⁹. The cross-correlation for a given catalogue was done by determining the closest entry to each OMCat source. We then plotted the distribution of the distances between the OMCat source and the closest catalogue source. Cross-correlation of the OMCat with catalogues with a high density of sources typically produced a distribution of distances with a strong peak at $\sim 0.2-0.3$ arcseconds and a FWHM of ~ 0.3 arcseconds, and a tail due to serendipitous matches; the higher the density of catalogue sources, the higher the serendipitous match rate at large distances. An OMCat source was generally considered to be matched if the distance between it and the catalogue source was less than the peak of the distribution $+2\sigma$. The catalogues and match criteria used are shown in Table 5 while the distributions are shown in Figure 17.

6.1. USNO Counterparts

Most of the sources in the OMCat have USNO counterparts. This suggests that the OMCat is shallower in the UV than the USNO is in the B and R bands. The OMCat is therefore not dominated by sources previously undetected at other wavelengths.

6.2. FUSE Counterparts

Of interest to studies of the halo of the Galaxy are UV-bright stars and AGN that can be used as background sources for measuring the column density, velocity, and metallicity of halo gas. Stars are of particular use in determining the distance to high and intermediate velocity gas (e.g., Danly et al. 1993), while AGN provide measures of the column density through the entire halo. Targets are usually found by combing catalogues of sources for objects with optical colors suggesting high UV fluxes. Since the fields in the OM-Cat were (usually) chosen for their X-ray sources,

rather than the UV sources in the same field, comparing the UV sources in the OMCat with the types of catalogues that have been used in the past to find UV-bright objects provides an indication of how many UV-bright sources may have been missed.

We have cross-correlated the OMCat with several UV catalogues; the GALEX catalogue, the Far Ultraviolet Explorer (FUSE) observation log (not technically a source catalogue), and the TD1 catalogue; the offset distributions are shown in Figure 17. We also cross-correlated with the Far-UV Space Telescope (Faust) Far-UV Point Source Catalogue, but did not find any matches, likely due to the small number of sources in that catalogue. There are a number of other EUV catalogues from EUVE and the ROSAT WFC, but the position uncertainties are $\gtrsim 1'$, so they are not useful for this study.

At the time that the first OMCat was constructed, FUSE was still operational and could have been used for follow-up spectroscopic studies. Even with the demise of FUSE, using the FUSE criteria for finding UV sources of interest to be studied with UV spectroscopy has application for future missions/instruments such as the HST Cosmic Origins Spectrograph. If searching the OMCat for FUSE observable sources produces a trivial result, then the OMCat is not likely to be of interest for future missions; a bountiful return would suggest that the OMCat will be useful.

The top panels of Figure 18 show the OM colorcolor diagram with the FUSE matches marked in red and coded by source type. AGN found from cross-correlating the OMCat with a number of AGN catalogues have also been plotted. The bulk of the FUSE observations with matching OM sources are AGN. The difficulty is that the AGN, early type stars, extragalactic star-forming regions, and some galaxies overlap in these colorcolor diagrams. We can define a long rectangular region along the early type star track as being contaminated by stars. Above and to the left is a large irregular region that has a significant population of AGN. The lower panels of Figure 18 show the OM UVW1 and UVM2 (or UVW2) magnitudes of the sources. Again, the OM sources matching FUSEobservations have been marked in red and coded by FUSE type. FUSE observed sources down to UVW1 magnitudes ~ 18.5 , which suggests sources

⁹ The USNO-B1.0 and 2MASS catalogues are maintained by the VizieR service of the Centre de Données Astronomiques de Strasbourg and were accessed through the HEASARC Browse interface.

Fig. 18.— Top Left: The UVW1-U versus UVW2-UVW1 color-color diagram, for all sources with $|b| > 46^{\circ}$ and with detection significances greater than three and uncertainties < 0.1 mag in each band. Red symbols are sources observed by FUSE. Boxes are AGN, + are main sequence and giant stars, \times are PN stars, Diamonds are white dwarfs, and Triangles are symbiotic stars. The source types are taken from the FUSE master catalogue. Green symbols are AGN from the 12^{th} Veron catalogue. Blue symbols are from the Sloan survey. Purple symbols are from the Kauffman/Sloan catalogue of AGN. The large boxes are the regions of interest for AGN (trapezoidal) and upper main sequence stars (rectangular). Top Right: The same plot for the UVW1-U versus UVW2-UVW1 color-color diagram. Bottom Left: The UVW1 versus UVM2 diagram for the same sources. Note that there are three "sequences" of sources, the main one which runs almost along the diagonal which is composed of early type stars and AGN, a more diffuse band offset to the right which is composed of late type stars with UVM2-UVW1>1.5, and a very short one to the left which is composed sources with UVM2-UVW1</br>
1.5, and a very short one to the left which is composed sources with UVM2-UVW1</br>
1.5, and a very short one to the left which is composed sources with UVM2-UVW1</br>
1.5, and a very short one to the left which is composed sources with UVM2-UVW1</br>
1.5, and a very short one to the left which is composed sources at the edge of the photocathode FOV. Bottom Right: The UVW1 versus UVW2 diagram for the sources in the UVW1-U versus UVW2-UVW1 color-color diagram. The same three sequences are distinguishable.

that are well detected by the OM should have been observable by FUSE.

We have selected potential spectroscopic targets with $|b| > 45^{\circ}$, detection significance > 3, $\sigma_U < 0.1$ magnitudes, $\sigma_{UVW1} < 0.1$ magnitudes, and σ_{UVM2} < 0.1 magnitudes or σ_{UVW2} < 0.1 magnitudes, which yielded ~ 1500 UVM2 candidates and ~ 1000 UVW2 candidates. (Even with identical coverage, one would still expect fewer UVW2 candidates simply because of the lower response in the UVW2 filter.) We then required the sources to fall within the boxes shown in the colorcolor diagrams of Figure 18, reducing the number of candidates to ~ 600 . We kept the candidates in the "stellar" box separate from those in the more extended "AGN" box. By visual inspection, we then removed all sources that were actually optical defects (bad pixels, ghosts, diffraction spikes, etc.) or were emission regions in nearby galaxies, or were diffuse with no point-like source. This selection reduced the candidate list to ~ 250 . Since we are interested in UV sources not in previous catalogues we then removed sources that had been observed by FUSE.

Combining the candidates obtained from the UVW1-U/UVM2-UVW1 color-color diagram with those obtained from the UVW1-U/UVW2-UVW1 color-color diagram, we found a total of 54 unique sources in the "AGN" box and a total of 97 unique sources in the "stellar" box. The magnitude distribution is similar to that of the survey as a whole; of the "AGN" box sources, 5 are fainter than UVW1=18.5 and of the "stellar" box sources, 10 are fainter than UVW1=18.5. The brightest 10% of the sources in both boxes are previously known AGN which were the explicit subject of study for the corresponding X-ray observations. Combining the two boxes, we obtained ~ 100 sources with UVW1<18.5 that have not been previously studied.

There is still the matter of source classification and the contamination of the source candidates (hoped to be stars and AGN) by galaxies. Of the candidate sources, somewhat over a third have SDSS counterparts with spectroscopic source types. Of the sources in the "AGN" box, $\sim 80\%$ are categorized as QSO and the remainder are categorized as galaxies. Of the sources in the "stellar" box, $\sim 40\%$ are categorized as QSO, $\sim 40\%$ are categorized as galaxies, and the remainder are categorized as galaxies.

egorized as stars. Thus, while the "AGN" box is a much cleaner sample of AGN, the "stellar" box still produces a similar number of AGN.

Of the candidates, only 9 (3 from the "AGN" box, 6 from the "stellar" box) fall on or near high velocity clouds. The remainder of the sources are uniformly distributed across the high Galactic latitude sky and will be useful for the study of the structure of the Galactic halo in the manner of Wakker et al. (2003).

Fig. 19.— Light Histogram: The distribution of the distance between an X-ray source and the closest OM source. Dotted Curve: The fitted probability distribution for the distance between the X-ray sources and the closest OM source for X-ray sources not correlated with OM sources (see text). Heavy Histogram: The difference between those two distributions, which should be the distribution of true matches.

6.3. X-ray Counterparts

6.3.1. Matching the Catalogues

We matched the XMM-Newton Serendipitous Source Catalogue (SSC, The Second XMM-Newton Serendipitous Source Pre-release Catalogue, XMM-Newton Survey Science Centre, 2006) against the OMCat. We first filtered out all of the XMM-Newton serendipitous sources that did not fall within the field of view of the corresponding OM observation. Because we did not know the relative positional uncertainty to expect when comparing the X-ray detections with the OM detections, we matched the SSC to the OMCat in

the same way that we matched the USNO catalogue to the OMCat. The distribution of the distance between the X-ray sources and the closest OM source is shown in Figure 19; the sharp peak at $\sim 0.5''$ is presumably due to true matches between X-ray and OM sources while the broader peak is due to uncorrelated sources. In order to determine the extent to which our matches are contaminated by serendipitous alignments, we calculated the probability distribution of Equation 1 for each source in the SSC that fell within the OM FOV using the density of OM sources in the FOV for the observation containing the SSC source. Because some of the SSC sources do have real matches, this calculation overestimates the probability distribution of serendipitous matches. In order to correct for this overestimation, we assumed that sources with distances of r < 8'' had a non-negligible probability of being real matches. We then summed over the probability distribution for r > 8'' and normalized that to the total number of matches found with r > 8''. We then used this normalized model distribution to determine the fraction of matches at distance r which are due to serendipitous coincidences of uncorrelated sources.

We have taken as "real" X-ray-OMCat matches all those with distances r < 2".5. At r = 2".5 there are still four times as many real matches as there are random coincidences but the contamination rate for r < 2".5 is $\sim 10\%$. Of the 53848 sources from the XMM Serendipitous Source catalogue falling within the FOV of the corresponding OM observations and having coordinate corrections from the USNO, 12986 have OM source counterparts, of which 1092 are expected to be spurious. It should be noted that in matching the X-ray sources to the OM sources, the USNO corrected coordinates provide a much closer match than do the original OM coordinates.

6.3.2. Results

The bulk of the X-ray sources are expected to be background AGN and Galactic stars. Given the observational interest in galaxies, there will also be a small, probably negligible, contribution from extragalactic X-ray binaries and star-forming regions. The question of interest when comparing catalogues at different energies is whether the Xray sources detected in the UV fall in distinctive

Fig. 20.— The UV color plotted against the log₁₀ of the 2-12/0.5-2 keV X-ray hardness ratio for all sources with good UV or X-ray colors and $|b| > 30^{\circ}$. For clarity, error bars are shown only when the Hard/Soft hardness ratio has a significance greater than 3 or the UVW1-U uncertainty is < 0.477 magnitudes. The diagonal line separates the sources clustered around the "AGN" colors from those clustered around the "stellar" colors. Histograms of the projected distributions are shown along each axis. Along the vertical axis the distribution of the X-ray hardness ratio is plotted for all of the sources (black), the sources to the upper left of the line (blue), and to the lower right of the line (red). Along the horizontal axis is plotted the UV color ratios for all the sources. The blue symbols are SDSS sources classified as QSO, the green symbols are SDSS sources classified as galaxies, and the red symbols are SDSS sources classified as stars. Since the SDSS sources chosen for spectroscopy were selected to have a low probability of being stars, based on their colors and being unresolved, the low number of stars, and that fact that they have AGN-like colors, should not be surprising. The × indicate sources with good UV colors, the + indicate sources with good X-ray colors, and source with both good UV and X-ray colors are marked with both symbols. For clarity, error bars equivalent to S/N < 3 are not shown.

portions of X-ray/UV color/hardness diagrams. Figure 20 compares the UVW1–U color (the UV color for which we have the greatest number of sources) with the 2.0-12.0/0.5-2.0 keV X-ray hardness. From Figure 15, we expect AGN to have UVW1–U \sim 0.4 and stars to have UVW1–U<0. The same behavior is observed in the colorhardness diagram, with an additional separation in X-ray hardness; the X-ray sources with UV colors of AGN have Log(Hard)-Log(Soft) peaked around 0.2 and the X-ray sources with UV col-

ors of stars have a broad distribution peaking at Log(Hard)-Log(Soft)< 0. This distribution reflects the well understood difference between the soft thermal X-ray spectra of stars and the harder power-law X-ray spectra of AGN. The combination of X-ray and UV colors are probably a more powerful star-AGN discriminator than either alone. The diagonal line in Figure 20 marks a reasonable separation between these two categories.

To test this separation we have cross-correlated the sources with good X-ray and UV data with the SDSS DR5 catalogue of sources with classifications made from the SDSS spectra. Indeed, the AGN (blue) are clustered as expected. The bulk of the galaxies (green) have stellar colors, but many have AGN-like colors. Since the SDSS sources chosen for spectroscopy were selected to have a low probability of being stars, based on their colors and being unresolved, the low number of stars (red), and that fact that they have AGN-like colors, should not be surprising.

The contours in Figure 21 show the density of SSC catalogue sources in the Hard (2.0-12.0 keV) versus Soft (0.5-2.0 keV) band space; the points show the locations of sources with UVW1-U colors. Not surprisingly, many of the sources with only soft X-ray detections have UV detections while there are only a few sources that have only hard X-ray detections that also have UV detections. The hard X-ray sources with UV detections tend to have AGN-like colors. To state it in the converse, very few hard X-ray sources (i.e., strongly absorbed sources) have UV counterparts.

The SSC sources with UV counterparts that also have QSO counterparts in the SDSS spectroscopic survey are shown in Figure 22. The sources cluster along the tracks expected if the X-ray and UV flux are related by

$$\log_{10} L_{2keV} = 0.721 \log_{10} L_{2500 \text{ Å}} + 4.531 \qquad (2)$$

as found by Steffan et al. (2006), where the monochromatic luminosities are in erg s⁻¹ Hz⁻¹. We assumed the QSO template spectrum from Kinney et al. (1996) for calculating the UV flux and magnitudes. We have assumed the photon index of the X-ray spectrum to be $\Gamma = 2.0$, and (for the plotted tracks) no internal absorption. Assuming internal absorption moves the tracks by $\log f_x \sim 0.1$, so the effect is not strong for this X-ray energy band. Although there is signif-

Fig. 21.— The contours show the density of sources from the entire SSC in the soft *versus* hard band parameter space. The fluxes are in erg cm⁻² s⁻¹. **Solid:** sources with 3σ detections in both bands, **Dashed:** sources with 3σ detections in only the hard band, and **Dotted:** sources with 3σ detections in only the soft band. The points are sources with UVW1–U colors.

Fig. 22.— SSC sources with OM counterparts in the UVW1 band and AGN counterparts in the SDSS spectroscopic survey. **Small boxes:** sources are color-coded by redshift: $0 \le z < 0.04$: dark blue, $0.04 \le z < 0.1$: light blue, $0.1 \le z < 0.4$: green, $0.4 \le z < 1.0$: orange, $1.0 \le z$: red. **Solid lines:** the expected tracks for QSOs, color coded by redshift: z = 0.001: purple, z = 0.004: dark blue, z = 0.01: light blue, z = 0.04: dark green, z = 0.1: light green, z = 0.4: yellow, z = 1.0: red. The black lines are lines of constant rest-frame 0.2-12.0 keV band luminosity from $\log L_x = 40$ to $\log L_x = 46$.

icantly more scatter than one would expect from the uncertainties, the sources do lie roughly where expected. It should be noted that this small sample of sources (XMM-Newton X-ray sources with OM counterparts and SDSS spectroscopic survey counterparts) seems to be a relatively unbiased sample of the SDSS spectral catalogue; the distribution of spectroscopic classification and redshift in the sample matches the distribution of all of the sources in the 12' radius SDSS spectroscopic catalogue extracts centered on the OM pointing directions. With the larger sample of OM sources with X-ray counterparts one will be able to begin to address the source of this scatter.

7. Summary

The OMCat provides a quick source of photometric data of point-like sources in the optical and near ultraviolet over an increasing fraction of the sky. The OMCat will continue to be augmented at the HEASARC as the XMM-Newton data becomes public. Although the short average exposure places a relatively high detection limit compared to optical catalogues such as USNO-B, the current detection limit provides suitably bright targets for current UV spectrometers, and provides high angular resolution data suitable for meaningful comparison with GALEX images. A first glance at the AGN counterparts in the OM-Cat suggests their UV properties are not particularly unexpected. No doubt more targeted querying of the OMCat will produce interesting science in several different fields.

It is expected that the current version of the OMCat will be superseded by a sigificantly improved processing produced by the *XMM-Newton* project. Until that catalogue is produced, the HEASARC will continue to augment the current version.

We would like to thank the referee, Marcel Agüeros, for many useful comments. We would like to thank Martin Still for many useful discussions about the current and future OMCats. We would like to thank Mike Arida for his help in making the OM data available through the HEASARC. We would like to thank Karen Levay, Randy Thompson, and Rick White for their help in making this data MAST accessible. We would

like to thank Luciana Bianchi for many useful discussions, as well as B.G. Anderson for his help with FUSE. We would also like to thank Lorenzo Principe for his help with this work.

This work would not have been possible without SAS, the Science Survey Consortium, and the OM PI team led by K. Mason at the Mullard Space Science Laboratory.

This research used data obtained through the Browse facility of the High Energy Astrophysics Science Archive Research Center (HEASARC). The OM object catalogue is now available through Browse ¹⁰ and in a static ASCII version¹¹. Several databases accessed through browse are actually held by the *VizieR* service at http://vizier.u-strasbg.fr. (Ochsenbein et al. 2000).

This research has made use of data from the *XMM-Newton* Serendipitous Source Catalogue, a collaborative project of the *XMM-Newton* Survey Science Center Consortium, http://xmmssc-www.star.le.ac.uk.

This research has made use of the *GALEX* GR2/GR3 database/archive at the Multimission Archive at STScI (MAST). STScI is operated by the Association of Universities for Research in Astronomy, Inc., under NASA contract NAS5-26555. Support for MAST for non-HST data is provided by the NASA Office of Space Science via grant NAG5-7584 and by other grants and contracts.

This research has made use of data obtained from Data Release 5 of the Sloan Digital Sky Survey (SDSS). Funding for the Sloan Digital Sky Survey has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Aeronautics and Space Administration, the National Science Foundation, the U.S. Department of Energy, the Japanese Monbukagakusho, and the Max Planck Society. The SDSS Web site is http://www.sdss.org/. The SDSS is managed by the Astrophysical Research Consortium (ARC) for the Participating Institutions. The Participating Institutions are The University of Chicago, Fermilab, the Institute for Advanced Study, the Japan Participation Group, The Johns Hopkins University, Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for
