#### Abstract

We study the lattice of finite-index extensions of a given finitely generated subgroup  $H$  of a free group  $F$ . This lattice is finite and we give a combinatorial characterization of its greatest element, which is the commensurator of  $H$ . This characterization leads to a fast algorithm to compute the commensurator, which is based on a standard algorithm from automata theory. We also give a sub-exponential and super-polynomial upper bound for the number of finite-index extensions of  $H$ , and we give a language-theoretic characterization of the lattice of finite-index subgroups of H. Finally, we give a polynomial time algorithm to compute the malnormal closure of H.

Keywords: free groups, subgroups, finite-index extensions

#### MSC: 20E05

This paper is part of the study of the lattice of finitely generated subgroups of a free group of finite rank F. Like most of the recent work on this topic, our paper makes crucial use of the graphical representation of the subgroups of F introduced in the seminal papers of Serre (1977 [\[8\]](#page-16-0)) and Stallings (1983 [\[11\]](#page-16-1)). This representation not only makes it easier to form an intuition and to prove properties of subgroups of F, but it also provides a convenient framework to efficiently solve algorithmic problems and compute invariants concerning these subgroups.

The particular object of study in this paper is the lattice of extensions of a given finitely generated subgroup  $H$  of  $F$ , and more specifically the sublattice of finite-index extensions of  $H$ . In this paper, all groups are subgroups of a fixed free group, and the notion of extension must be understood in this context.

It is elementary to verify that  $H$  has only finitely many finite-index extensions, and it is known that if  $K$  and  $L$  are finite-index extensions of  $H$ , then the subgroup they generate, namely  $\langle K, L \rangle$ , has finite index over H as well (Green-berg's theorem, see [\[11\]](#page-16-1)). Therefore  $H$  has a maximum finite-index extension  $H<sub>f</sub>$ , which is effectively constructible, and the finite-index extensions of H form a full convex sublattice of the lattice of subgroups of F.

This paper contains a detailed discussion of the lattice of finite-index extensions of H. Our main contributions are the following.

We show that the maximum finite-index extension  $H_{\text{fi}}$  of H is the commensurator of H, and we give a combinatorial (graph-theoretic) characterization of  $H_{fi}$ . This characterization leads to efficient algorithms to compute all finiteindex extensions of H, and to compute  $H_{fi}$  – the latter in time  $\mathcal{O}(n \log n)$ . We also give a rather tight upper bound on the number of finite-index extensions of H: there are at most  $\mathcal{O}(\sqrt{n} n^{\frac{1}{2} \log_2 n})$  such extensions, where n is the number of vertices in the graphical representation of  $H$ . Note that this upper bound is sub-exponential but super-polynomial.

The consideration of the subgroups of the form  $H<sub>f</sub>$ , which have no proper finite-index extensions, leads us to the dual study of the lattice of finite-index subgroups of a given subgroup, and we give a combinatorial (language-theoretic) characterization of each such lattice.

Finally, we use our better understanding of the lattice of extensions of a subgroup of  $F$ , to give a polynomial time algorithm to compute the malnormal closure of a given subgroup.

As we already indicated, we use in a fundamental way the graphical representation of finitely generated subgroups of  $F$ , including a detailed study of the different steps of the computation of this representation (given a set of generators for the subgroup  $H$ ), whose study was at the heart of an earlier paper by the authors [\[10\]](#page-16-2). It is particularly interesting to see that language-theoretic results and arguments play an important role in this paper: that is, we sometimes consider the graphical representation of a subgroup not just as an edge-labeled graph, but as a finite state automaton. Such considerations are present in almost all the results of this paper, but they become crucial at a rather unexpected juncture: the design of an efficient algorithm to compute the maximal finiteindex extension  $H_f$  of H. Indeed, the very low complexity we achieve is due to the possibility of using a standard automata-theoretic algorithm, namely the computation of the minimal automaton of a regular language.

Section [1](#page-2-0) summarizes a number of well-known facts about free groups and the representation of their finitely generated subgroups, which will be used freely in the sequel (see  $[11, 12, 5, 7, 10]$  $[11, 12, 5, 7, 10]$  $[11, 12, 5, 7, 10]$  $[11, 12, 5, 7, 10]$  $[11, 12, 5, 7, 10]$  for more details). Section [2](#page-5-0) is the heart of the paper: it starts with a technical study of the different steps of the algorithm to compute the graphical representation of a given subgroup, and a description of those steps which preserve finite-index (Section [2.2\)](#page-7-0). These technical results are then used to characterize the maximal finite-index extension  $H<sub>f</sub>$  (Section [2.3\)](#page-9-0), to relate the computation of  $H_{fi}$  and the minimization of certain finite-state automata (Section [2.4\)](#page-10-0), to evaluate the maximal number of finite-index extensions of a given subgroup (Section [2.5\)](#page-11-0), and to describe an invariant of the lattice of finite-index subgroups of a given subgroup (Section [2.6\)](#page-12-0).

Finally, we apply the same ideas in Section [3,](#page-14-0) to study the malnormal closure of a subgroup, and to show that it can be computed in polynomial time.

## <span id="page-2-0"></span>1 Subgroups of free groups and Stallings graphs

Let F be a finitely generated free group and let  $A = \{a_1, \ldots, a_r\}$  be a fixed basis of F. Let  $\bar{A} = {\bar{a}_1, \ldots, \bar{a}_r}$  be a disjoint copy of A and let  $\bar{A} = A \cup \bar{A}$ : as usual, we extend the map  $a \mapsto \bar{a}$  from the set A to all words by letting  $\bar{a} = a$  if  $a \in A$  and  $\overline{ua} = \overline{a} \overline{u}$  if  $a \in \tilde{A}$  and  $u \in \tilde{A}^*$ . As usual again, the elements of F are identified with the *reduced words* over the alphabet A, that is, the words that do not contain a sequence of the form  $a\bar{a}$   $(a \in \tilde{A})$ . If  $u \in \tilde{A}^*$  is an arbitrary word, we denote by  $\text{red}(u)$  the corresponding reduced word, that is, the word obtained from u by repeatedly deleting all sequences of the form  $a\bar{a}$  ( $a \in A$ ).

A reduced word  $u \in F$  is *cyclically reduced* if u cannot be written as  $u = av\bar{a}$ with  $a \in A$  and  $v \in F$ . Every reduced word u can be factored in a unique way in the form  $u = xy\bar{x}$ , with y cyclically reduced.

If  $H$  is a subgroup of  $F$ , an *extension* of  $H$  is any subgroup  $G$  containing H and we write  $H \leq G$ . If H is finitely generated, we also write  $H \leq_{fg} G$ . If H has finite index in G, we say that G is a *finite-index extension* of H and we write  $H \leq_{\text{fi}} G$ . Finally, we write  $H \leq_{\text{ff}} G$  if H is a free factor of G.

#### 1.1 The graphical representation of a subgroup

It is well known (since Serre's and Stalling's fundamental work [\[8,](#page-16-0) [11\]](#page-16-1)) that every finitely generated subgroup  $H \leq_{fg} F$  admits a unique graphical representation of the form  $A(H) = (\Gamma(H), 1)$ , where  $\Gamma(H)$  is a finite directed graph with Alabeled edges and 1 is a designated vertex of  $\Gamma(H)$ , subject to the combinatorial conditions below. Here, a graph is a pair (V, E) where V is the set of *vertices* and  $E \subseteq V \times A \times V$  is the set of *edges*; the *in-degree* (resp. *out-degree*) of a vertex  $v \in V$  is the number of edges in E of the form  $(v', a, v)$  (resp.  $(v, a, v')$ ); and the *degree* of v is the sum of its in- and out-degree. Every pair  $A(H)$  satisfies the following:

- the (underlying undirected) graph is connected;

- for each  $a \in A$ , every vertex is the source (resp. the target) of at most one a-labeled edge;

- and every vertex, except possibly 1, has degree at least 2.

Moreover, every pair (Γ, 1) with these properties is said to be *admissible*, and it is the representation of a finitely generated subgroup of  $F$ . In addition, given a finite set of generators of  $H$ , the representation of  $H$  is effectively computable. We refer the reader to [\[11,](#page-16-1) [5,](#page-16-4) [7,](#page-16-5) [12,](#page-16-3) [10\]](#page-16-2) for some of the literature on this construction and its many applications, and to Section [2.1](#page-6-0) below on the construction of  $\mathcal{A}(H)$ .

We sometimes like to view the A-labeled graph  $\Gamma(H)$  as a transition system over the alphabet A: if p, q are vertices of  $\Gamma(H)$ ,  $a \in A$  and  $(p, a, q)$  is an edge of  $\Gamma(H)$ , we say that a labels a path from p to q and  $\bar{a}$  labels a path from q to p, written  $p \stackrel{a}{\longrightarrow} q$  and  $q \stackrel{\bar{a}}{\longrightarrow} p$ . If  $u \in \tilde{A}^*$  is a word (reduced or not) and  $u = va$  $(a \in \tilde{A})$ , we say that  $p \stackrel{u}{\longrightarrow} q$  (*u labels a path from p to q*) if  $p \stackrel{v}{\longrightarrow} p' \stackrel{a}{\longrightarrow} q$  for some vertex  $p'$ . In particular, a reduced word is in  $H$  if and only if it labels a loop at vertex 1. Moreover, if we have a path  $p \stackrel{u}{\longrightarrow} q$ , then we also have a path  $p \stackrel{\mathsf{red}(u)}{\longrightarrow} q.$ 

If  $H \leq_{fg} G \leq_{fg} F$ , then there is a *homomorphism* from  $\mathcal{A}(H)$  into  $\mathcal{A}(G)$ , that is, a map  $\varphi$  from the vertex set of  $\Gamma(H)$  to the vertex set of  $\Gamma(G)$  such that  $-\varphi(1) = 1$  and

- if  $p \xrightarrow{a} q$  in  $\Gamma(H)$   $(p, q$  vertices,  $a \in \tilde{A}$ , then  $\varphi(p) \xrightarrow{a} \varphi(q)$  in  $\Gamma(G)$ .

It is not difficult to verify that this morphism, if it exists, is unique, and we denote it by  $\varphi_H^G$ . It is well known (see [\[8,](#page-16-0) [11,](#page-16-1) [5,](#page-16-4) [7\]](#page-16-5)) that if  $\varphi_H^G$  is one-to-one, then  $H \leq_{\text{ff}} G$ .

Finally, we say that the homomorphism  $\varphi_H^G$  is a *cover*, if it satisfies

- if p, q are vertices of  $\Gamma(H)$ ,  $a \in \tilde{A}$  and  $\varphi_H^G(p) \stackrel{a}{\longrightarrow} \varphi_H^G(q)$  in  $\Gamma(G)$ , then  $p \stackrel{a}{\longrightarrow} q'$  in  $\Gamma(H)$  for some vertex q' such that  $\varphi_H^G(q') = \varphi_H^G(q)$ . In that case, all sets of the form  $(\varphi_H^G)^{-1}(q)$  (q a vertex of  $\Gamma(G)$ ) have the same cardinality.

Covers have the following property, which we will use freely in the sequel.

**Lemma 1.1** If  $\varphi: \mathcal{A}(H) \to \mathcal{A}(G)$  *is a cover, p is a vertex of*  $\mathcal{A}(H)$  *and*  $u \in F$ *labels a loop of*  $\mathcal{A}(G)$  *at*  $\varphi(p)$ *, then*  $\mathsf{red}(u^m)$  *labels a loop of*  $\mathcal{A}(H)$  *at* p for some *integer*  $m > 1$ *.* 

## 1.2 Covers, cyclically reduced subgroups and finite-index extensions

Let us say that H is *cyclically reduced* (with respect to the basis A) if every vertex of  $\Gamma(H)$  has degree at least equal to 2. If H is not cyclically reduced, then the designated vertex 1 of  $\Gamma(H)$  has degree 1 and  $\Gamma(H)$  consists of two parts:  $tail(\Gamma(H))$ , which contains the designated vertex 1 and all degree 2 vertices that can be connected to vertex 1 through other degree 2 vertices; and the rest of  $\Gamma(H)$ , which is called the *core* of  $\Gamma(H)$ , written  $\mathsf{cc}(\Gamma(H))$ . We let  $\mathsf{t}_H(1)$  be the shortest word which labels a path from 1 to a vertex in  $cc(\Gamma(H))$  and let  $\tau_H(1)$ be the vertex of  $cc(\Gamma(H))$  thus reached (if H is cyclically reduced, then  $t_H(1)$ ) is the empty word and  $\tau_H(1) = 1$ . We write  $t(1)$  and  $\tau(1)$  if the subgroup H is clear from the context.

<span id="page-3-0"></span>The tail and the core of  $\Gamma(H)$  have intrinsic characterizations. The charac-terization of the core is well-known (see [\[11,](#page-16-1) Exercise 7.3(a)]) and that of the tail is an elementary consequence.

**Remark 1.2** Let  $H \leq_{fg} F$  and let p be a vertex of  $\Gamma(H)$ . Then p is a vertex of  $cc(\Gamma(H))$  if and only if some cyclically reduced word u labels a path from p to p.  $□$ 

**Proof.** By definition, if H is not cyclically reduced, then tail( $\Gamma(H)$ ) consists of a single path from vertex 1 to vertex  $t(1)$  (excluding the latter vertex): it is therefore elementary to verify that no non-empty cyclically reduced word labels a loop at a vertex in  $\text{tail}(\Gamma(H)).$ 

Let now p be a vertex in  $\mathsf{cc}(\Gamma(H))$ : then p has degree at least 2, and if it has degree exactly 2, then neither of the two edges adjacent to it leads to a vertex in tail( $\Gamma(H)$ ). Therefore, one can find distinct letters  $a, a' \in \tilde{A}$  such that  $p \stackrel{a}{\longrightarrow} q$  and  $p \stackrel{a'}{\longrightarrow} q'$ , with q and q' in cc( $\Gamma(H)$ ) as well. Iterating this reasoning, one can show that there exist arbitrarily long paths within  $cc(\Gamma(H))$ , starting from p and labeled by reduced words of the form au and  $a'u'$ . Since  $\Gamma(H)$  is finite, vertices are repeated along these paths, and we consider the earliest such repetition after the initial  $p$ . If  $p$  itself is the first repeated vertex along the path labeled au, we have a loop  $p \xrightarrow{au} p$  such that au is cyclically reduced, and we are done. The situation is similar if  $p$  is the first repeated vertex along the path labeled  $a'u'$ . Otherwise, let r and r' be the first repeated vertices along the two paths. Then  $r \neq p$ ,  $r' \neq p$ , and  $\textsf{cc}(\Gamma(H))$  has paths of the form  $p \stackrel{au}{\longrightarrow} r$ ,  $p \stackrel{a'u'}{\longrightarrow} r', r \stackrel{v}{\longrightarrow} r$  and  $r' \stackrel{v'}{\longrightarrow} r'$  such that  $auv\bar{u}\bar{a}, a'u'v'\bar{u}'\bar{a}'$  are reduced. Then the word  $\overline{a}u v \overline{u} \overline{a} a' u' v' \overline{u'} \overline{a'}$  is cyclically reduced, and it labels a loop at p in  $\Gamma(H)$ . This concludes the proof. □

**Remark 1.3** Let  $H \leq_{fg} F$ . Then  $t(1)$  is the maximum common prefix of the non-trivial elements of  $H$ . non-trivial elements of  $H$ .

**Proof.** Since every non-trivial element of H is the label of a loop at 1 in  $\Gamma(H)$ , it is clear that  $t(1)$  is a common prefix to all these words.

By Remark [1.2,](#page-3-0) there exists a cyclically reduced word  $u$  labeling a loop at  $\tau(1)$ . Then both  $t(1)ut(1)$  and  $t(1)\bar{u}t(1)$  are reduced words in H, and their maximum common prefix is  $t(1)$ . This concludes the proof. □

<span id="page-4-0"></span>We can now state the following extension of the classical characterization of finite-index extensions of cyclically reduced subgroups in terms of covers.

**Proposition 1.4** *Let*  $H \leq_{fg} G \leq_{fg} F$ . *Then*  $t_G(1)$  *is a prefix of*  $t(H)$ *. Moreover,*  $H \leq_{\text{fi}} G$  *if and only if*  $t_H(1) = t_G(1)$  *and the restriction of*  $\varphi_H^G$  *is a cover from*  $(cc(\Gamma(H)), \tau_H(1))$  *onto*  $(cc(\Gamma(G)), \tau_G(1))$ *. If that is the case, the index of* H in G is the common cardinality of the subsets  $\varphi_H^G$ −1 (q) *(*q *a vertex of*  $cc(\Gamma(G))$ *)*.

**Proof.** Let  $\varphi = \varphi_H^G$ . If u is cyclically reduced and labels a loop at a vertex p of  $cc(\Gamma(H))$ , then u labels a loop at  $\varphi(p)$  in  $\Gamma(G)$ , and that vertex is in the core of  $\Gamma(G)$  by Fact [1.2.](#page-3-0) It follows that  $t_H(1)$  labels a path from the origin in  $\Gamma(G)$ to a vertex in  $\textsf{cc}(\Gamma(G))$ . In particular,  $\textsf{t}_G(1)$  is a prefix of  $\textsf{t}_H(1)$ .

If  $t_G(1)$  is a proper prefix of  $t_H(1)$ , we have  $t_H(1) = t_G(1)at$  for some  $a \in A$ and  $t \in F$ . Since  $\tau_G(1)$  is in  $cc(\Gamma(G))$ , there exist a cyclically reduced word of the form bu, with first letter  $b \neq a$ , which labels a loop at  $\tau_G(1)$  in  $cc(\Gamma(G))$ . Then the words  $t_G(1)(bu)^n \overline{t_G(1)}$  are all reduced, and the cosets  $Ht_G(1)(bu)^n \overline{t_G(1)}$ are all in  $G$ . Moreover, these cosets are pairwise disjoint since  $H$  contains no reduced word of the form  $t_G(1)(bu)^d \overline{t_G(1)}$ ,  $d \neq 0$ . Thus, if  $H \leq_{\text{fi}} G$ , then  $t_H(1) = t_G(1)$ . It follows immediately that  $\varphi$  maps core vertices to core vertices and tail vertices to tail vertices.

Let us now assume that  $\Gamma(H)$  and  $\Gamma(G)$  have the same tails, and let us denote by  $t(1)$  the word  $t_H(1) = t_G(1)$ . Then  $H' = \overline{t(1)}Ht(1)$  and  $G' = \overline{t(1)}Gt(1)$  are cyclically reduced, and  $H \leq_{\text{fi}} G$  if and only if  $H' \leq_{\text{fi}} G'$ . Thus we may now assume that G and H are cyclically reduced. If  $\varphi$  is not a cover, there exists a vertex p of  $\Gamma(H)$  such that  $\Gamma(G)$  has a loop at  $\varphi(p)$  labeled by a cyclically reduced word bu  $(b \in A)$  and  $\Gamma(H)$  has no b-labeled edge out of p. Let v label a path from 1 to p in  $\Gamma(H)$  (and hence in  $\Gamma(G)$ ). By the same reasoning as above, the cosets  $Hv(bu)^n\bar{v}$  are pairwise distinct, and contained in G. Thus, if  $H \leq_{\text{fi}} G$ , then  $\varphi$  is a cover.

The converse is verified as follows: if  $\varphi$  is a cover, let  $u_1, \ldots, u_d$  be reduced words labeling paths in  $\Gamma(H)$  from 1 to the elements  $1 = p_1, \ldots, p_d$  of  $\varphi^{-1}(1)$ . If  $g \in G$ , then g labels a loop at 1 in  $\Gamma(G)$ , and since  $\varphi$  is a cover, g labels a path in  $\Gamma(H)$  from 1 to  $p_i$  for some *i*. Therefore  $g \in Hu_i$ : thus G is the union of finitely many H-cosets. ⊓⊔

Corollary 1.5 *The extensions, and the finite-index subgroups of a cyclically reduced subgroup are cyclically reduced as well.*

## <span id="page-5-0"></span>2 Finite-index extensions of a subgroup H

It follows from the characterization of finite-index extensions by covers, that if  $H \leq_{\text{fi}} G$ , then  $\varphi_H^G$  is onto<sup>[1](#page-5-1)</sup>. Therefore H has only a finite number of finiteindex extensions, and that number can be bounded above by the number of binary relations on  $\Gamma(H)$ : if that graph has n vertices, then H has at most  $2^{n^2}$ finite-index extensions. We give a better upper bound in Section [2.5.](#page-11-0)

Moreover, the collection of finite-index extensions of  $H$  is effectively computable. In addition, it is elementary to use these graphical representations to show that the join of two finite-index extensions of  $H$  is again a finite-index extension (see Stalling's proof of Greenberg's theorem [\[11\]](#page-16-1)). It follows that if  $H \leq_{\text{fg}} F$ , then H admits an effectively computable maximum finite-index extension  $H<sub>f</sub>$ . The results of Section [2.4](#page-10-0) below yield an efficient algorithm to compute the set of finite-index extensions of a given subgroup  $H$ , and its maximum finite-index extension  $H_{\text{fi}}$ .

<span id="page-5-2"></span><span id="page-5-1"></span><sup>&</sup>lt;sup>1</sup>The converse is not true, see [\[7\]](#page-16-5) for a detailed study of the extensions  $H \leq_{fg} G$  such that  $\varphi_H^G$  is onto.

**Remark 2.1** We just observed that every finitely generated subgroup of  $F$  has a finite number of finite-index extensions. However, it usually has infinitely many finite-index subgroups. More precisely, every non-trivial subgroup  $H \leq_{fg}$ F admits a finite-index subgroup of index r for each  $r \geq 1$ . Indeed, let  $\mathcal{A}(H)$  =  $(\Gamma(H), 1)$  and let Q be the vertex set of  $\Gamma(H)$ . Define  $\Gamma_r$  be the A-labeled graph with vertex set  $Q \times \{1, \ldots, r\}$  and with the following edge set: for each edge  $(p, a, q)$  of  $\Gamma(H)$ , there is an edge  $((p, i), a, (q, i + 1))$  for each  $1 \leq i < r$  and an edge  $((p, r), a, (q, 1))$ . Then  $\Gamma_r$  is an admissible graph, the map  $\pi: (p, i) \mapsto p$ defines a cover from  $\Gamma_r$  to  $\Gamma(H)$ , and if  $H_r$  is the subgroup represented by  $(\Gamma_r,(1,1)),$  then  $H_r$  has index r in H. □

### <span id="page-6-0"></span>2.1 i-steps and finite-index extensions

Let  $H \leq G$  be finitely generated subgroups of F and let  $g_1, \ldots, g_n$  be reduced words such that  $G = \langle H, g_1, \ldots, g_n \rangle$ . Let  $G_0 = H$  and let  $G_i = \langle G_{i-1}, g_i \rangle$  $(1 \leq i \leq n)$ . We may of course assume that  $g_i \notin G_{i-1}$ , so  $G_{i-1} \neq G_i$ .

Then  $\mathcal{A}(G_i)$  is obtained from  $\mathcal{A}(G_{i-1})$  by, first, adding sufficiently many new vertices and edges to create a new path from vertex 1 to itself, labeled by  $g_i$ ; and second, by *reducing*<sup>[2](#page-6-1)</sup> the resulting graph, that is, repeatedly identifying vertices p and p' such that  $q \stackrel{a}{\longrightarrow} p$  and  $q \stackrel{a}{\longrightarrow} p'$  for some vertex q and some letter  $a \in \tilde{A}$ , see for instance [\[11,](#page-16-1) [12,](#page-16-3) [5,](#page-16-4) [10\]](#page-16-2). Depending on the length of prefixes of  $q_i$ and  $\bar{g}_i$  that can be read from vertex 1 in  $\Gamma(G_{i-1})$ , this procedure amounts to one of the two following moves:

- a *reduced expansion*, or *re-step* (we write  $\mathcal{A}(G_{i-1}) \longrightarrow_{\mathsf{re}}^{(p,w,q)} \mathcal{A}(G_i)$ ), that is, we add a new path labeled by a factor  $w$  of  $g_i$ , from some vertex  $p$  to some vertex q of  $\Gamma(G_{i-1})$  in such a way that the resulting graph is admissible (needs no reduction);

- or an *i-step* (we write  $\mathcal{A}(G_{i-1}) \longrightarrow_i^{p=q} \mathcal{A}(G_i)$ ), that is, we identify a pair of vertices  $(p, q)$  of  $\Gamma(G_{i-1})$ , and we reduce the resulting graph.

Remark 2.2 Let us comment on these steps, with reference to Stallings's algo-rithm [\[11\]](#page-16-1). If  $H = \langle g_1, \ldots, g_n \rangle$ , Stallings produces  $\mathcal{A}(H)$  by reducing (folding) a bouquet of n circles, labeled  $g_1, \ldots, g_n$  respectively. For our purpose, we decompose this operation in  $n$  steps, adding one generator at a time and producing successively the  $\mathcal{A}(\langle h_1, \ldots, h_i \rangle)$   $(1 \leq i \leq n)$ . Each of these steps is either an re-step or an i-step. re-step or an i-step.

<span id="page-6-2"></span>We refer the readers to [\[10,](#page-16-2) Section 2] for a detailed analysis of these moves and we record the following observation.

**Lemma 2.3** Let  $G, H \leq_{fg} F$ . If  $H \leq_{fi} G$ , then only *i-steps are involved in the transformation from*  $\Gamma(H)$  *to*  $\Gamma(G)$ *.* 

<span id="page-6-1"></span><sup>&</sup>lt;sup>2</sup>This reduction operation is the iteration of Stallings's *folding* operation [\[11\]](#page-16-1); our terminology emphasizes the fact that this is a generalization of the reduction of a word (the iterated process of deleting factors of the form  $a\bar{a}$ ,  $a \in \tilde{A}$ ).

**Proof.** Let  $H = G_0 \leq G_1 \leq \ldots \leq G_n = G$  be as in the above discussion. Note that  $H \leq_{\text{fi}} G$  if and only if  $G_{i-1} \leq_{\text{fi}} G_i$  for each  $1 \leq i \leq n$ . If  $\mathcal{A}(G_{i-1}) \longrightarrow_{\text{ref}}$  $\mathcal{A}(G_i)$ , then the homomorphism  $\varphi_{G_{i-1}}^{G_i}$  is one-to-one, so  $G_{i-1} \leq_{\text{ff}} G_i$  and in particular,  $G_i$  is not a finite-index extension of  $G_{i-1}$ . □

#### <span id="page-7-0"></span>2.2 Which i-steps yield finite-index extensions?

If p is a vertex of  $cc(\Gamma(H))$ , we let  $\widetilde{L}_p(H)$  be the language accepted by  $cc(\Gamma(H))$ , seen as a finite state automaton with initial state  $p$  and all states final: that is, the set of (possibly non-reduced) words in  $\tilde{A}^*$  that label a path in  $\textsf{cc}(\Gamma(H))$ starting at vertex p. Let then  $L_p(H)$  be the set of reduced words in  $\widetilde{L}_p(H)$  which is also the set of all  $\text{red}(u)$   $(u \in \widetilde{L}_p(H))$ , and also the set of prefixes of words in the subgroup represented by the pair  $({\rm cc}(\Gamma(H)), p)$ . Let us first record the following elementary remark.

<span id="page-7-2"></span>**Remark 2.4** If  $p \xrightarrow{u} q$  is a path in  $\text{cc}(\Gamma(H))$ , then  $L_q(H) = \{\text{red}(\bar{u}x) \mid x \in \mathbb{R}^d\}$  $L_p(H)$ . □

<span id="page-7-1"></span>We now refine the result of Lemma [2.3.](#page-6-2)

**Proposition 2.5** *Let*  $H \leq_{fg} F$  *and let*  $p, q$  *be distinct vertices in*  $\Gamma(H)$ *. Let*  $G$ *be the subgroup of* F *such that*  $\mathcal{A}(H) \longrightarrow_{i}^{p=q} \mathcal{A}(G)$ *. Then*  $H \leq_{\text{fi}} G$  *if and only if* p, q are in  $cc(\Gamma(H))$  and  $L_p(H) = L_q(H)$ , *if and only if* p, q are in  $cc(\Gamma(H))$ *and*  $L_p(H) = L_q(H)$ *.* 

**Proof.** Let us first assume that  $H \leq_{\text{fi}} G$  and let  $\varphi = \varphi_H^G$ . By Proposition [1.4,](#page-4-0)  $\varphi$  is a bijection from tail(H) onto tail(G) and, since  $\varphi(p) = \varphi(q)$ , the vertices p and q must both be in  $cc(\Gamma(H))$ .

If  $p, q \in \text{cc}(\Gamma(H))$  and  $\widetilde{L}_p(H) \neq \widetilde{L}_q(H)$ , we consider (without loss of generality) a word  $u \in \widetilde{L}_p(H) \setminus \widetilde{L}_q(H)$ , with minimum length, say  $u = va$  with  $a \in \widetilde{A}$ . By definition, there exist paths  $p \xrightarrow{v} p' \xrightarrow{a} p''$  and  $q \xrightarrow{v} q'$ , but no path  $q' \xrightarrow{a} q''$ in cc(Γ(H)). Observe that  $\mathcal{A}(H) \longrightarrow_{i}^{p'=q'} \mathcal{A}(G)$ . If there is a path  $q' \stackrel{a}{\longrightarrow} q''$  in  $\Gamma(H)$ , then we also have  $\mathcal{A}(H) \longrightarrow_{i}^{p''=q''} \mathcal{A}(G)$  and since  $p'' \in \text{cc}(\Gamma(H))$  and  $q'' \in \text{tail}(\Gamma(H))$ , we conclude to a contradiction by Proposition [1.4.](#page-4-0) We now assume that there is no path  $q' \stackrel{a}{\longrightarrow} q''$  in  $\Gamma(H)$ .

We claim that there exists  $w \in F$  such that aw is cyclically reduced and  $p' \stackrel{aw}{\longrightarrow} q'$  in  $\mathsf{cc}(\Gamma(H))$ . Let indeed  $p'' \stackrel{z}{\longrightarrow} q'$  be a path of minimal length in  $\operatorname{cc}(\Gamma(H))$  (there exists one by connectedness). Since  $p'' \in \operatorname{cc}(\Gamma(H))$ , there exists a path  $p'' \xrightarrow{b} r$  for some  $b \in \tilde{A}$ ,  $b \neq \bar{a}$ , and as in the proof of Remark [1.2,](#page-3-0) there exists a reduced word of the form bt labeling a loop at  $p''$ . Let  $w = \text{red}(btz)$ : then we have a path  $p'' \stackrel{w}{\longrightarrow} q'$ . By minimality of the length of z,  $\bar{t} \bar{b}$  is not a prefix of z, so w starts with letter b, and hence aw is reduced. In fact, aw is cyclically reduced since there is no path  $q' \stackrel{a}{\longrightarrow} q''$ .

Let  $1 \stackrel{t}{\longrightarrow} q'$  be a path in  $\Gamma(H)$ . Then red $(taw\bar{t}) \in G$ , and hence there exists  $m > 1$  such that  $\text{red}(t(aw)^m \bar{t}) \in H$ . Again, since there is no path  $q' \stackrel{a}{\longrightarrow} q''$ , the word ta is reduced. By replacing  $m$  by a sufficiently large multiple, we find that ta is a prefix of red $(t(aw)^m\bar{t})$ , and hence that ta labels a path from 1 in  $\Gamma(H)$ : this contradicts the absence of a path  $q' \stackrel{a}{\longrightarrow} q''$ .

Thus we have proved that, if  $H \leq_{\text{fi}} G$ , then  $p, q \in \text{cc}(\Gamma(H))$  and  $\widetilde{L}_p(H) =$  $\widetilde{L}_q(H)$ . The latter condition immediately implies that  $L_p(H) = L_q(H)$ . We now assume that  $p, q \in \text{cc}(\Gamma(H))$  and  $L_p(H) = L_q(H)$ , and we show that  $H \leq_{\text{fi}} G$ . We first establish a technical fact.

<span id="page-8-0"></span>**Lemma 2.6** *Let*  $r_i \xrightarrow{z_i} s_{i+1}$  ( $z_i \in F$ ,  $0 \leq i \leq k$ ) be paths in  $cc(\Gamma(H))$ , such  $that r_i, s_i \in \{p, q\}$  *for each*  $1 \leq i \leq k$ *. Then there exists a path*  $r_0 \stackrel{\text{red}(z_0 \cdots z_k)}{\longrightarrow} t$  *in*  $cc(\Gamma(H)).$ 

**Proof.** The proof is by induction on k, and is trivial for  $k = 0$ . If  $k > 0$ , then there is a path  $r_1 \stackrel{\text{red}(z_1...z_k)}{\longrightarrow} t$  in  $\text{cc}(\Gamma(H))$ . Since  $L_p(H) = L_q(H)$ , there is also a path  $s_1 \longrightarrow^{\text{red}(z_1 \cdots z_k)} t'$  for some  $t' \in \text{cc}(\Gamma(H))$ , and therefore a path  $r_0 \overset{\text{red}(z_0 \cdots z_k)}{\longrightarrow} t'$ as required.

We want to show that G has finitely many H-cosets. Let  $u \in G$ : then u labels a loop at 1 in  $\Gamma(G)$ . Let B be the automaton obtained from  $\Gamma(H)$  by identifying vertices p and q, but without performing any reduction. Then  $\Gamma(G)$ is the result of the reduction of  $\beta$ . In particular (say, in view of [\[10,](#page-16-2) Fact 1.4]),  $u = \text{red}(v)$  for some word  $v \in \tilde{A}^*$  labeling a loop at 1 in  $\mathcal{B}$ . By definition of  $\mathcal{B}$ , the word v factors as  $v = v_0 \cdots v_k$ , in such a way that  $\Gamma(H)$  has paths of the form  $1 \xrightarrow{v_0} s_1, r_i \xrightarrow{v_i} s_{i+1} (1 \leq i \leq k)$  and  $r_k \xrightarrow{v_k} 1$ , and the vertices  $r_1, s_1, \dots, r_k, s_k$ are all equal to p or q. As observed in Section [1,](#page-2-0)  $\Gamma(H)$  also has paths

$$
1\overset{\mathrm{red}(v_0)}{\longrightarrow} s_1,\ r_i\overset{\mathrm{red}(v_i)}{\longrightarrow} s_{i+1} \ (1\leq i
$$

In particular, we have  $\text{red}(v_0) = \text{t}(1)w_0$  and  $\text{red}(v_k) = w_k \overline{\text{t}}(1)$  for some  $w_0, w_k \in$ F, and there are paths  $1 \xrightarrow{\mathbf{t}(1)} \tau(1) \xrightarrow{w_0} s_1$  and  $r_k \xrightarrow{w_k} \tau(1) \xrightarrow{\mathbf{t}(1)}$  $\rightarrow$  1. Note that the paths  $\tau(1) \xrightarrow{w_0} s_1, r_i \stackrel{\text{red}(v_i)}{\longrightarrow} s_{i+1}$   $(1 \leq i < k)$  and  $r_k \xrightarrow{w_k} \tau(1)$  are set entirely within  $cc(\Gamma(H))$ , since no reduced word-labeled path between vertices in  $cc(\Gamma(H))$  can visit a vertex in  $\text{tail}(\Gamma(H)).$ 

By Lemma [2.6,](#page-8-0) there exists a path  $\tau(1) \stackrel{\text{red}(w_0v_1\cdots v_{k-1}w_k)}{\longrightarrow} t$  for some vertex t in cc(Γ(H)). Let h be a shortest-length word such that  $t \stackrel{h}{\longrightarrow} \tau(1)$  in cc(Γ(H)). Then  $z = t(1) \text{red}(w_0v_1 \cdots v_{k-1}w_k)$  h  $\bar{t}(1)$  labels a loop at vertex 1 in  $\Gamma(H)$ , so red $(z) \in H$ . By construction, we have  $u = \text{red}(\mathsf{t}(1)w_0v_1 \cdots v_{k-1}w_k\overline{\mathsf{t}}(1)),$  so  $u \in H$  red(t(1)  $\bar{h}$   $\bar{t}$ (1)). Since h was chosen to be a geodesic in  $cc(\Gamma(H))$ , it can take only finitely many values, and this completes the proof that G has finitely many H-cosets.  $□$  We note the following consequence of this proof.

Corollary 2.7 Let  $H \leq_{fg} F$  and let  $p, q \in cc(\Gamma(H))$ . Then  $L_p(H) = L_q(H)$  if *and only if*  $L_p(H) = L_q(H)$ *.* 

#### <span id="page-9-0"></span>2.3 The lattice of finite-index extensions of H

We further refine Proposition [2.5](#page-7-1) as follows: we consider an extension  $H \leq_{\text{fi}}$ G and a pair  $(r, s)$  of vertices of  $\Gamma(H)$ , whose identification yields a finiteindex extension of H. Then we show that identifying the vertices of  $\Gamma(G)$ corresponding to  $r$  and  $s$ , also yields a finite-index extension of  $G$ .

<span id="page-9-1"></span>**Lemma 2.8** *Let*  $H \leq_{\text{fi}} G \leq_{\text{fg}} F$  *and let*  $\varphi = \varphi_H^G$ *. Let* p *be a vertex of*  $\text{cc}(\Gamma(H))$ *. Then*  $L_p(H) = L_{\varphi(p)}(G)$  *and*  $L_p(H) = L_{\varphi(p)}(G)$ *.* 

**Proof.** If  $p \xrightarrow{u} r$  in  $\text{cc}(\Gamma(H))$ , then the  $\varphi$ -image of this path is a path  $\varphi(p) \xrightarrow{u} \varphi(r)$ , which is entirely contained in  $\mathsf{cc}(\Gamma(G))$  by Proposition [1.4.](#page-4-0) In particular,  $L_p(H) \subseteq$  $L_{\varphi(p)}(G).$ 

Conversely, suppose that  $\varphi(p) \stackrel{u}{\longrightarrow} r'$  is a path in  $\mathsf{cc}(\Gamma(G))$ . Since  $\varphi$  is a cover from  $\mathsf{cc}(\Gamma(H))$  onto  $\mathsf{cc}(\Gamma(H))$ , u labels some path  $p \xrightarrow{u} r$  in  $\mathsf{cc}(\Gamma(H))$ , and hence  $u \in L_p(H)$ . Thus  $L_p(H) = L_{\varphi(p)}(G)$ . □

<span id="page-9-2"></span>Together with Proposition [2.5,](#page-7-1) Lemma [2.8](#page-9-1) immediately implies the following statements.

#### Corollary 2.9 *Let*  $H \leq_{fg} F$ .

- *1. Let*  $H \leq_{\text{fi}} G$  *and let*  $\varphi = \varphi_H^G$ *. If*  $p, q$  *are vertices of*  $\Gamma(H)$ *,*  $\mathcal{A}(H) \longrightarrow_{\text{i}}^{p=q}$  $\mathcal{A}(K)$  and  $\mathcal{A}(G) \longrightarrow_{\mathsf{i}}^{\varphi(p)=\varphi(q)} \mathcal{A}(K')$ , then  $H \leq_{\mathsf{fi}} K$  if and only if  $G \leq_{\mathsf{fi}} K'$ .
- 2.  $H \leq_{\text{fi}} G$  *if and only if*  $\mathcal{A}(G)$  *is obtained from*  $\mathcal{A}(H)$  *by identifying some pairs of vertices*  $(p,q)$  *in*  $cc(\Gamma(H))$  *such that*  $L_p(H) = L_q(H)$ *, and then reducing the resulting graph.*

The identification of all pairs of vertices  $(p, q)$  such that  $L_p(H) = L_q(H)$ yields the minimum quotient of  $\mathcal{A}(H)$  and hence the maximum finite-index extension  $H<sub>f<sub>i</sub></sub>$  of H. In addition, we find that  $H<sub>f<sub>i</sub></sub>$  is exactly the *commensurator* of H (the set  $\textsf{Comm}_F(H)$  of all elements  $g \in F$  such that  $H \cap H^g$  has finite index in both H and  $H<sup>g</sup>$ ), a fact that can also be deduced from [\[5,](#page-16-4) Lemma 8.7].

<span id="page-9-3"></span>**Theorem 2.10** Let  $H \leq_{fg} F$  and let  $H_{fi}$  be its maximum finite-index extension.

- 1.  $A(H_i)$  *is obtained from*  $A(H)$  *by identifying all pairs of vertices* p, q of  $cc(\Gamma(H))$  *such that*  $L_p(H) = L_q(H)$ *. No reduction is necessary.*
- 2.  $H_{fi} = \text{Comm}_F(H)$ .

**Proof.** In view of Corollary [2.9,](#page-9-2)  $\mathcal{A}(H_f)$  is obtained from  $\mathcal{A}(H)$  by identifying all pairs of vertices p, q of  $cc(\Gamma(H))$  such that  $L_p(H) = L_q(H)$ , and then by reducing the resulting graph  $\mathcal{B}$ . If  $p \xrightarrow{a} r$  and  $q \xrightarrow{a} s$   $(a \in \tilde{A})$  are paths in  $cc(\Gamma(H))$  and if  $L_p(H) = L_q(H)$ , then  $L_r(H) = L_s(H)$  by Remark [2.4.](#page-7-2) Thus  $\beta$ is already reduced, which concludes the proof of the first statement.

The fact that  $Comm(H)$  is a subgroup and a finite-index extension of H is proved, for instance, in [\[5,](#page-16-4) Prop. 8.9]. Conversely, suppose that  $H \leq_{\text{fi}} G$  and  $g \in G$ . Since conjugation by g is an automorphism of G, we have  $H<sup>g</sup> \leq_{\text{fi}} G$ . Now the intersection of finite-index subgroups, again has finite index, so  $H \cap H<sup>g</sup> \leq_{\text{fi}} G$ and hence  $H \cap H^g \leq_{\text{fi}} H$  and  $H \cap H^g \leq_{\text{fi}} H^g$ . Thus  $g \in \text{Comm}_F(H)$ , which concludes the proof. ⊓⊔

#### <span id="page-10-0"></span>2.4 Computing finite-index extensions

Recall the notion of minimization of a deterministic finite-state automaton (see [\[6\]](#page-16-6) for instance). Let  $\mathcal{B} = (Q, i, E, T)$  be such an automaton, over the alphabet B, with Q the finite set of states,  $i \in Q$  the initial state,  $E \subseteq Q \times B \times Q$  the set of transitions and  $T \subseteq Q$  the set of accepting states, and let L be the language accepted by  $\mathcal{B}$ , that is, the set of words in  $B^*$  that label a path from p to a state in  $T$ . Then the minimal automaton of  $L$  is obtained by identifying the pairs of states  $(p, q)$  such that the automata  $(Q, p, E, T)$  and  $(Q, q, E, T)$  accept the same language.

In our situation, the alphabet is  $\tilde{A}$  and  $\tilde{L}_p(H)$  is the language accepted by the automaton  $\mathcal{B}_p$ , whose states and transitions are given by  $cc(\Gamma(H))$ , with initial state  $p$  and all states final. Therefore Corollary [2.9](#page-9-2) and Theorem [2.10](#page-9-3) show that the identification of two vertices  $p, q \in \text{cc}(\Gamma(H))$  yields a finite-index extension if and only if p and q are identified when minimizing  $\mathcal{B}_{\tau(1)}$ . Moreover,  $cc(\Gamma(H_{fi}))$  is given by the states and transitions of the minimal automaton of  $L_{\tau(1)}(H)$ .

<span id="page-10-1"></span>The classical Hopcroft algorithm (see  $|6|$ ) minimizes an *n*-state automaton in time  $\mathcal{O}(n \log n)$ , so we have the following result.

**Proposition 2.11** *Let*  $H \leq_{fg} F$ *, and let n be the number of vertices of*  $\Gamma(H)$ *.* 

- $cc(\Gamma(H_{\rm fi}))$  *is obtained by minimizing the automaton given by the vertices* and edges of  $cc(\Gamma(H))$ *, with all states final (the initial state does not matter in that situation).*
- *One can compute*  $\Gamma(H_f)$  *in time*  $\mathcal{O}(n \log n)$ *.*
- *One can decide in time* O(n log n) *whether identifying a given set of pairs of vertices of* Γ(H) *will produce a finite-index extension of* H*.*

Remark 2.12 It may be that for the particular automata at hand (over a symmetrized alphabet, with all states final), the complexity of Hopcroft's algorithm might be better than  $\mathcal{O}(n \log n)$ , even linear. It has also been observed that in many instances, Myhill's automata minimization algorithm exhibits a

better performance than Hopcroft's, in spite of a  $\mathcal{O}(n^2)$  worst-case complexity. Brzozowski's algorithm [\[2\]](#page-16-7) also performs remarkably well in practice [\[3\]](#page-16-8). ⊓⊔

#### <span id="page-11-0"></span>2.5 Counting finite-index extensions

Recall that, if  $\Gamma$  is an A-labeled graph, the *product*  $\Gamma \times_A \Gamma$  (also called the *fiber product*, or the *pull-back*, of two copies of Γ) is the A-labeled graph whose vertex set is the set of pairs  $(p, q)$  of vertices of  $\Gamma$  and whose edges are the triples  $((p,q), a, (p', q'))$  such that  $(p, a, q)$  and  $(p', a, q')$  are edges of  $\Gamma$ . This graph is not admissible, nor even connected in general (the vertices of the form  $(p, p)$ ) form a connected component that is isomorphic to  $\Gamma$ ). Note that there is a u-labeled path in  $\Gamma \times_A \Gamma$  from  $(p, q)$  to  $(p', q')$ , if and only if  $\Gamma$  has paths  $p \stackrel{u}{\longrightarrow} p'$ and  $q \xrightarrow{u} q'$ .

<span id="page-11-1"></span>If p, q are vertices of  $cc(\Gamma(H))$ , we let  $p \sim q$  if and only if  $L_p(H) = L_q(H)$ .

#### Proposition 2.13 *Let*  $H \leq_{fg} F$ .

- *The relation*  $\sim$  *is a union of connected components of*  $cc(\Gamma(H)) \times$ <sub>*Acc*( $\Gamma(H)$ )*.*</sub>
- Let p, q be vertices of  $cc(\Gamma(H))$ . Then  $p \sim q$  if and only if the first and *the second component projections, from the connected component of*  $(p, q)$ *in*  $cc(\Gamma(H)) \times_A cc(\Gamma(H))$  *to*  $cc(\Gamma(H))$  *are both covers.*

Proof. The first statement follows directly from Remark [2.4,](#page-7-2) which shows that if  $p \sim q$  and there is a path  $(p, q) \stackrel{u}{\longrightarrow} (p', q')$ , then  $p' \sim q'$ .

Let us now assume that  $p \sim q$  and let us show that the first component projection is a cover from the connected component of  $(p, q)$  onto  $\mathsf{cc}(\Gamma(H))$ . Let  $(r, s)$  be a vertex in that connected component: then there exists  $u \in F$ such that  $p \xrightarrow{u} r$  and  $q \xrightarrow{u} s$ . Let  $r \xrightarrow{a} r'$   $(a \in \tilde{A})$  be an edge in  $\Gamma(H)$ . Then  $ua \in L_p(H)$ , so  $ua \in L_q(H)$ , and hence (since  $\Gamma(H) \times_A \Gamma(H)$  is deterministic), there exists an a-labeled path  $s \xrightarrow{a} s'$ . Therefore there exists an a-labeled path  $(r, s) \stackrel{a}{\longrightarrow} (r', s')$ . Thus the first component projection is a cover. The proof concerning the second component projection is identical.

Conversely, suppose that the first and the second component projections, from the connected component of  $(p, q)$  in  $cc(\Gamma(H)) \times_A cc(\Gamma(H))$  to  $cc(\Gamma(H))$ are covers, and let  $u \in L_p(H)$ . Then  $\textsf{cc}(\Gamma(H))$  has a path  $p \xrightarrow{u} r$ . It is an elementary property of covers that this path can be lifted to a path in cc( $\Gamma(H)$ ) × A cc( $\Gamma(H)$ ), of the form  $(p, q) \stackrel{u}{\longrightarrow} (r, s)$ . The second component projection of that path yields a path  $q \stackrel{u}{\longrightarrow} s$  in  $\textsf{cc}(\Gamma(H))$ , and hence  $u \in L_q(H)$ . □

Let  $f(n)$  be the maximal number of finite-index extensions of a subgroup  $H \leq_{fg} F$  such that  $\Gamma(H)$  has at most *n* vertices. By Proposition [2.13,](#page-11-1) every pair  $(p, q)$  such that  $p \sim q$  is in the connected component of a pair of the form  $(1, r)$  for some  $r > 1$ . Moreover, this connected component has elements of the form  $(i, j)$  for all  $1 \leq i \leq n$ , so the graph resulting from the identification of 1 and r (or from p and q) has at most  $n/2$  vertices. Thus  $f(1) = 1$  and  $f(n) \le n f(\lfloor n/2 \rfloor)$  for all  $n \ge 2$ . It follows that  $f(n) \le n^{\frac{1}{2}(1 + \log_2 n)}$ .

**Proposition 2.14** *Let*  $H \leq_{fg} F$ *. If*  $cc(\Gamma(H))$  *has n vertices, then*  $H$  *has at*  $m$ ost  $n^{\frac{1}{2}(1+\log_2 n)}$  *finite-index extensions.* 

<span id="page-12-2"></span>Example 2.15 By means of lower bound, we consider the following example. Let  $e_1, \ldots, e_k$  be the canonical basis of the vector space  $\mathbb{Z}_2^k$ , let  $\varphi$  be the morphism from the free group F over  $A = \{a_1, \ldots, a_k\}$  into the additive group  $\mathbb{Z}_2^k$ , mapping  $a_i$  to  $e_i$ , and let  $H = \text{ker } \varphi$ . Then H is normal and finite-index, so all its extensions have finite index and they are in bijection with the set of quotients of  $\mathbb{Z}_2^k$ , hence with the set of subgroups of  $\mathbb{Z}_2^k$ , or equivalently with the set of subspaces of  $\mathbb{Z}_2^k$ .

Let  $\ell_{d,k}$  be the number of linearly independent d-tuples in  $\mathbb{Z}_2^k$   $(d \geq 1)$ . Then  $\ell_{1,k} = 2^k - 1$ . If  $d \geq 2$ , a d-tuple  $(x_1, \ldots, x_d)$  is linearly independent if and only if  $(x_1, \ldots, x_{d-1})$  is linearly independent and  $x_d$  does not belong to the subspace generated by  $x_1, \ldots, x_{d-1}$ , so that  $\ell_{d,k} = \ell_{d-1,k}(2^k - 2^{d-1})$ . Now the set of cardinality d linearly independent subsets has  $m_{d,k} = \ell_{d,k}/d!$  elements, and the number of dimension d subspaces of  $\mathbb{Z}_2^k$  is

$$
s_{d,k} = \frac{m_{d,k}}{m_{d,d}} = \frac{\ell_{d,k}}{\ell_{d,d}} = \frac{(2^k - 1)(2^k - 2)(2^k - 4) \cdots (2^k - 2^{d-1})}{(2^d - 1)(2^d - 2)(2^d - 4) \cdots (2^d - 2^{d-1})}.
$$

Finally, the number of subspaces of  $\mathbb{Z}_2^k$  is equal to  $\sum_{d=0}^k s_{d,k}$ , with  $s_{0,k} = 1$ .

We observe that for each  $0 \leq i < d < k$ ,  $\frac{2^k - 2^i}{2^d - 2^i}$  $\frac{2^k - 2^i}{2^d - 2^i} > 2^{k-d}$ , so that  $s_{d,k} > 2^{(k-d)d}$ . By considering  $d = \lfloor \frac{k}{2} \rfloor$ , we find that  $\sum s_{d,k} > 2^{k^2/4}$ .

Finally, we note that  $\Gamma(H)$  is the Cayley graph of  $\mathbb{Z}_2^k$  with respect to the basis  $e_1, \ldots, e_d$  (a graph known as the dimension k hypercube), so that  $\Gamma(H)$  has  $n =$ 2<sup>k</sup> vertices. As a result, H has more than  $n^{\frac{1}{4} \log_2 n}$  finite-index extensions. □

## <span id="page-12-0"></span>2.6 The lattice of finite-index subgroups of  $G$

Let us call fi-maximal a subgroup  $G \leq_{fg} F$  which has no proper finite-index extension, that is (in view of Theorem [2.10\)](#page-9-3), such that  $G = \text{Comm}_F(G)$ . If G is fi-maximal, let  $FIS(G)$  be the set of all finite-index subgroups of  $G$ , that is, the set of subgroups  $H \leq_{fg} F$  such that  $H_f = G$ . Note that distinct fi-maximal subgroups yield disjoint lattices of finite-index subgroups.

**Remark 2.16** Let  $G \leq_{fg} F$  be non-trivial and fi-maximal. Then  $\mathsf{FIS}(G)$  forms a convex sublattice of the lattice of subgroups of  $F$ , with greatest element  $G$ . This sublattice is always infinite (see Remark [2.1\)](#page-5-2) and without a least element. □

<span id="page-12-1"></span>Lemma [2.8](#page-9-1) provides us with an invariant for every sublattice of the form  $\mathsf{FIS}(G)$  (with G fi-maximal).

**Proposition 2.17** Let H, K  $\leq_{fg}$  F. Then  $H_{fi} = K_{fi}$  *if and only if*  $t_H(1) =$  $t_K(1)$  and  $\widetilde{L}_{\tau(1)}(H) = \widetilde{L}_{\tau(1)}(K)$ , if and only if  $t_H(1) = t_K(1)$  and  $L_{\tau(1)}(H) =$  $L_{\tau(1)}(K)$ .

**Proof.** If  $H_{fi} = K_{fi}$ , then  $H, K \leq_{fi} H_{fi}$ , and Proposition [1.4](#page-4-0) and Lemma [2.8](#page-9-1) show directly that  $t_H(1) = t_{H_f}(1) = t_K(1), \ \tilde{L}_{\tau(1)}(H) = \tilde{L}_{\tau(1)}(H_f) = \tilde{L}_{\tau(1)}(K)$ and  $L_{\tau(1)}(H) = L_{\tau(1)}(H_{\rm fi}) = L_{\tau(1)}(K)$ .

We now prove the converse. More precisely, we show that if  $H$  and  $K$  are fi-maximal,  $t_H(1) = t_K(1)$  and  $L_{\tau(1)}(H) = L_{\tau(1)}(K)$ , then  $H = K$ . First we note that  $\mathcal{A}(H^{\mathbf{t}_H(1)}) = (\textsf{cc}(\Gamma(H)), \tau(1))$  and in particular,  $H^{\mathbf{t}_H(1)}$  is cyclically reduced and fi-maximal. Thus, it suffices to prove the expected result (namely, that  $H = K$ ) under the hypothesis that H and K are cyclically reduced.

By Remark [2.4,](#page-7-2) the set of all  $L_p(H)$   $(p \in \Gamma(H))$  coincides with the set  $\{ \{ \text{red}(\bar{u}x) \mid x \in L_1(H) \} \mid u \in L_1(H) \}.$  In addition, since H is fi-maximal, if  $u, v \in L_1(H)$  with  $1 \stackrel{u}{\longrightarrow} p$  and  $1 \stackrel{u}{\longrightarrow} q$  and  $\{ \text{red}(\bar{u}x) \mid x \in L_1(H) \} = \{ \text{red}(\bar{v}x) \mid x \in L_1(H) \}$  $x \in L_1(H)$ , then  $p = q$ . It also follows from the same fact that, again if H is fi-maximal, there is an edge  $(p, a, q)$  in  $\Gamma(H)$  if and only if  $L_q(H) = \{ \text{red}(\bar{a}x) \mid$  $x \in L_p(H)$ . Thus, the cyclically reduced fi-maximal subgroup H is entirely determined by the set  $L_1(H)$ . This concludes the proof. determined by the set  $L_1(H)$ . This concludes the proof.

The pairs  $(t, L)$  that are equal to  $(\mathsf{t}(1), \widetilde{L}_{\tau(1)}(G))$  for some subgroup  $G \leq_{\mathsf{fg}} F$ are characterized as follows. Recall that an *i-automaton* [\[9\]](#page-16-9) is a deterministic automaton  $(Q, i, E, T)$  over the alphabet A such that,  $(p, a, q) \in E$  if and only if  $(q, \bar{a}, p) \in E$  for all vertices p, q and  $a \in A$ . The automata  $\mathcal{B}_p$  discussed in Section [2.4](#page-10-0) are i-automata.

**Proposition 2.18** *Let*  $t \in F$  *and let*  $L \subseteq \tilde{A}^*$  *be a rational language. The following conditions are equivalent.*

- *(1) There exists a subgroup*  $H \leq_{\text{fg}} F$  *such that*  $t = t(1)$  *and*  $L = \widetilde{L}_{\tau(1)}(H)$ *.*
- *(2) There exists a* fi-maximal subgroup  $H \leq_{fg} F$  such that  $t = t(1)$  and  $L =$  $L_{\tau(1)}(H)$ .
- *(3)* L *is accepted by an i-automaton with all states accepting and such that, for each state* p, there exist transitions  $(p, a, q)$  and  $(p, b, r)$  *for at least two distinct letters*  $a, b \in \overline{A}$ *. In addition, if t is not the empty word, then*  $t = t'a$  *for a letter*  $a \in \tilde{A}$  *such that*  $\bar{a} \notin L$ *.*
- *(3') The minimal automaton of* L *is an i-automaton with all states accepting* and such that, for each state p, there exist transitions  $(p, a, q)$  and  $(p, b, r)$ *for at least two distinct letters*  $a, b \in \tilde{A}$ *. In addition, if t is not the empty word, then*  $t = t'$ *a for a letter*  $a \in \tilde{A}$  *such that*  $\bar{a} \notin L$ *.*
- *(4)* t *and* L *satisfy the following conditions:*
	- *(4.1)* L *is closed under taking prefixes;*
	- $(4.2)$  *if*  $u, v \in L$ *, then*  $u\overline{u}v \in L$ *;*
	- $(4.3)$  *if*  $uv\overline{v}w \in L$ *, then*  $uw \in L$ *;*
	- *(4.4)* if  $ua \in L$  *with*  $a \in \tilde{A}$ *, then*  $uab \in L$  *for some*  $b \in \tilde{A}$  *such that*  $b \neq \bar{a}$ *.*

(4.5) if t is not the empty word, then  $t = t' a$  for a letter  $a \in \tilde{A}$  such that  $\bar{a} \notin L$ .

Proof. Conditions (1) and (2) are equivalent by Proposition [2.17.](#page-12-1)

Proposition [2.11](#page-10-1) shows that (1) implies (3'), which in turn implies (3). Let us now assume that (3) holds and let  $\Gamma$  be the A-labeled graph induced by the states and transitions of the minimal automaton of L. The extra condition given shows that every vertex of  $\Gamma$  is visited by a loop labeled by a cyclically reduced word. It follows that, if  $G$  is the subgroup whose graphical representation is  $\mathcal{A}(G) = (\Gamma, q_0)$ , with  $q_0$  the initial state, then G is cyclically reduced,  $L =$  $L_{q_0}(G)$ . The condition on the word t shows that Condition (1) holds with  $H = G^t$ .

Condition (3) easily implies Condition (4). Let us now assume that Con-dition (4) holds. By [\[9,](#page-16-9) Theorem 4.1], Properties  $(4.2)$  and  $(4.3)$  show that L is accepted by an i-automaton. Property (4.1) shows that all states of that automaton are final, and Property  $(4.4)$  shows that, for each state p, there exist transitions  $(p, a, q)$  and  $(p, b, r)$  for at least two distinct letters  $a, b \in A$ . Thus Condition (4) implies Condition (3), which concludes the proof. Condition  $(4)$  implies Condition  $(3)$ , which concludes the proof.

## <span id="page-14-0"></span>3 Malnormal closure

A subgroup H of F is *malnormal* if  $H<sup>g</sup> \cap H = 1$  for each  $g \notin H$ . Malnormality was proved decidable in [\[1\]](#page-16-10), and a simple decision algorithm was given in [\[5\]](#page-16-4), based on the following characterization [\[5,](#page-16-4) [4\]](#page-16-11).

<span id="page-14-1"></span>**Proposition 3.1** *Let*  $H \leq_{fg} F$ . *Then*  $H$  *is malnormal if and only if every connected component of*  $\Gamma(H) \times_A \Gamma(H)$ *, except for the diagonal complement, is a tree, if and only if, for every*  $p \neq q \in \textsf{cc}(\Gamma(H))$ *,*  $L_p(H) \cap L_q(H)$  *is finite.* 

This yields directly an  $\mathcal{O}(n^2 \log n)$  decision algorithm, where n is the number of vertices of  $cc(\Gamma(H))$ . It also yields the following corollary.

Corollary 3.2 Let  $H \leq_{fg} F$ . If  $H$  *is malnormal, then*  $H$  *is* fi-maximal, that is, H *has no proper finite-index extension.*

**Proof.** By Corollary [2.9,](#page-9-2) if H is not fi-maximal, then there exist vertices  $p \neq q$ in  $\text{cc}(\Gamma(H))$  such that  $L_p(H) = L_q(H)$ , and hence such that  $L_p(H) \cap L_q(H) =$  $L_p(H)$  is infinite. In particular, H is not malnormal.

<span id="page-14-2"></span>It is shown in [\[7,](#page-16-5) Prop. 4.5] that for every finitely generated subgroup  $H \leq_{fg} F$ , there exists a least malnormal extension  $H_{\text{mal}}$ , called the *malnormal closure* of  $H$ , that  $H_{\text{mal}}$  is finitely generated and effectively computable, and that the rank of  $H_{\text{mal}}$  is less than or equal to the rank of H [\[7,](#page-16-5) Corol. 4.14]. In fact, [\[7\]](#page-16-5) shows that  $\Gamma(H_{\text{mal}})$  is obtained from  $\Gamma(H)$  by a series of i-steps. The algorithm computing  $H_{\text{mal}}$  then consists in computing all the quotients of  $\Gamma(H)$ and verifying, for each of them, whether it represents a malnormal subgroup. We now give a much better, polynomial-time algorithm.

**Theorem 3.3** Let  $H \leq_{fg} F_n$ . The malnormal closure of H is computed by *repeatedly applying the following construction: in*  $\Gamma(H)$ *, identify all pairs*  $(p,q)$ *of distinct vertices in*  $cc(\Gamma(H))$ *, such that*  $L_p(H) \cap L_q(H)$  *is infinite and reduce the resulting graph.*

**Proof.** Let  $H_0 = H$  and let  $H_{i+1}$  be the subgroup of F such that  $\Gamma(H_{i+1})$  is obtained from  $\Gamma(H_i)$  by, first identifying all pairs p, q of vertices of  $cc(\Gamma(H_i))$ such that  $L_p(H_i) \cap L_q(H_i)$  is infinite, and then reducing the resulting graph. Since  $\Gamma(H_{i+1})$  has less vertices than  $\Gamma(H_i)$ , this defines a finite sequence of subgroups

$$
H = H_0 < H_1 < \ldots < H_k
$$

where  $k \geq 0$  and  $H_k$  is malnormal. We want to show that  $H_k$  is the least malnormal extension of H.

Let K be any malnormal subgroup of F such that  $H \leq K$ . By Takahasi's theorem (see for instance [\[7\]](#page-16-5)), there exists a subgroup G such that  $H \leq G \leq K$ such that  $G$  is obtained from  $H$  by a sequence of i-steps, and  $K$  is obtained from G by a sequence of re-steps (this fact can also be deduced from [\[10,](#page-16-2) Prop.  $(2.6)$ .

Let  $p, q \in \textsf{cc}(\Gamma(H))$  such that  $L_p(H) \cap L_q(H)$  is infinite. It is elementary to verify that  $L_p(H) \subseteq L_{\varphi_H^G(p)}(G) \subseteq L_{\varphi_G^K(\varphi_H^G(p))}(K)$ . In particular,  $\varphi_G^K(\varphi_H^G(p)) \cap$  $\varphi_G^K(\varphi_{H_\bullet}^G(q))$  is infinite. Since K is malnormal, it follows from Proposition [3.1](#page-14-1) that  $\varphi_G^K(\varphi_H^G(p)) = \varphi_G^K(\varphi_H^G(q))$ . But  $\varphi_G^K$  is one-to-one by definition, so we have  $\varphi_H^G(p) = \varphi_H^G(q)$ . It follows that G is obtained from  $H_1$  by a sequence of i-steps, and in particular,  $H_1 \leq G \leq K$ . Iterating this reasoning, we find that  $H_k \leq K$ , which concludes the proof which concludes the proof.

**Corollary 3.4** *Let*  $H \leq F$ *. If*  $\Gamma(H)$  *has n vertices, then one can compute*  $\Gamma(H_{\text{mal}})$  *in time*  $\mathcal{O}(n^3 \log n)$ *.* 

Proof. According to the algorithm given in Proposition [3.3,](#page-14-2) we first need to compute the connected components of  $cc(\Gamma(H)) \times_A cc(\Gamma(H))$  – done in time  $\mathcal{O}(n^2 \log n)$  –, identifying which are trees and which are not – done in time  $\mathcal{O}(n^2)$ –, identifying the vertices of  $cc(\Gamma(H))$  involved in a non-diagonal connected component and reducing the resulting graph to obtain  $\Gamma(H_1)$  – which is done in time  $\mathcal{O}(n \log n)$ . Thus  $\Gamma(H_1)$  is computed from  $\Gamma(H_0)$  in time  $\mathcal{O}(n^2 \log n)$ .

This part of the algorithm is iterated k times, to compute  $\Gamma(H_k) = \Gamma(H_{\text{mal}})$ , and we have  $k < n$  since the number of vertices of the  $\Gamma(H_i)$  forms a properly decreasing sequence. This concludes the proof. □
