

Logic Integer Programming Models for Signaling Networks

Utz-Uwe Haus*

Kathrin Niermann*

Klaus Truemper[#]

Robert Weismantel*

Abstract

We propose a static and a dynamic approach to model biological signaling networks, and show how each can be used to answer relevant biological questions. For this we use the two different mathematical tools of Propositional Logic and Integer Programming. The power of discrete mathematics for handling qualitative as well as quantitative data has so far not been exploited in Molecular Biology, which is mostly driven by experimental research, relying on first-order or statistical models. The arising logic statements and integer programs are analyzed and can be solved with standard software. For a restricted class of problems the logic models reduce to a polynomial-time solvable satisfiability algorithm. Additionally, a more dynamic model enables enumeration of possible time resolutions in poly-logarithmic time. Computational experiments are included.

Key Words: biological signaling networks, modeling, integer programming, satisfiability, monotone boolean functions

1 Introduction

Cellular decisions are determined by highly complex molecular interactions. In some biological systems like *Saccharomyces* or *E. coli*, detailed measurements of the interacting molecules, including reaction kinetics, have successfully been performed, allowing the construction of quantitative models (Feist et al., 2007). In many other systems such extensive measurements are not available, because of practical experimental restrictions or ethical constraints. However, in these cases, there is often still a sizable amount of qualitative information available, but a lack of suitable predictive modeling tools.

We focus here on interactions in form of signal transduction processes. For such a process we assume that a set of molecules that are important for the biological unit is known. The biological unit reacts to external signals or environmental challenges like stimulation or infection. Typically,

*Institut für Mathematische Optimierung, Otto-von-Guericke-Universität Magdeburg, Universitätsplatz 2, D-39106 Magdeburg, Germany, phone: +49 391 6718646, fax: +49 391 6711171, e-mail: {haus,niermann,weismantel}@imo.math.uni-magdeburg.de

[#]Department of Computer Science, University of Texas at Dallas, Richardson, Texas 75080, USA, phone: +1 972 883-2712, email:truemper@utdallas.edu

the molecules may be subdivided into input components (e.g. receptors), intermediate components and output components (e.g. transcription factors): When an external signal arrives, this signal is processed through the entire unit by first influencing a subset of the input components. Activation state or presence/absence information is propagated through intermediate nodes towards some of the output molecules. Based on the assumption that we know the “local” mechanism of activation, it is our goal to predict the global behavior of the system, identifying the underlying network structure. For our purposes ‘activation’ can mean any interaction that can be explained biologically: A protein may be considered activated after phosphorylation, Ca^{++} flux may be detected, or a component may change its location within the biological unit. Similarly, ‘biological unit’ need not be restricted to a single cell or compartment, but any collection of components that are to be considered.

Subsequently we propose a logic and an integer programming model to analyze the static behavior of signaling networks. With both approaches one is able to verify the biological modeling, find potential failure modes and determine suitable intervention strategies. But some phenomena in biological units like time delays and (negative) feedback loops can not be modeled in this static fashion. Thus we focus on the dynamics of signaling networks in the second part. We extend the previous models so that activations can be modeled as occurring at different time points or with different signaling speed. In this section we present a generic framework for computations with the dynamic model which can use solvers specific to each of the modeling techniques, logic and integer programming, as oracles. This ability requires a basic understanding of the transformation from satisfiability systems to integer programming models and vice versa. Therefore we discuss both sides in the static as well as in the dynamic context hand in hand. The last section provides computational tests showing the appropriateness of our techniques.

2 Modeling Logical Interactions

The simplest model of signaling processes is to collect local data in the form of logical formulas, that can be written down in propositional logic (Saez-Rodriguez et al., 2007): Introduce logical variables for each component under consideration, and write down implication formulas for experimentally proven knowledge statements like “*MEK activates ERK*” as

$$\text{MEK} \rightarrow \text{ERK}$$

and “*In the absence of (activated) pten and ship1 we find that pi3k generates (active) pip3*” as

$$\neg \text{pten} \wedge \neg \text{ship1} \wedge \text{pi3k} \rightarrow \text{pip3}.$$

Let the formulas be denoted as S_i with $i \in \{1, \dots, s\}$. We can then identify the formula $S = \bigwedge_{i=1}^s S_i$ with the model of the biological unit considered: All logical statements S_i should be valid at the same time to model the global behavior of the unit. We will, as usual, use $A \rightarrow B$ as abbreviation of $(\neg A) \vee B$, and $A \leftrightarrow B$ instead of $(A \rightarrow B) \wedge (B \rightarrow A)$. For the reader unfamiliar with the formalism of propositional logic we refer to (Büning and Lettmann, 1999).

We will henceforth assume that all implications in the set S_i are given in OR-form $\bigvee_{j \in L_i^A} A_j \rightarrow \bigvee_{j \in L_i^B} B_j$ for literals A_j, B_j . Here, L_i^A is the set of literals appearing on the left in formula i . We will also require that the set S has been extended with reverse implications by first aggregating formulas with the same right-hand-side, and then adding the reverse implication. Thus, for each set of literals $R = \{B_j | j \in L_i^B \text{ for some } i \in \{1, \dots, s\}\}$ appearing on the right-hand-side of the implications indexed by $I = \{i | S_i = (\bigvee_{j \in L_i^A} A_j \rightarrow \bigvee_{r \in R} r)\}$, we also find the implication $\bigvee_{i \in I} \bigvee_{j \in L_i^A} A_j \leftarrow \bigvee_{r \in R} r$ in S . This enforces that every activation must have a ‘cause’ within the given model.

The question whether there exists a pattern of activations satisfying all formulas of S is an instance of the satisfiability (SAT) problem (Truemper, 2004). In general, this problem is to ask for a *truth assignment* such that the logical formula in CNF form is TRUE:

Definition 1 (CNF, truth assignment, satisfiable).

1. A *clause* α is a disjunction of literals, i.e. $\alpha = A_1 \vee \dots \vee A_n$ with literals A_i .
2. A formula α is in *Conjunctive Normal Form* (CNF) if and only if α is a conjunction of clauses.
3. A formula α is in *k-Conjunctive Normal Form* (*k*-CNF) if and only if α is a conjunction of *k*-clauses, i.e. every clause consists of at most *k* literals.
4. A *truth assignment* Γ of a propositional formula α is defined by

$$\Gamma : \{\alpha | \alpha \text{ is a propositional formula}\} \rightarrow \{0, 1\}.$$

It can be calculated according to three rules:

- (i) $\Gamma(\neg \alpha) := 1$, iff $\Gamma(\alpha) = 0$
- (ii) $\Gamma(\alpha \vee \beta) := 1$, iff $\Gamma(\alpha) = 1$ or $\Gamma(\beta) = 1$
- (iii) $\Gamma(\alpha \wedge \beta) := 1$, iff $\Gamma(\alpha) = 1$ and $\Gamma(\beta) = 1$

5. A propositional formula α is *satisfiable* if and only if there exists a truth assignment Γ , so that $\Gamma(\alpha) = 1$.

Definition 2. A *model* m of a CNF formula C is a satisfying truth assignment of C . The set of all models of C are denoted by $\text{models}(C)$. We denote that m assigns 1 (0) to variable x by $m(x) = 1$ ($m(x) = 0$). If $m(x) = 1$ implies $m^*(x) = 1$ for two models m and m^* , we say that $m \leq m^*$. If neither $m \leq m^*$ nor $m \geq m^*$ is true, the two models are *incomparable*. We call a model *maximal* (*minimal*) if there is no model m^* such that $m < m^*$ ($m > m^*$). We denote the set of all maximal (minimal) models of C by $\text{maximal}(C)$ ($\text{minimal}(C)$).

Problem 1 (SAT). Given a CNF (3-CNF) formula C , the *SAT* (*3-SAT*) problem is to decide if C is satisfiable and, if so, to return a possible model.

In the setting of SAT problems we can also answer the question whether, given a partial set of activations, there exists a solution for the entire formula S , by fixing some logical variables in S to the prescribed values and solving the SAT problem for the remaining formula S' . We are thus prepared to introduce the signaling network satisfiability problem (IFFSAT) as:

Problem 2 (IFFSAT). Let

$$S = \left\{ S_i = \bigvee_{j \in L_i^A} A_j \leftrightarrow \bigvee_{j \in L_i^B} B_j \right\}$$

be a set of $s = |S|$ equivalence formulas over the literal set L , and $L_0, L_1 \subseteq L$ two sets of variables to be fixed. An instance of the *IFFSAT* problem is of the form

$$\bigwedge_{i=1}^s S_i \wedge \bigwedge_{x \in L_0} (\neg x) \wedge \bigwedge_{x \in L_1} x. \quad (\text{IFFSAT})$$

Much research has been done to find effective solution algorithms for subclasses of SAT (Truemper, 2004). There is, however, no algorithm that can efficiently (Garey and Johnson, 1979) check satisfiability for arbitrary propositional formulas, as we have to consider for this application:

Lemma 1. *The satisfiability problem for problems of the form (IFFSAT) is equivalent to 3-SAT, hence NP-complete.*

Proof. We only need to show that 3-SAT instances can be written in IFFSAT form. Using \approx to designate logical equivalence this can be seen as follows:

$$\begin{aligned} & \bigwedge_{j \in I} x_1^j \vee x_2^j \vee x_3^j \\ & \approx \bigwedge_{j \in I} \left[(x_1^j \vee x_2^j \leftrightarrow u_1^j) \wedge (u_1^j \vee x_3^j) \right] \\ & \approx \bigwedge_{j \in I} (x_1^j \vee x_2^j \leftrightarrow u_1^j) \wedge \bigwedge_{j \in I} (u_1^j \vee x_3^j \leftrightarrow u_2^j) \wedge \bigwedge_{j \in I} u_2^j \end{aligned}$$

This is an instance of IFFSAT form in which at most $2|I|$ literals and $2|I|$ propositional formulas were added. \square

Figure 1: A small signaling network from Example 1. The dashed lines denote inhibition while the black node means a logic and.

As already known to Dantzig (Dantzig, 1963), SAT problems can be formulated as integer programs, i.e. feasibility or optimization problems over linear systems of inequalities, where the solutions are required to be integral. For an overview of this field see (Bertsimas and Weismantel, 2005). For the IFFSAT problem the associated integer program (IP) is constructed by introducing $|L|$ binary variables x_l and their complements \bar{x}_l , and translating each IFF formula into the system

$$\begin{aligned}
 \sum_{j \in L_i^A} x_{A_j} - x_{B_k} &\geq 0 && \text{for all } S_i \in S, k \in L_i^B \\
 -x_{A_j} + \sum_{k \in L_i^B} x_{B_k} &\geq 0 && \text{for all } S_i \in S, j \in L_i^A \\
 x_l + \bar{x}_l &= 1 && l \in L \\
 x_p = 1, x_q &= 0 && p \in L_1, q \in L_0
 \end{aligned} \tag{1}$$

where we will assume that for non-negated literals $A \in L$ the variable x_A , and for negated literals $\neg A \in L$, \bar{x}_A has been used in the formulation of the inequalities.

Remark 1. The integer programming formulation (1) of (IFFSAT) has the form of a *generalized set cover problem*

$$Ax \geq 1 - n(A), \quad x \in \{0, 1\}, \tag{2}$$

where $n(A)$ is the number of negative entries in the corresponding row of A .

We illustrate the presented methods with the help of a small example.

Example 1. The inequality description to the network shown in Figure 1 reads

$$\begin{aligned}
 (1 - x_A) + (1 - x_B) &\geq (1 - x_D) && x_D + x_E &\geq x_F \\
 (1 - x_A) &\leq (1 - x_D) && x_D &\leq x_F \\
 (1 - x_B) &\leq (1 - x_D) && x_E &\leq x_F \\
 x_C &= x_E && (1 - x_G) &= x_D \\
 x_F &= x_G && x_G &= x_H \\
 x_l &\in \{0, 1\} \quad \forall l
 \end{aligned} \tag{3}$$

Several scenarios can be tested with these inequalities. First of all certain input and output patterns can be checked for validity. For this purpose fix x_A , x_B , x_C and x_H to the desired value and solve the IP with arbitrary objective value. If it is feasible, the input/output pattern is a valid assignment. If one is interested in the output of the network for a prescribed input pattern, one fixes the inputs to interesting values again and solves the IP with the objective to maximize x_H . The returned objective value is the value of H . In the example the input pattern $x_A = 0$, $x_B = 1$, $x_C = 0$ gives and output $x_H = 1$.

Another issue for modeling signaling networks is to check the completeness of the model. This can be done by checking whether the set described by the inequalities (3) contains feasible points. Our example is feasible, as the point $(x_A, x_B, x_C, x_D, x_E, x_F, x_G, x_H) = (1, 1, 0, 1, 0, 0, 0, 0)$ is valid.

Potential failure modes and corresponding suitable intervention strategies can be found by testing knock-in/knock-out scenarios and checking if this forces other variables to obtain a specific value. Knock-in/knock-out scenarios are done by fixing various variables to a desired value. To test whether other variables are thereby fixed, we solve different IPs. Two IPs are needed for checking if two variables have a certain value. In our example we set $x_E = 0$ and $x_H = 1$. To check whether e.g. x_D and x_A need to be fixed, we solve the IP with the objective function $x_D + x_A$. The solution is 1 and the variables are $x_D = 0$ and $x_A = 1$. Thus, we know that x_D must have the value 0. Another optimization problem with the objective to minimize x_A gives the solution 0, and thus x_A is not necessarily 1 but can have both values.

3 Some Complexity Results for IFFSAT

The IFFSAT problem becomes easier if certain structural properties are fulfilled, as has been shown in (Haus et al., 2007). From now on we will restrict the signaling networks to equivalence formulas with only one literal on the right-hand-side, i.e. $|L_i^B| = 1 \forall i$, unless it is explicitly stated differently.

Initially we have to transform IFFSAT to a special form that allows us to perform the subsequent analysis.

Definition 3 (cascade form). A signaling network (IFFSAT) is called *in cascade form* if for all clauses S_i it holds that $|L_i^A| \leq 2$ and $|L_i^B| = 1$.

Remark 2. Any signaling network can be transformed to cascade form by introducing additional literals and equivalence clauses. Indeed, this can be achieved by recursively applying the following replacement:

$$S_i = \left\{ \left(\bigvee_{j \in J_i} A_j \right) \leftrightarrow B \right\}$$

gets replaced by

$$S'_i = \{A_1 \vee A_2 \leftrightarrow C\}$$

and

$$S''_i = \left\{ \left(\bigvee_{j \in J_i \setminus \{1,2\}} A_j \right) \vee C \leftrightarrow B \right\}$$

where C is a new literal.

Secondly we will review some notation from logic.

Definition 4. Let S be a 3-CNF formula. The undirected *graph* $G(S)$ is defined by the variables of S as its nodes and for every 2-clause of S there is an edge between the corresponding nodes.

Definition 5 (cutnode, cutnode condition).

1. Let a, b and c be nodes of a graph. We call c an *a/b cutnode* if removing c from the graph disconnects the nodes a and b .
2. An IFFSAT instance S in cascade form fulfills the *cutnode condition* if for every equivalence formula S_i, B_i is an A_{1i}/A_{2i} cutnode in $G(S)$.

After IFFSAT is transformed to cascade form, the cutnode condition can easily be checked by computing the connected components of $G(S)$. In (Haus et al., 2007) it is proved that

Theorem 2. *If an instance of IFFSAT in cascade form satisfies the cutnode condition, it can be solved in linear time.*

The cutnode condition is a restriction to realistic networks but the following example shows that, e.g., feedback loops do not in general contradict the condition.

Example 2. The network defined by

formula	2-clause(s)
$A \vee B \leftrightarrow C$	$\neg A \vee C, \neg B \vee C$
$A \rightarrow D$	$\neg A \vee D$
$D \rightarrow E$	$\neg D \vee E$
$\neg E \rightarrow A$	$E \vee A$

Figure 2: Graph of the network from Example 2.

shown in Figure 2 has a cycle with an odd number of negations, but satisfies the cutnode condition (there is one equivalence formula, and its output C is a cutnode).

For the inequality description (1) some nice polyhedral properties can be obtained. One of them is *unimodularity* (Bertsimas and Weismantel, 2005), which leads to integral relaxations of the polyhedron, for the smallest nonempty IFFSAT problems.

Definition 6 (unimodularity). A matrix $\mathbf{A} \in \mathbf{Z}^{m \times n}$ of full row rank is *unimodular* if the determinant of each basis of \mathbf{A} is ± 1 .

Lemma 3. *The submatrix of a single equivalence clause S_i in the IP model (1) is unimodular if the set L_i^A has cardinality 2 and L_i^B has cardinality 1.*

Proof. Consider the case where the formula considered is exactly $A \vee B \leftrightarrow C$ with non-negated atoms A, B, C . The matrix $U = \begin{pmatrix} 1 & 1 & -1 \\ -1 & 0 & 1 \\ 0 & -1 & -1 \end{pmatrix}$ is clearly unimodular. Hence, $M = \begin{pmatrix} U & 0 \\ 1 & 1 \end{pmatrix}$, where 1 denotes a 3×3 unit matrix, is unimodular.

All other cases arise from M by unimodular row operations, i.e. subtracting the complementarity constraint in the top 3 rows. \square

Even for the simple formulas $(A \vee B) \leftrightarrow (C \vee D)$ as well as $(A \vee B \vee C) \leftrightarrow D$, the inequality description (1) is non-unimodular. However, the linear relaxation of (1) for one equivalence formula with arbitrary large L_i^A and L_i^B is still integral:

Lemma 4. *The inequality description of a single equivalence clause S_i in the IP model (1) is integral.*

Proof. See (Hooker, 2007, p. 338). \square

These integrality results cannot be generalized to IFFSAT problems with an arbitrary number of equivalence formulas, as the next example shows.

Example 3. We consider a set of two equivalences that model a small negative feedback cycle, i.e.

$$S = \{(x_1 \vee \bar{x}_3 \leftrightarrow x_4) \wedge (x_2 \vee x_4 \leftrightarrow x_3)\}.$$

The integer programming formulation from (1) has the following LP relaxation:

$$\begin{array}{rcl}
x_1 + \bar{x}_3 - x_4 \geq 0 & & x_2 - x_3 + x_4 \geq 0 \\
-x_1 + x_4 \geq 0 & & -x_2 + x_3 \geq 0 \\
-\bar{x}_3 + x_4 \geq 0 & & +x_3 - x_4 \geq 0 \\
x_i + \bar{x}_i = 1, & & 0 \leq x_i \leq 1.
\end{array}$$

Computing the vertices we find both integral and fractional points:

x_1	x_2	x_3	\bar{x}_3	x_4
0	0	1/2	1/2	1/2
0	1/2	1/2	1/2	1/2
1/2	0	1/2	1/2	1/2
1/2	1/2	1/2	1/2	1/2
0	1	1	0	0
1	0	1	0	1
1	1	1	0	1

It should be noted that not all vertices are fractional, which means that this SAT instance is not infeasible.

4 Dynamics of Signaling Networks

In practical applications signaling networks often turn out to be infeasible. This is not reasonable in a biological sense, but it can occur due to delayed reactions modeled as instantaneous, or due to modeling errors. Especially (negative) feedback loops with time delays make the static models infeasible, but at the same time have a huge impact on the functionality of a signaling network since certain activation cascades can be enabled initially and switched off at a later time point to avoid overreaction. In order to model the dynamics of a signaling network we introduce an extension of IFFSAT, the *requirement IFFSAT problem*.

Problem 3 (RIFFSAT). Let a set R of $r = |R|$ equivalence formulas of the form

$$R = \left\{ R_i = \bigvee_{j \in L_i^A} (A_j \wedge y_j) \leftrightarrow (B_i \wedge \bigvee_{j \in L_i^A} y_j) \right\} \quad (4)$$

over the literal set $L \cup Y$ be given, where Y is the set of requirement variables. Let $L_0, L_1 \subseteq L \cup Y$, sets of fixings, be given, then the *RIFFSAT* problem is to find a satisfying solution of

$$\bigwedge_{i=1}^r R_i \wedge \bigwedge_{x \in L_0} (\neg x) \wedge \bigwedge_{x \in L_1} x. \quad (\text{RIFFSAT})$$

In the signaling network context $y_j = 1$ denotes influence of the corresponding component A_j on the right hand side while $y_j = 0$ denotes no effect. In case $y_j = 0$ for all $j \in L_i^A$, we request B_i to be free.

Remark 3. We ask the requirement variable y_j of A_j to be the different for every IFF formula in which A_j occurs on the left hand side, and to be equal to $\bigvee_{k \in L_i^A} y_k$ if A_j is the right hand side of clause R_i .

We denote by \mathcal{F} the set of all 0/1-points for which (RIFFSAT) is TRUE, i.e.

$$\mathcal{F} = \left\{ x \in \{0, 1\}^{2|L|} \mid \Gamma(\bigwedge_{i=1}^r R_i \wedge \bigwedge_{x \in L_0} (\neg x) \wedge \bigwedge_{x \in L_1} x) = 1 \right\}.$$

Usually one is interested in solving (RIFFSAT) with special properties on the set of requirement variables y_j^i , like a maximal or minimal models over y . Such a problem can be solved by a variation of SAT, namely MAXVAR SAT (see (Truemper, 2004)). Here a satisfiable CNF system C and a set T with TRUE/FALSE fixings of a variable subset is given, such that C is not satisfiable if all variables are fixed according to T . The task is to determine a maximal subset T^* of T so that C is satisfiable. In our setting T can be $\{y_1 = \dots = y_{|L|} = \text{TRUE}\}$. MAXCLS SAT is also a related problem. We remark that both problems are special cases of MAXSAT, which can not be approximated polynomially better than $8/7$ (Håstad, 2001) and hence it is *NP-complete*.

Besides the presented method from logic one can also find a maximal solution with the help of integer programming techniques.

Lemma 5 (inequality description for RIFFSAT). *Given one equivalence formula $R_i \in R$ as in (4), introduce $n_i = |L_i^A|$ additional binary variables $Y_i = \{x_{y_1}, \dots, x_{y_{n_i}}\}$. Then the corresponding set of feasible points \mathcal{F}_{R_i} can be described by $n_i + n_i \cdot 2^{n_i-1}$ inequalities plus binary constraints of the form:*

$$\begin{aligned} x_{B_i} &\geq x_{A_j} - (1 - x_{y_j}) & j \in L_i^A \\ x_{B_i} &\leq \sum_{k \in S} x_{A_k} + (1 - x_{y_j}) + \sum_{k \notin S} x_{y_k} & j \in S, \emptyset \neq S \subseteq L_i^A \\ x_l &\in \{0, 1\} & l \in L_i^A \cup \{B_i\} \cup Y_i \\ 1 &= x_l + \bar{x}_l \end{aligned} \quad (5)$$

x_{A_1}	x_{A_2}	x_{A_3}	\cdots	x_{A_n}	x_{B_i}	y_1	y_2	y_3	\cdots	y_n
<i>n</i> points exploiting all free y_j :										
1	0	0	\cdots	0	1	1	1	1	\cdots	1
1	0	0	\cdots	0	1	1	0	1	\cdots	1
\vdots	\vdots	\vdots	\ddots	\vdots	\vdots	\vdots	\vdots	\vdots	\ddots	\vdots
1	0	0	\cdots	0	1	1	1	1	\cdots	0
<i>n</i> - 1 points exploiting all free x_{A_j} :										
1	1	0	\cdots	0	1	1	1	1	\cdots	1
1	0	1	\cdots	0	1	1	1	1	\cdots	1
\vdots	\vdots	\vdots	\ddots	\vdots	\vdots	\vdots	\vdots	\vdots	\ddots	\vdots
1	0	0	\cdots	1	1	1	1	1	\cdots	1
two possible points with $x_{B_i} = 0$:										
1	0	0	\cdots	0	0	0	1	1	\cdots	1
1	1	0	\cdots	0	0	0	1	1	\cdots	1

Table 1: $2n + 1$ linearly independent points for $x_{B_i} \geq x_{A_1} - y_1$.

We will assume that \bar{x}_i is used in the inequality description if the corresponding atom is negated. To derive the inequality description for (RIFFSAT), introduce such inequalities for all R_i , $i = 1, \dots, r$, and fix the variables according to L_0 and L_1 .

Remark 4. Note that this formulation still preserves the form of a generalized set covering problem. In addition, for each fixed x_y the formulation reduces to an instance of (1).

Maximizing the sum over all requirement variables x_{y_j} yields one maximal feasible solution. However, there are many inequalities needed to describe the feasible points. It turns out that all of them are needed:

Lemma 6. *The inequalities for a single relaxed equivalence clause (5) are facets for the convex hull of their integral points \mathcal{F} .*

Proof. We will show that for every inequality there exist $\dim(\text{conv}(\mathcal{F})) = 2n+1$ affine independent, integral points fulfilling the corresponding inequality with equality, where $n = |L_i^A|$.

$x_{B_i} \geq x_{A_j} - (1 - y_j)$: For reasons of symmetry we restrict the analysis to $j = 1$. The $2n + 1$ linearly independent points are displayed in Table 1.

$$x_{B_i} \leq \sum_{j \in S} x_{A_j} + (1 - y_i) + \sum_{j \notin S} y_j;$$

For an easier notation, let us assume that the first k indices belong to the selected set S and $l = 1$. In Table 2 the linearly independent points are presented.

This concludes the proof. \square

Lemma 6 thus implies that the inequalities that are needed to describe $\text{conv}(\mathcal{F})$ definitely include all constraints in (5). Hence, the number of inequalities is exponential in the number of inputs of the clause. This motivates to explore alternative, extended formulations for modeling \mathcal{F} based on a cascade representation of their underlying IFFSAT instance.

Lemma 7. *Each RIFFSAT instance can be transformed to cascade form.*

Table 2: $2n+1$ linearly independent points for $x_{B_i} \leq \sum_{j \in S} x_{A_j} + (1-y_1) + \sum_{j \notin S} y_j$, with $S = \{1, \dots, k\}$.

The recursive construction is analogous to the IFFSAT case, handling each conjunction as one literal and introducing variables of y -type for the artificial variables.

Although transforming the RIFFSAT instance to this specific form leads to more variables and equivalence formulas, the growth of the instance is only quadratic. Recall that $r = |R|$ and let n be the largest number of inputs of all clauses. Then, due to the transformation, the number of literals and clauses in the RIFFSAT instance increases by at most $2r(n - 2)$ and $r(n - 2)$, respectively. In contrast to that there are $6(r + r(n - 2))$ inequalities needed to encode the signaling network in cascade form compared to $(n + n \cdot 2^{n-1})r$ inequalities in the IP representation of Lemma 6. Both counts leave out binary constraints and fixings. Hence, it is a reasonable tool to reduce the complexity of the inequality description.

So far both approaches, MAXVAR SAT as well as IP, provide one maximal feasible solution. But one is interested in all maximal solutions with respect to the requirement variables to find suitable intervention strategies or to plan specific experiments verifying an actual network structure. In order to find the set of all maximal models (see Definition 2) or all maximal feasible solutions with respect to the y -variables it is necessary to use a ‘clever enumeration method’. For this purpose we want to make use of the joint generation algorithm (Fredman and Khachiyan, 1996). This method checks whether a pair of monotone boolean functions are dual. The problem is equivalent to finding all maximal models of a monotone CNF formula.

Definition 7 (monotone CNF). Let C be a CNF expression and let Z be a subset of the literals L . Then C is called *down-monotone* (*up-monotone*) in Z if from $m^*(Z, L \setminus Z)$ satisfying C it follows that $m(Z, L \setminus Z)$ satisfies C for all $m(Z) \leq m^*(Z)$ ($m(Z) \geq m^*(Z)$) and $m(L \setminus Z) = m^*(L \setminus Z)$.

An integral set is down-monotone in the vector z if $(x, z^*) \in P$ leads to $(x, z) \in P$ for all $z \leq z^*$.

Remark 5. A CNF formula is down-monotone in x if all literals of x have only negative occurrence.

Note that RIFFSAT is not necessarily down-monotone in y as the next example shows:

Example 4. We consider the easy RIFFSAT instance

$$Z = (A \wedge y_A) \vee (B \wedge y_B) \leftrightarrow C \wedge (y_A \vee y_B).$$

It is not down-monotone in $Y = \{y_A, y_B\}$ since the truth assignment

$$A = 1 \quad B = 0 \quad y_A = 1 \quad y_B = 1 \quad C = 1$$

satisfies Z , while

$$A = 1 \quad B = 0 \quad y_A = 0 \quad y_B = 1 \quad C = 1$$

does not.

As RIFFSAT instances are non-monotone in general, we apply a transformation proposed by (Kavvadias et al., 2000) to monotonize the requirement variables of non-monotone CNF terms. The method preserves the set of maximal models while the general models can differ. Therefore the positive y -variables are eliminated according to a recursive resolution procedure:

1. Expand the RIFFSAT instance K to CNF form.
2. Choose a variable y_k that occurs as positive and negative literal in K .

3. Divide the clauses into three parts $S_{y_k} \cup S_{\bar{y}_k} \cup A_{y_k}$, the set of clauses with occurrence of y_k , of \bar{y}_k , and no occurrence at all. In this context ‘ \cup ’ denotes a conjunction. We write $K_i = (C_i \vee y_k)$ for $K_i \in S_{y_k}$, $i = 1, \dots, |S_{y_k}|$, and $K_j = (D_j \vee \bar{y}_k)$ for $K_j \in S_{\bar{y}_k}$, $j = 1, \dots, |S_{\bar{y}_k}|$. Thus, C_i and D_j are disjunctions of all other variables apart from y_k .
4. Compute all *resolvents* R_{y_k} of each pair of clauses in S_{y_k} and $S_{\bar{y}_k}$ with respect to y_k , i.e. $R_{y_k} = \{(C_i \vee D_j) \mid K_i \in S_{y_k}, K_j \in S_{\bar{y}_k}\}$.
5. The expression $K_{y_k} = R_{y_k} \cup S_{\bar{y}_k} \cup A_{y_k}$ is monotone in y_k , since y_k has only negative occurrences.

Theorem 8 (Kavvadias et al. 2000). *With the above transformation it holds that $\text{models}(K) \subseteq \text{models}(K_{y_k})$ and $\text{maximal}(K) = \text{maximal}(K_{y_k})$.*

Thus, we can apply this concept recursively and obtain a CNF expression which is monotone in the y -variables and hence, we can utilize the joint generation algorithm (Fredman and Khachiyan, 1996) to compute the invariant maximal models.

However, it is easy to see that the transformation can lead to an exponentially larger expression. But in the case of RIFFSAT instances the number of clauses even decreases.

Monotonizing the requirement variables in one $R_i \in R$, formula (4) reduces the clauses to

$$\begin{aligned} & \bigwedge_{j \in L_i^A} \left((\neg A_j \vee \neg y_j \vee B_i) \wedge \bigvee_{k \in L_i^A} A_k \vee (\neg y_j \vee \neg B_i) \right) \\ & \approx \left(\bigvee_{j \in L_i^A} (A_j \wedge y_j) \rightarrow B_i \right) \wedge \left(\bigvee_{j \in L_i^A} (C \wedge y_j) \rightarrow \bigvee_{k \in L_i^A} A_k \right). \end{aligned} \quad (6)$$

In terms of inequalities this is modeled by

$$\begin{aligned} x_{B_i} & \geq x_{A_j} - (1 - x_{y_j}) \\ x_{B_i} & \leq \sum_{k \in L_i^A} x_{A_k} + (1 - x_{y_j}) \quad j \in L_i^A \\ x_l & \in \{0, 1\} \\ 1 & = x_l + \bar{x}_l \quad l \in L_i^A \cup \{B_i\} \cup Y_i. \end{aligned} \quad (7)$$

Introducing such constraints for every $R_i \in R$ gives the monotonized version of (RIFFSAT). We denote by \mathcal{F}_{mon} the set of integral points fulfilling (6) and thus also (7) for each $i = 1, \dots, r$.

Lemma 9. *The system (6), and thus (7), are monotone in y and have the same maximal y -solutions as (RIFFSAT) and (5).*

Proof. From the inequalities it is easy to see that it is down-monotone in y , since pushing one y component to 0, say $x_{y_j} = 0$, only relaxes both inequalities containing x_{y_j} . In particular, this means that the same A and B components are feasible for $x_{y_j} = 0$ as for $x_{y_j} = 1$. In the logic formula one can see the down-monotonicity in y by expanding the implications to CNF. All y -variables occur as negated atoms.

To prove the accordance of the maximal solutions we can focus on a single RIFFSAT formula $\bigvee_{i=1}^n (A_i \wedge y_i) \leftrightarrow B \wedge \bigvee_{i=1}^n y_i$, $I = \{1, \dots, n\}$, because the y variables are disjoint for every RIFFSAT formula and thus the monotonized version of RIFFSAT can be built by monotonizing each formula R_i .

We will show that the following two integer programs (V) and (W) have the same optimal solutions with respect to the y components.

$$\begin{aligned}
\max \quad & \sum_{i=1}^n x_{y_i} \\
\text{s.t.} \quad & x_B \geq x_{A_j} - (1 - x_{y_j}) & j \in I \\
& x_B \leq \sum_{k \in S} x_{A_k} + (1 - x_{y_j}) + \sum_{k \notin S} x_{y_k} & j \in S, \emptyset \neq S \subseteq I \\
& x_l \in \{0, 1\} & l \in \{A_l, y_l, B\} \\
& 1 = x_l + \bar{x}_l & l \in \{A_l, y_l, B\}
\end{aligned} \tag{V}$$

and

$$\begin{aligned}
\max \quad & \sum_{i=1}^n x_{y_i} \\
\text{s.t.} \quad & x_B \geq x_{A_j} - (1 - x_{y_j}) & j \in I \\
& x_B \leq \sum_{k=1}^n x_{A_k} + (1 - x_{y_j}) & j \in I \\
& x_l \in \{0, 1\} & l \in \{A_l, y_l, B\} \\
& 1 = x_l + \bar{x}_l & l \in \{A_l, y_l, B\}
\end{aligned} \tag{W}$$

For an ease of notation we will subsequently use the index l for the variable x_l . Let A_l and y_l denote (A_1, \dots, A_n) and (y_1, \dots, y_n) . Let \mathcal{F}_V and \mathcal{F}_W be the set of integral points of problem (V) and (W), respectively, and let x^{*L} indicate the optimal solution of problem (L), $L=V,W$. Then, y^{*L} denotes the corresponding y components. Note that $\mathcal{F}_V \subset \mathcal{F}_W$.

Case 1: If there are no A_l, B components fixed to a certain value, there exists an $x^{*L} \in \mathcal{F}_L$ with $y^{*L} = \mathbf{1}$. For example, the vector $(A_l, y_l, B) = (\mathbf{0}, \mathbf{1}, 0)$ is feasible for both IPs. Thus the optimal solutions are equal.

Case 2: If some A_l, B components are fixed to 0 or 1, there are two critical cases in which there exists no $x^L \in \mathcal{F}_L$ such that $y^L = \mathbf{1}$ for $L=V,W$.

The first one is $A_l = \mathbf{0}$ and $B = 1$. Here, $y^{*L} = \mathbf{0}$ is necessary for both L since the second type of inequalities of (W), which are also valid for (V), forces B immediately to 0 if one $y_j = 1$. Thus, the optimal values match.

The second critical configuration is that $A_i = 1$ for $i \in I_1 \subseteq I$ with $I_1 \neq \emptyset$ and $A_j = 0, j \notin I_1$, but $B = 0$. The optimal y solution is $y_i^{*L} = 0$ for $i \in I_1$ and $y_j^{*L} = 1, j \notin I_1, L=V,W$, by the first type of inequalities, which is valid for both programs. It forbids to lift another y_i^L to 1 as this switches B also to 1.

If x_{y_j} variables are fixed to 0 or 1, it influences both objective values equally. Thus, the objective value of the integer programs (V) and (W) coincide in every possible case which concludes the proof. \square

Lemma 10. *The inequality system (7) describes $\text{conv}(\mathcal{F}_{mon})$ when substituting $\{0, 1\}$ by $[0, 1]$.*

A proof for the Lemma can be found in the Appendix. Note that the system (7) are even a facet description for $\text{conv}(\mathcal{F}_{mon})$ as the inequalities (5) are facets for $\text{conv}(\mathcal{F})$ and all feasible points are preserved.

The LP relaxation of a monotonized dynamic IP (7) containing more than one formula, i.e. $r \geq 2$, is not integral in general as the following example shows.

Example 5. Consider the monotonized version of the dynamic IP (7) of the signaling network from

Figure 3: A signaling network with two negative feedback loops from Example 6. The dashed line denotes inhibition.

Example 3. Its linear relaxation is the following polyhedron

$$\begin{aligned}
 x_1 - (1 - y_1) &\leq x_4 & x_2 - (1 - y_2) &\leq x_3 \\
 (1 - x_3) - (1 - y_3) &\leq x_4 & x_4 - (1 - y_4) &\leq x_3 \\
 x_1 + (1 - x_3) + (1 - y_1) &\geq x_4 & x_2 + x_4 + (1 - y_2) &\geq x_3 \\
 x_1 + (1 - x_3) + (1 - y_3) &\geq x_4 & x_2 + x_4 + (1 - y_4) &\geq x_3 \\
 0 \leq x_i, y_i &\leq 1 \text{ for } i = 1, \dots, 4
 \end{aligned}$$

This polyhedron is not integral, since e.g. $(\mathbf{x}, \mathbf{y}) = (1/2, 1, 1/2, 1/2, 1, 1/2, 1, 1)$ is a vertex. But it also has integral vertices like $(0, 0, 1, 0, 1, 0, 1, 0)$ so that it is not infeasible.

To illustrate the use of the dynamic model we give a small example of a signaling network.

Example 6. Consider the network defined by

$$\begin{aligned}
 x_C &\geq x_A - (1 - y_A) & x_A &\geq x_E - (1 - y_E) \\
 x_C &\leq x_A + (1 - y_A) & x_A &\leq x_E + (1 - y_E) \\
 x_C &\geq x_B - (1 - y_B) & x_F &\geq x_D - (1 - y_D) \\
 x_C &\leq x_B + (1 - y_B) & x_F &\leq x_D + (1 - y_D) \\
 x_D &\geq x_C - (1 - y_C) & x_G &\geq (1 - x_F) - (1 - y_F) \\
 x_D &\leq x_C + (1 - y_C) & x_G &\leq (1 - x_F) + (1 - y_F) \\
 x_E &\geq (1 - x_D) - (1 - y_D) & x_B &\geq x_G - (1 - y_G) \\
 x_E &\leq (1 - x_D) + (1 - y_D) & x_B &\leq x_G + (1 - y_G) \\
 x_l, y_l &\in \{0, 1\} \quad \forall l
 \end{aligned}$$

which is illustrated in Figure 3. As there are two negative feedbacks involved, using the static approach leads to infeasibility. Thus, we are interested in the dynamics like possibly late reactions, i.e. in maximal feasible subnetworks. In this case there are different possibilities to disturb the cycles. One can either set $y_C = 0$ and the rest to 1 or cut two disjoint arcs each in one cycle, e.g. $y_E = 0$ and $y_G = 0$. The remaining variables can then be 1. With this guideline and precise experiments the practitioner can then identify how the network structure actually looks like. Of course, the obtained y values also give hints at suitable intervention strategies.

Remark 6. Note that one can also model timing information using the RIFFSAT formulation: Let $T \in \mathbb{Z}_+$, a time horizon, be given. Then, for every $t \in \{1, \dots, T\}$ we have different signaling networks, because of distinct reaction times. Due to these delays it is possible for a molecule to be absent at one point t_1 , but to be present at t_2 . This can be modeled by T copies of the same networks but each with a different y^t vectors $t = 1, \dots, T$, which imply absence or presence of each interdependence in the biological unit at time point t . Each y^t vector is according to Equation (5). In this setting the changes of the signaling network over time is encoded by the difference of two consecutive y^t vectors, $y^t - y^{t-1}$, $t \geq 2$.

Our proposed approach is also able to handle extra information about the structure of the network over time. Such information can be statements like if an interactions is present at time point t^* , it is present for all $t \geq t^*$, or an interaction is only valid for exactly one $t \in \{1, \dots, T\}$. It can be expressed in terms of logical formulas/inequalities over the y^t .

Table 3: In/Out fixing of TCR from (Saez-Rodriguez et al., 2007).

5 Computations

We have tested the ideas presented in this paper on the TCR-signaling network from (Saez-Rodriguez et al., 2007), as well as several randomly generated signaling networks. To demonstrate that the integer programming formulation is in fact useful to test feasibility of scenarios (on the full model or in knock-in/knock-out tests), we performed several tests: Table 3 shows feasibility tests for all possible combinations of input/output values in the TCR model. Computations were performed using CPLEX 9.1 and Allegro Common Lisp 8.1 on a SUN-Fire-V890 with 1.2 GHz. Even though the IPs do not generally reduce to an LP description, the whole instances could be solved within two minutes.

Due to the lack of real instances we generated three types of random signaling networks which are built with different probability distributions so that each has a distinct structure. For technical reasons we deviate slightly from the standard form of a signaling network: we construct IFFformulas of the form $\bigvee_{j \in J} A_j \rightarrow B$ (OR-clauses) and $\bigwedge_{j \in J} A_j \rightarrow B$ (AND-clauses). All types are constructed according to the following procedure:

1. Set the number of components n and operation nodes m and fix the proportion of AND- and OR-nodes A/O . In our random types A/O will always be equal to 0.5.
2. Determine, with respect to A/O , which operation nodes are AND- and which are OR-nodes. Therefore the realization of a random variable X which probability distribution reflects the ratio A/O is generated. Clearly this means, $P(X = AND) = A/O = 1 - P(X = OR)$.
3. List all components from 1 to n .
4. Let a_i be the number of inputs of operation node $i = 1, \dots, m$. Determine a_i as a realization of A_i with $A_i \sim R$ with some probability distribution R . Note that R changes for the different generated types.
5. Choose the input and output components for each operation node separately by generating the realization k of a random variable K , which is uniformly distributed on the set $\{1, \dots, n\}$. The resulting number k refers to the index of the components. If a component is selected more than once, the duplicates are deleted leading to a smaller input degree. Note that for the selection of the output component of operation node i , the input components of i must not be taken into account.
6. Decide if S_k or \bar{S}_k is assigned as an input, with a random number taking two equally probable values.

For the first type of random networks, we generate the number of inputs according to a χ_f^2 -distribution. The parameter of this distribution f , the degrees of freedom, equals the mean of

Table 4: Overview of the properties of type I networks, which are specified by number of components – number of operations. We always generated two networks, a and b, of the same size.

A_i . Hence, we set A_i to be χ_3^2 -distributed with three degrees of freedom in order to derive a ‘lean’ signaling network similar to the TCR network with three inputs per operation node on average. Results are displayed in Table 4. The number of molecules is denoted by ‘# subs’, ‘# ops’ denotes the number of AND/OR operations used and ‘min/max/avg in’ means the minimal/maximal/average number of elements on the left hand side of all IFFSAT formulas S_i . The number of inputs and outputs to the network are stated as ‘sources’ and ‘sinks’. The size of the IP is depicted in the following two rows. The IPs could be solved very fast even in large cases and without any branch and bound nodes used. The number of paths between sources and sinks is relatively large, there are, e.g., 14, 15, 33 and 21424 paths.

Additionally the shortest path between sinks and sources has length 2, even in the large networks. This is not a realistic network structure. To avoid this feature we force the network to hold more layers. This is done by generating several type I networks, such that the sinks of the previous network are the sources of the next one. Type II networks contain three Type I networks glued together, which is reasonable as the shortest path in the TCR model is 5. Type II networks are similar to the real model with respect to input degree number of paths and path length. Computations are listed in Table 5 and are as fast as in the Type I case. The number of paths from input to output layer decreases to 2, 1, 11, 422 and 9243, while its average length increases. Note that the number of components and operations characterizing the different networks differ from the entries in the table since they specify the amount of components and operations in each Type I network.

After the first two types were constructed similarly, the third type is generated distinctly. We set $R := U[1, 15]$, i.e. A_i is uniformly distributed on the interval $[1, 15]$. To obtain integral input degrees, the generated random number is rounded up to the next integer. This results in an average input number of eight. Hence, the networks have comparably many arcs and are more or less ‘thick’. The number of paths between sink and source are like in Type I networks quite high, e.g. 24, 51, 26 494. In Table 6 the computational results are displayed.

Next, we employed the joint-generation method (Fredman and Khachiyan, 1996) as implemented in (Haus, 2008) to compute all minimal infeasible and maximal feasible vectors y . The

A Appendix

Proof of Lemma 10. Without loss of generality let $I = \{1, \dots, n\}$ implying the RIFFSAT formula $\bigvee_{i=1}^n (A_i \wedge y_i) \leftrightarrow B \wedge \bigvee_{i=1}^n y_i$, $I = \{1, \dots, n\}$. Thus, let

$$\mathcal{F}_{mon} = \left\{ \left(\begin{array}{c} \mathbf{A} \\ \mathbf{y} \\ B \end{array} \right) \in \{0, 1\}^{2n+1} : B \geq A_i - (1 - y_i) \quad \forall i = 1, \dots, n \right. \\ \left. B \leq \sum_{j=1}^n A_j + (1 - y_i) \quad \forall i = 1, \dots, n \right\}$$

and

$$P = \left\{ \left(\begin{array}{c} \mathbf{A} \\ \mathbf{y} \\ B \end{array} \right) \in [0, 1]^{2n+1} : B \geq A_i - (1 - y_i) \quad \forall i = 1, \dots, n \right. \\ \left. B \leq \sum_{j=1}^n A_j + (1 - y_i) \quad \forall i = 1, \dots, n \right\}.$$

We need to show that $P = \text{conv}(\mathcal{F}_{mon})$. It is clear that $\text{conv}(\mathcal{F}_{mon}) \subseteq P$. For the converse, assume that P has a fractional vertex $\mathbf{f} = (\mathbf{A}, \mathbf{y}, B)$. Since for a vertex $2n + 1$ inequalities have to be tight, \mathbf{f} has at least one integral component (there are only $2n$ inequalities without box conditions). Let n_f be the number of fractional components of \mathbf{f} ; $0 \leq n_f \leq 2n$. It is to show that $n_f > 0$ gives a contradiction.

Let k_1 be the number of tight inequalities of the first type and k_2 the one of type two inequalities, $k_1 + k_2 = n_f$. I_j denotes the corresponding equality index set of type $j = 1, 2$. To show the Lemma we will distinguish between three cases:

- (i) $k_1 > 0 \wedge k_2 > 0$,
- (ii) $k_1 = n_f > 0 \wedge k_2 = 0$,
- (iii) $k_1 = 0 \wedge k_2 = n_f > 0$.

Case (i): Let $I_1, I_2 \neq \emptyset$.

Since $B = \sum_{j=1}^n A_j + (1 - y_l)$ for all $l \in I_2$, y_l must have the same value for all $l \in I_2$. Additionally, for $i \in I_1$ and $l \in I_2$ it holds that

$$A_i - (1 - y_i) = \sum_{j=1}^n A_j + (1 - y_l) \quad \Leftrightarrow \quad 0 = \sum_{j \neq i} A_j + (1 - y_i) + (1 - y_l).$$

Since all variables are non-negative, we find that $A_j = 0 \quad \forall j \neq i$, $y_i = y_l = 1 \quad \forall l \in I_2$ and $A_i = B$. Thus, $A_{I \setminus \{i\}} = \mathbf{0}$, $y_{I_1 \cup I_2} = \mathbf{1}$ and the only possible fractional components of \mathbf{f} are y_j for $j \in I \setminus (I_1 \cup I_2) = \{l_1, \dots, l_k\}$ and $B = A_i$. But if they are fractional, we can construct a convex combination of integral points in \mathcal{F}_{mon} , because the variables are all strictly between 0 and 1 and

all possible 0/1 combinations of the fractional variables are feasible points. For this purpose let w.l.o.g. the fractional $y_{I \setminus (I_1 \cup I_2)}$ be ordered so that $y_{l_1} \leq \dots \leq y_{l_m} \leq B \leq y_{l_{m+1}} \leq \dots \leq y_{l_k}$, and let $\mathbf{v}_S^A = \sum_{i \in S} \mathbf{e}_i^A$, $S \subseteq I$, where \mathbf{e}_i^A is the i -th unity vector on the A -variables and the remaining $n+1$ components are 0. \mathbf{v}_S^y is analogously defined; $\mathbf{e}_B \in \{0, 1\}^{2^{n+1}}$ is the unity vector of B . Then the convex combination for \mathbf{f} is

$$\begin{aligned} \mathbf{f} = & y_{l_1}(\mathbf{e}_i^A + \mathbf{v}_I^y + \mathbf{e}_B) + (y_{l_2} - y_{l_1})(\mathbf{e}_i^A + \mathbf{v}_{I \setminus \{l_1\}}^y + \mathbf{e}_B) + \dots + (B - y_{l_m}) \\ & (\mathbf{e}_i^A + \mathbf{v}_{I \setminus \{l_1, \dots, l_m\}}^y + \mathbf{e}_B) + (y_{l_{m+1}} - B) \mathbf{v}_{I \setminus \{l_1, \dots, l_m\}}^y + \dots + (1 - y_{l_k}) \mathbf{v}_{I_1 \cup I_2}^y. \end{aligned}$$

If several components have the same value, this construction reduces them to one convex multiplier, i.e. in the next vector they will all occur as 0. Thus, \mathbf{f} is no vertex of P . ζ

Case (ii): Let $I_1 = \{1, \dots, k_1\}$ and $I_2 = \emptyset$.

The number of integral components of \mathbf{f} must be greater or equal to $n + 1$, because $n_f = k_1 \leq n$. Thus, there exists an index $j \in I_1$ such that the equality $B = A_j - (1 - y_j)$ contains at least two integral variables. Thus, all contained variables are integral and in particular B is integral. In the equalities where only B is known to be integral, say $B = A_k - (1 - y_k)$, $k \in I_1$, A_k and y_k can be fractional. There are two cases to be considered: $B = 1$ and $B = 0$.

B=1: $:A_i = 1 - (1 - y_i) \forall i \in I_1 \Leftrightarrow 2 = A_i + y_i :A_i = y_i = 1$. Thus, the only fractional components of \mathbf{f} can be $A_{I \setminus I_1}$ and $y_{I \setminus I_1}$. As $B = 1$ and $A_i = y_i = 1$ for all $i \in I_1$, there is a ‘reason’ for B being 1. Therefore the fractional components can be convexly combined as in case (i) since $A_{I \setminus I_1}$ and $y_{I \setminus I_1}$ can be any 0/1 combination to complete a feasible point for P . Hence, \mathbf{f} is no vertex. ζ .

B=0: $:A_i = 1 - y_i \forall i \in I_1$. Let $\{p_1, \dots, p_m\} = I_1^f \subseteq I_1$ denote the index set of the fractional A -variables in I_1 and thus their corresponding y -variables, which also have to be fractional according to the equality. For $j \in I \setminus I_1$ the inequalities imply that $A_j + y_j < 1$. We proceed similar to the previous case. W.l.o.g. assume that $A_i \leq y_i \forall i \in I_1^f$ and that $A_{p_1} \leq y_{p_1} \leq A_{p_2} \leq \dots \leq A_{p_l} \leq y_{p_l} \leq A_{p_m}$, with $j_i \in I \setminus I_1, i = 1, \dots, l$, are the ordered fractional components. For ease of notation we will leave out the integral A_i and $y_i, i \in I_1 \setminus I_1^f$ and consider only the remaining components \mathbf{f}^* . Accordingly, $\mathbf{v}_S^A, \mathbf{v}_S^y$ and \mathbf{e}_B are adjusted to the new dimension. Then,

$$\begin{aligned} \mathbf{f}^* = & A_{p_1}(\mathbf{v}_{I_1^f \cup I \setminus I_1}^A + \mathbf{v}_{I \setminus I_1}^y) + (y_{j_1} - A_{p_1})(\mathbf{v}_{(I_1^f \cup I \setminus I_1) \setminus \{p_1\}}^A + \mathbf{v}_{I \setminus I_1 \cup \{p_1\}}^y) + (A_{p_2} - y_{p_1})(\mathbf{v}_{(I_1^f \cup I \setminus I_1) \setminus \{p_1\}}^A + \\ & \mathbf{v}_{I \setminus I_1 \cup \{p_1\} \setminus \{j_1\}}^y) + \dots + (A_{p_l} - A_{p_{m-1}})(\mathbf{e}_{j_l}^A + \mathbf{v}_{I_1^f \cup \{j_l\}}^y) + (y_{j_l} - A_{p_l})\mathbf{v}_{I_1^f \cup \{j_l\}}^y + (y_{p_1} - y_{p_2})\mathbf{v}_{I_1^f}^y. \end{aligned}$$

The vectors used in this representation are all elements of P . Furthermore the convex multiplier sum up to 1, as $A_i + y_i = 1$ for $i \in I_1^f$. Thus, \mathbf{f} is not a vertex. ζ

Case (iii): Let $I_2 = \{1, \dots, k_2\}$ and $I_1 = \emptyset$.

Analogous to case (i), it follows that $y_1 = \dots = y_{k_2}$. We also know that there are $n_f = k_2$ fractional components of \mathbf{f} .

If these fractional components are $y_i, i \in I_2$, the other variables are all integral. But the equality $B = \sum_{j=1}^n A_j + (1 - y_i)$ for all $i \in I_2$ and the integrality of all involved variables but y_i yield that $y_i \in \{0, 1\} \forall i \in I_2$ and therefore \mathbf{f} is integral.

Thus, y_i must be integral for all $i \in I_2$. We need to distinguish between 6 cases:

- a) A_i for $i \in I^A \subseteq I$ is fractional ($|I^A| = k_2$),
- b) y_i for $i \in I^y \subseteq I \setminus I_2$ is fractional ($|I^y| = k_2$),
- c) $B, A_i, i \in I^A \subseteq I$ are fractional ($|I^A| = k_2 - 1$),
- d) $B, y_i, i \in I^y \subseteq I \setminus I_2$ are fractional ($|I^y| = k_2 - 1$),
- e) $A_i, y_j, i \in I^A \subseteq I, j \in I^y \subseteq I \setminus I_2$ are fractional ($|I^A| + |I^y| = k_2$),
- f) $B, A_i, y_j, i \in I^A \subseteq I, j \in I^y \subseteq I \setminus I_2$ are fractional ($|I^A| + |I^y| = k_2 - 1$),

The case where only B is fractional does not have to be considered as equality in at least one type two inequality immediately forces B to be integral, as well.

a) With the equality it also follows that $\sum_{i \in I^A} A_i \in \{0, 1\}$.

- $\sum_{i \in I^A} A_i = 0 : A_i = 0 \forall i \in I^A$. $\cancel{}$
- $\sum_{i \in I^A} A_i = 1$. $B = \sum_{j=1}^n A_j + (1 - y_l), l \in I_2 : B = 1, A_i = 0, i \in I \setminus I^A, y_l = 1, l \in I_2$. As $B = 1$, we only need one $A_i, i \in I^A$ to be 1, independent of the y pattern, for a feasible point. Let $I^A = \{i_1, \dots, i_m\}$, then \mathbf{f} can be convexly combined by

$$\mathbf{f} = A_{i_1}(\mathbf{e}_{i_1}^A + \mathbf{v}_{I_2}^y + \mathbf{v}_S^y + \mathbf{e}_B) + \dots + A_{i_m}(\mathbf{e}_{i_m}^A + \mathbf{v}_{I_2}^y + \mathbf{v}_S^y + \mathbf{e}_B)$$

for the subset S of $I \setminus I_2$, where $y_j = 1$. Since we know that $\sum_{i \in I^A} A_i = 1$, we have a real convex combination. $\cancel{}$

b) As $I^y \cap I_2 = \emptyset, \sum_{j=1}^n A_j + (1 - y_k) = B < \sum_{j=1}^n A_j + (1 - y_i), i \in I^y : y_i < y_k$ for all $k \in I_2$.

- $y_k = 0$ for $k \in I_2 : y_i < 0$ for $i \in I^y$. $\cancel{}$
- $y_k = 1$. Thus, either $B = 0 = A_1 = \dots = A_n$ or (w.l.o.g.) $B = 1 = A_1, A_2 = \dots = A_n = 0$. In both cases, we can choose any y_{I^y} pattern to get a feasible point in P . Therefore, one can follow the same procedure to construct a convex combination of integral points as in case (i). $\cancel{}$

c) Again, equality implies $B - \sum_{i \in I^A} A_i \in \{0, 1\}$.

- $B - \sum_{i \in I^A} A_i = 1 : B = 1, A_i = 0, i \in I^A$. $\cancel{}$
- $B - \sum_{i \in I^A} A_i = 0 \Leftrightarrow 0 = \sum_{j \notin I^A} A_j + (1 - y_k) \forall k \in I_2$
 $: A_j = 0, j \notin I^A$ and $y_k = 1, k \in I_2$. Additionally, $y_j \in \{0, 1\}$ for $j \in I \setminus I_2$ and for a subset $S \subseteq I \setminus I_2, y_j = 1$. Then we can convexly combine integral elements of P to obtain \mathbf{f} . For this, let $I^A = \{i_1, \dots, i_m\}$:

$$\mathbf{f} = A_{i_1}(\mathbf{e}_{i_1}^A + \mathbf{v}_{I_2}^y + \mathbf{v}_S^y + \mathbf{e}_B) + \dots + A_{i_m}(\mathbf{e}_{i_m}^A + \mathbf{v}_{I_2}^y + \mathbf{v}_S^y + \mathbf{e}_B) + (1 - \sum_{i \in I^A} A_i)(\mathbf{v}_{I_2}^y + \mathbf{v}_S^y)$$

Therefore, \mathbf{f} is no vertex. $\cancel{}$

d) Since $B = \sum_{j=1}^n A_j + (1 - y_k), k \in I_2$ and all variables involved except for B are integral, B must be integral as well. Hence, we are in case b). $\cancel{}$

e) As shown in case b) it follows that $y_i < y_k$ for all $i \in I^y$ and $k \in I_2$ and with this $y_k = 1 \forall k \in I_2$. This implies that $B = \sum_{j=1}^n A_j$ and hence $\sum_{i \in I^A} A_i \in \{0, 1\}$.

- $\sum_{i \in I^A} A_i = 0 : A_i = 0 \forall i \in I^A$. The only remaining fractional components are $y_j, j \in I^Y$. The possible cases for the integral components are analogous to case b) and they can be convexly combined as in case (i). $\not\leftarrow$
- $\sum_{i \in I^A} A_i = 1 : A_i = 0 \ i \notin I^A, B = 1, y_j = 1, j \in I_2$. We again want to apply the scheme used in case (i), i.e. look for the minimum within the fractional components, set all fractional components to 1 in the convex combinator, multiply it by the lowest value, then take the minimal difference between the fractional entries and the previous minimum, set the component of the previous minimum to 0 and multiply it by the difference of the two. For this purpose it is necessary to make sure that there is always at least one $A_i, i \in I^A$, that is one in the convex combinator. This can be achieved by adjusting the system a little bit to a combination of the procedures of case (i) and case (iii), a): We set only one A_i at a time to 1 until its value is reached and then the next becomes 1. For the y components an arbitrary pattern can be chosen. For an easier description assume that $I^A = \{i_1, \dots, i_m\}, I^Y = \{j_1, \dots, j_k\}$ and $A_{i_1} \leq y_{j_1} \leq A_{i_2} \leq \dots$:

$$\begin{aligned} \mathbf{f} = & A_{i_1}(\mathbf{e}_{i_1}^A + \mathbf{v}_{I_2}^y + \mathbf{v}_{I^Y}^y + \mathbf{e}_B) + (y_{j_1} - A_{i_1})(\mathbf{e}_{i_2}^A + \mathbf{v}_{I_2}^y + \mathbf{v}_{I^Y}^y + \mathbf{e}_B) \\ & + (A_{i_2} - y_{j_1})(\mathbf{e}_{i_2}^A + \mathbf{v}_{I_2}^y + \mathbf{v}_{I^Y \setminus \{j_1\}}^y + \mathbf{e}_B) + \dots \end{aligned}$$

Since $\sum_{i \in I^A} A_i = 1$ it follows that the construction yields a real convex combination. $\not\leftarrow$

f) In this case one can construct a convex combination of \mathbf{f} by using a combination of the cases e) and c). $\not\leftarrow$

In all cases the fractional vertex \mathbf{f} could be convexly combined and thus can not be a vertex. This implies $P = \text{conv}(\mathcal{F}_{\text{mon}})$ \square
