A theory that describes how to load negative charge into a nonlinear, three-dimensional plasma wakefield is presented. In this regime, a laser or an electron beam blows out the plasma electrons and creates a nearly spherical ion channel, which is modified by the presence of the beam load. Analytical solutions for the fields and the shape of the ion channel are derived. It is shown that very high beam-loading efficiency can be achieved, while the energy spread of the bunch is conserved. The theoretical results are verified with the Particle-In-Cell code OSIRIS.

Plasma-based acceleration relies on an underdense plasma to transfer the energy from a laser beam or an electron beam to a trailing bunch of electrons or positrons $[1,\ 2]$. The beam load is accelerated in a wake moving with a velocity near the speed of light, c, until the driver's energy is exhausted or—in the case of a laser driver—until it outruns the plasma wave. Major advances in both laser- and beam-driven accelerators have recently been achieved in a regime in which the fields of the driver are so intense, they push all plasma electrons aside, generating a pure ion channel [3].

For the laser-driven accelerator [1], experiments [4, 5] have inferred and simulations [6, 7, 8] have demonstrated that electrons self-injected into the ion channel can form a quasi-monoenergetic beam. Externally injected, low-charge bunches have been shown to improve the reproducibility and the quality of the final electron beam [9]. In the beam-driven case [2], stable acceleration of the tail of a 42GeV electron beam culminated in the doubling of the energy of some electrons in less than 1 meter [10]. The high-gradient acceleration of a short trailing electron bunch in the wake of a driving beam, which is central to the afterburner concept [11], has also been achieved [12]. A theory that describes the wakefield in this blowout regime has recently been developed [13, 14].

While there has been tremendous progress both experimentally and theoretically on understanding how wakes are excited in the 3D nonlinear regime, there has been little work on how the trailing beam loads the wake. In the linear regime, the issue of beam loading was addressed in Ref. [15], where the wakefield generated by the trailing bunch was superimposed on that of the driver to yield the final accelerating field. Thus, the maximum charge that can be loaded was evaluated and the current profile that makes the wakefield within the bunch flat was determined. Ref. [15] also discussed the effects of transverse beam loading, emittance, and phase slippage, and concluded that beams with spot sizes much smaller than those of the wake are required.

When blowout occurs, the accelerating field is identical within each transverse slice of the ion channel [13, 14], so as opposed to the linear regime, transverse beam loading does not affect the energy spread of the beam. Additionally, because the focusing force in the ion channel is linear, the emittance is conserved. Therefore, the most important consideration for reducing the energy spread is keeping the accelerating field constant along the propagation direction. We note that for high-energy physics applications, narrow trailing bunches are still needed for matched beams and for reducing synchrotron radiation losses [15].

In an estimate offered in Ref. [16], the number of particles was found to scale with the normalized volume of the bubble (or the square root of the laser power). The same scaling was obtained in Ref. [17] but the coefficient, determined by simulations, was more than three times larger than the one estimated in Ref. [16]. These results are not necessarily contradictory because, in principle, one can choose to accelerate either a small number of particles to high energy or a large number of particles to low energy. The question of merit is not just how many electrons can be loaded, but what kind of electron bunch can most efficiently convert the energy available in the wake of the driver into kinetic energy uniformly distributed to its electrons.

In Ref. [13], the wakefield E_z in each transverse slice was found to be proportional to the product of the local radius of the ion channel r_b and the slope $dr_b/d\xi$, where (ξ, r_b) are cylindrical coordinates with $\xi = ct - z$ and the driver is moving toward positive z. The shape of the bubble is represented by the trajectory of the innermost particle given by Eq. (11) in Ref. [13]. This description is valid between the points where the particle trajectories cross, at the very front and the very back of the bubble. To make progress analytically, we take the ultrarelativistic limit, where the normalized maximum radius of the ion channel is $\omega_p R_b/c \gg 1$. The equation for the inner-

FIG. 1: The electron density from a PIC simulation with OSIRIS [18] for $k_p R_b = 5$ is presented. The beams move to the right. The broken black line traces the blowout radius in the absence of the load. On the bottom, the red (black) line is the lineout of the wakefield $E_z(\xi, r_b = 0)$ when the beam load is present (absent).

most particle trajectory reduces to (see Ref. [13]):

$$r_b \frac{d^2 r_b}{d\xi^2} + 2 \left[\frac{dr_b}{d\xi} \right]^2 + 1 = \frac{4\lambda(\xi)}{r_b^2}$$
 (1)

where we adopt normalized units, with length normalized to the skin-depth c/ω_p , density to the plasma density n_p , charge to the electron charge e, and fields to $mc\omega_p/e$. The term on the right hand side of Eq. (1) can describe the charge per unit length of an electron beam and/or the ponderomotive force of a laser [13]. Here we are interested in the back half of the bubble, where the wakefield is accelerating and the quantity $2\pi\lambda(\xi)$, with $\lambda(\xi) = \int_0^\infty r n_b dr$, is the charge per unit length of the beam load.

We define $\xi=0$ at the location where r_b is maximum, i.e., $\frac{dr_b}{d\xi}|_{\xi=0}=0$. In Ref. [13], it was shown that for $\omega_p R_b/c\gg 1$, the wakefield is $E_z\simeq \frac{1}{2}r_b\frac{dr_b}{d\xi}$; therefore, $E_z(\xi=0)\simeq 0$. For $\xi>0$, the electrons are attracted by the ion channel back toward the ξ -axis with $\frac{dr_b}{d\xi}|_{\xi>0}<0$ until $\xi=\xi_s$ where beam loading starts. For $\xi\geq\xi_s$, the electrons feel the repelling force from the charge of the accelerating beam, in addition to the force from the ion channel. The additional repelling force decreases the slope of the sheath $\frac{dr_b}{d\xi}$, thereby lowering the magnitude of E_z . This can be seen in the simulation results in Fig. 1, where the trajectory of the innermost electron for an unloaded wake is drawn on top of the electron density for a loaded wake, and the corresponding wakefield for the two cases is also plotted. The method for choosing the

charge profile of the load is described below.

If the repelling force is too large and the beam too long, the electrons in the sheath will reverse the direction of their transverse velocity at some ξ_r , where $\frac{dr_b}{d\xi}|_{\xi=\xi_r}=0$, and consequently $E_z(\xi_r)=0$. This is a very undesirable configuration because it implies that the front of the bunch feels a much stronger accelerating force than the back.

We are interested in trajectories for which $r_b(\xi>0)$ decreases monotonically. λ may then be expressed as a function of r_b : $\lambda(\xi)=l(r_b)$. Substituting $r_b''=r_b'\frac{dr_b'}{dr_b}$, where the prime denotes differentiation with respect to ξ , Eq. (1) reduces to $\frac{dr_b'}{dr_b}=\frac{4l(r_b)-r_b^2[2(r_b')^2+1]}{r_b^3r_b'}$, which can be integrated to yield:

$$E_z \simeq \frac{1}{2} r_b \frac{dr_b}{d\xi} = -\frac{r_b}{2\sqrt{2}} \sqrt{\frac{16 \int^{r_b} l(\zeta) \zeta d\zeta + C}{r_b^4} - 1}$$
 (2)

Before further analyzing Eq. (2), we comment on salient features of the unloaded case $(l(r_b) = 0)$. Evaluating the constant in Eq. (2) from the condition $E_z(r_b = R_b) = 0$, we obtain:

$$E_z(r_b) \simeq \frac{1}{2} r_b \frac{dr_b}{d\xi} = -\frac{r_b}{2\sqrt{2}} \sqrt{\frac{R_b^4}{r_b^4} - 1}, R_b \ge r_b > 0 \quad (3)$$

Eq. (3) can be integrated from the top of the bubble $r_b(\xi = 0) = R_b$ to yield the innermost particle trajectory for $0 < r_b \le R_b$:

$$\frac{\xi}{R_b} = 2E\left(\arccos\left(\frac{r_b}{R_b}\right) \left| \frac{1}{2} \right) - F\left(\arccos\left(\frac{r_b}{R_b}\right) \left| \frac{1}{2} \right) \right. \tag{4}$$

where $F(\varphi|m), E(\varphi|m)$ are the incomplete elliptic integrals of the first and second kind [19].

To minimize the energy spread on the beam, we seek the beam profile that results in $E_z(r_b \leq r_s) = \frac{1}{2} r_b \frac{dr_b}{d\xi}|_{r_b=r_s} \simeq \text{constant} \equiv -E_s$ within the bunch. The shape of the bubble in this case is described by the parabola $r_b^2 = r_s^2 - 4E_s(\xi - \xi_s)$. For $0 \leq \xi \leq \xi_s$, E_z is given by Eq. (3). E_s is found by requiring that the wakefield is continuous at ξ_s : $E_s = \frac{r_s}{2\sqrt{2}} \sqrt{\frac{R_b^4}{r_s^4} - 1}$. For $\xi_s \leq \xi \leq \xi_s + \frac{r_s^2}{4E_s}$, where $\xi_s + \frac{r_s^2}{4E_s}$ is the location at which the sheath reaches the ξ -axis, the profile of $\lambda(\xi)$ that leads to a constant wakefield is trapezoidal with maximum at $\lambda(\xi_s) = \sqrt{E_s^4 + \frac{R_b^4}{2^4}}$ and minimum at $\lambda(\xi_s + \frac{r_s^2}{4E_s}) = E_s^2$:

$$\lambda(\xi) = \sqrt{E_s^4 + \frac{R_b^4}{2^4}} - E_s(\xi - \xi_s)$$
 (5)

and he total charge $Q_s = 2\pi \int_{\xi_s}^{r_s^2/(4E_s)} \lambda(\xi) d\xi$ is:

$$Q_s \times E_s = \frac{\pi R_b^4}{16} \tag{6}$$

Eq. (6) illustrates the tradeoff between the number of particles that can be accelerated and the accelerating gradient. Because $Q_s \times E_s$ is the energy absorbed per unit length, Eq. (6) also indicates that the efficiency from the wake to the beam load does not depend on the field E_s , as long as the charge profile is chosen appropriately. In Fig. 1, the charge of the beam load was chosen using Eq. (6) for $E_s = 0.35R_b$. For this E_s , the location ξ_s can be obtained either from a simulation for an unloaded wake or from Eq. (3)-(4), and the charge profile from Eq. (5).

In a linear wake, a wide electron bunch with total charge Q_l and transverse spot size A, loaded at some ξ_0 with the appropriate profile [15] can also lead to a flat wakefield $(E_l = \frac{m\omega_p c}{n_0} \frac{n_1}{n_0} \cos(k_p \xi_0))$ within the bunch. The total accelerating force is: $Q_l \times E_l = \frac{E_0^2}{8\pi} A (1 - \frac{E_l^2}{E_0^2})$, where $\frac{E_0^2}{8\pi} A$ is the energy per unit length of the wake in front of the bunch, and $\frac{E_l^2}{8\pi} A$ that behind it. The efficiency, $(1 - \frac{E_l^2}{E_0^2})$, increases for a decreasing accelerating gradient and reaches 100% for $E_l = 0$. This is in stark contrast to the blowout regime, where the efficiency η_b is constant for any E_s .

To calculate the efficiency η_b , let us assume that the bunch is terminated at some ξ_f , where $\Delta \xi_f \equiv \xi_f - \xi_s < \frac{r_s^2}{4E_s}$. After this point the wakefield is described by Eq. (2) with $l(r_b \leq r_f \equiv r_b(\xi_f)) = 0$. From the boundary condition $E_z(r_f) = -E_s$, we obtain $E_z(0 < r_b \leq r_f) \simeq -\frac{r_b}{2\sqrt{2}}\sqrt{\frac{\widetilde{R}_b^4}{r_b^4}} - 1$, where $\widetilde{R}_b^4 = R_b^4\left(\frac{r_f^4}{R_b^4} + \frac{r_f^2}{r_s^2} - \frac{r_f^2r_s^2}{R_b^4}\right)$. In Ref. [16], it was shown that the energy in the fields of a bubble is proportional to R_b^5 . Therefore, the energy per unit length available to the bunch $\mathcal{E}_{\text{avail}}$ scales as R_b^4 , and that left behind it $\mathcal{E}_{\text{lost}}$ scales as \widetilde{R}_b^4 . We define the beam-loading efficiency as $\eta_b \equiv (\mathcal{E}_{\text{avail}} - \mathcal{E}_{\text{lost}})/\mathcal{E}_{\text{avail}}$. Substituting the expression for \widetilde{R}_b :

$$\eta_b \equiv \frac{\mathcal{E}_{\text{avail}} - \mathcal{E}_{\text{lost}}}{\mathcal{E}_{\text{avail}}} = 1 - (\widetilde{R}_b/R_b)^4 = \frac{\widetilde{Q}_s}{Q_s}$$
(7)

where \widetilde{Q}_s is the charge of a trapezoidal bunch that is described by Eq. (5) but terminated at $\xi_s + \Delta \xi_f$ instead of $\xi_s + \frac{r_s^2}{4E_s}$. We note that the efficiency approaches 100% for $\Delta \xi_f \to \frac{r_s^2}{4E_s} \Rightarrow \widetilde{Q}_s \to Q_s$. Because the mathematical formulation involves approximations, there is still some energy in the plasma behind the bunch, even with the optimal $\lambda(\xi)$. This is the case in Fig. 1, where a second bubble with radius $R_{b2} \sim R_b/2$ does appear, but because $Q_s \times E_s \propto R_b^4$, the efficiency is still $\eta_b \sim 90\%$. The wakefield within the bunch in Fig. 1 is constant, in agreement with the theory. We note that a 10% deviation of the total charge for a fixed bunch length leads to a wake that is no longer flat.

It is illustrative to compare the amount of charge that can be loaded into linear and nonlinear wakes. If we assume for the linear wake an effective $A \simeq c^2/\omega_p^2$, which is required for high efficiency and good beam quality [15], we have:

$$\frac{Q_l \times E_l}{mc^2/r_e} = \frac{1}{8\pi} \times \left(\frac{n_1}{n_0}\right)^2 \times \sin^2(k_p \xi_0) \tag{8}$$

$$\frac{Q_s \times E_s}{mc^2/r_e} = \frac{1}{4^3} \times (k_p R_b)^4 \tag{9}$$

where $r_e = e^2/(mc^2)$ is the classical electron radius. In the linear regime, the density perturbation is $n_1/n_0 \ll 1$. In the blowout regime, because the total accelerating force scales with the fourth power of the blowout radius, a radius $k_p R_b \sim 5$ leads to a total force ~ 1000 times larger than that in the linear regime. Eq. (9) can be converted into an engineering formula:

$$\frac{Q_s}{1nC} \times \frac{eE_s}{mc\omega_p} \simeq 0.047 \times \sqrt{\frac{10^{16}cm^{-3}}{n_p}} \times (k_pR_b)^4 \quad (10)$$

For a bi-Gaussian beam driver with $k_p\sigma_z\sim 1$ and $k_p\sigma_r\ll 1$ we have $k_pR_b\simeq 2\sqrt{\frac{n_b}{n_0}}(k_p\sigma_r)^2\equiv 2\sqrt{\Lambda}$ [14], and for a matched laser driver $k_pR_b\simeq 2\sqrt{a_0}$ [14], where a_0 is the normalized vector potential. Both for a beam driver with 3×10^{10} electrons and $\sigma_r\ll\sigma_z=16.8\mu m$ in a plasma with $n_p=10^{17}cm^{-3}$, and for a matched laser-driver with power P=200TW in a plasma with $n_p=1.2\times 10^{18}cm^{-3}$, we have $k_pR_b\simeq 4$. Choosing $\frac{eE_s}{mc\omega_p}=\frac{k_pR_b}{2}\simeq 2$, we obtain $Q_s\simeq 1.9nC$ for the beam-driven case and $Q_s\simeq 0.55nC$ for the laser-driven one.

Another analytically tractable case is that of a bunch with a flat-top profile starting at $\xi = \xi_{\bar{s}}$: $l(0 < r_b \le r_{\bar{s}}) = l_0$. The behavior of the flat-top bunch is important because it is similar to that of a Gaussian bunch (see below). For such bunches, Eq. (2) becomes:

$$E_z(0 < r_b \le r_{\bar{s}}) \simeq -\frac{r_b}{2\sqrt{2}} \sqrt{\frac{8l_0(r_b^2 - r_{\bar{s}}^2) + R_b^4}{r_b^4} - 1}$$
 (11)

There are three distinct cases, all of which can be solved analytically. For small charge per unit length $l_0 < R_b^4/(8r_s^2)$, the plasma electrons reach the ξ -axis quickly with some remaining kinetic energy. For $l_0 > R_b^4/(8r_s^2)$, there is a minimum radius $r_m = \sqrt{4l_0 - \sqrt{(4l_0)^2 + R_b^4 - 8l_0r_s^2}}$, for which $E_z(\xi_m) = 0$ and the transverse velocity of the innermost particle changes sign as described earlier. At ξ_m , the bunch must be terminated; otherwise, for $\xi > \xi_m$, it will experience a decelerating field. Because the plasma electrons do not return on the ξ -axis, they still have some potential energy. Thus, for $l_0 \neq R_b^4/(8r_s^2)$, there is always some energy in the plasma behind the bunch.

For a flat-top bunch, the beam-loading efficiency is maximized if $l_0 = R_b^4/(8r_{\bar{s}}^2)$. Then the shape of the bub-

ble and the wakefield are given by:

$$8l_0 = r_b^2 + \frac{1}{2} \left(\xi - \xi_{\bar{s}} + \sqrt{2} \sqrt{8l_0 - r_{\bar{s}}^2} \right)^2$$
 (12)

$$E_z = -\frac{1}{4}(\xi - \xi_{\bar{s}}) + E_z(\xi = \xi_{\bar{s}}) \tag{13}$$

and the innermost particle will reach the ξ -axis at $\xi_{\bar{s}}+\Delta\xi_{\bar{s}}$, where $\Delta\xi_{\bar{s}}=\frac{\sqrt{2}}{r_{\bar{s}}}(R_b^2-\sqrt{R_b^4-r_{\bar{s}}^4})$. In this case, the energy absorption per unit length is identical to that of an optimal trapezoidal bunch $2\pi l_0\Delta\xi_{\bar{s}}\langle|E_z|\rangle=Q_s\times E_s$. The difference in the accelerating force experienced by the front and the back of the bunch will tend to increase the bunch's energy spread. This can be avoided either by injecting the bunch with an initial energy chirp to compensate for the effect caused by the field in Eq. (13) or by using a monoenergetic trapezoidal bunch.

If the driver travels with a velocity slower than that of the accelerating electrons, these electrons will move with respect to the wake. In this context, it is interesting to see what happens if a flat-top electron bunch optimized for some ξ_1 is instead placed at ξ_2 and ξ_3 , both smaller than ξ_1 .

FIG. 2: Wakefield lineouts for (a) a flat-top electron bunch and (b) a Gaussian bunch with the same charge at three different locations $\xi_1(\text{red}), \xi_2(\text{blue}), \xi_3(\text{green})$ is plotted from theory (solid lines (a)) and simulations (symbols (a), (b)).

In Fig. 2(a), we compare the lineouts of the wakefield $E_z(\xi,r_b=0)$ from three 2D cylindrically symmetric simulations with the theoretical results for flat-top beams. For each simulation, an electron bunch with $l_0=0.25R_b^2$ and length $\Delta \xi_{\bar{s}}=0.27R_b$ is loaded at one of three locations: $\xi_1=0.67R_b, \xi_2=0.53R_b, \xi_3=0.31R_b$. The open

red squares correspond to loading at ξ_1 , the solid blue diamonds to ξ_2 , and the open green circles to ξ_3 . The solid lines are derived from the theory (for $l_0 > R_b^4/(8r_{\bar{s}}^2)$, the particle trajectory in the region $\xi_{\bar{s}} \leq \xi < \xi_m$ can be written in terms of the integral $E(\varphi|m)$) and are in excellent agreement with the simulations in all three cases.

We repeated the simulations using Gaussian bunches with the same number of particles as in the flat-top cases and $N_b(z) = \frac{N_b}{\sqrt{2\pi}\sigma_z}e^{-z^2/(2\sigma_z^2)}$, where $\sigma_z = \Delta \xi_{\bar{s}}/(2\sqrt{2})$. Each bunch is placed so that its center is at a distance $\sqrt{2}\sigma_z$ from ξ_1, ξ_2 , and ξ_3 for the three simulations. The results, shown in Fig. 2(b), confirm that the Gaussian bunches may be treated using the theory for flat-top bunches. In both Fig. 2(a) and 2(b), we observe that the wakefield is relatively flat regardless of the placement of the bunch. The initial negative slope is balanced by a smaller positive slope for most of the acceleration process

The main approximation in the theory, $k_p R_b \gg 1$, is expected to hold for $k_p R_b \gtrsim 3$. However, the formalism described here can still be applied if one numerically solves Eq. (11) of Ref. [13].
