(Dated: October 29, 2018)

We prove that a broad array of capacities of a quantum channel are continuous. That is, two channels that are close with respect to the diamond norm have correspondingly similar communication capabilities. We first show that the classical capacity, quantum capacity, and private classical capacity are continuous, with the variation on arguments ϵ apart bounded by a simple function of ϵ and the channel's output dimension. Our main tool is an upper bound of the variation of output entropies of many copies of two nearby channels given the same initial state; the bound is linear in the number of copies. Our second proof is concerned with the quantum capacities in the presence of free backward or two-way public classical communication. These capacities are proved continuous on the interior of the set of non-zero capacity channels by considering mutual simulation between similar channels.

I. INTRODUCTION

There are several notions of capacity for a noisy quantum communication channel. For example, we may be interested in a channel's capacity for either classical [1, 2], private classical [3], or quantum [3, 4, 5] communications. We may have access to auxiliary resources in addition to the channel, such as entanglement, one-way classical communication from the sender to receiver, from the receiver to the sender, or two-way classical communications. In all of these situations, there is a sensible notion of capacity that can be studied. Except when free auxiliary entanglement is available, where the problem is effectively solved [6], the various capacities of even very simple channels are unknown.

One property that we would hope for in a capacity is continuity. From a practical point of view there will always be a certain amount of channel uncertainty in real systems. In this setting, if nearby channels had dramatically different capacities, the theory of quantum capacities would be of limited value. However, from a mathematical point of view continuity is not at all obvious—very similar channels can become quite far apart given many copies, and the capacity is operationally defined in terms of an asymptotic number of channel uses. This is not a problem when a single-letter capacity formula is available, in which case we can reason about the formula directly, but when only a multi-letter formula is available (or worse, none at all) the problem of continuity becomes a challenge.

The continuity of channel capacities has been considered before. For example, in their study of the quantum erasure channel [7], Bennett, DiVincenzo, and Smolin implicitly assumed the continuity of the quantum channel capacity to upper bound the capacity of this channel. For the erasure channel, this assumption was rigorously justified later in [8]. Keyl and Werner explicitly considered continuity of the quantum channel capacity in [9], where it was shown that the capacity is lower semi-continuous. Continuity of the Holevo information (whose regularization gives a multi-letter formula for the classical capacity) was considered in [10], where it was shown to be continuous for finite dimensional outputs and lower semi-continuous in general.

A related set of questions concerns the continuity of entropic quantities and entanglement measures, which are functions on quantum states. For example, Fannes [11] found a tight bound on the variation of von Neumann entropy of finite dimensional states. This was subsequently used by Nielsen to study the continuity of entanglement of formation [12]. As another example, Donald and Horodecki proved the continuity of the relative entropy of entanglement [13]. The continuity of asymptotic (i.e., regularized) entanglement measures was studied by Vidal in [14], which were shown to be continuous in any open set of distillable states. More recently, Alicki and Fannes generalized the continuity result in [15] to conditional entropy, and used it to prove the continuity of squashed entanglement [16].

In this work we show the continuity of various communication capacities of quantum channels with finite output

dimensions. For the unassisted capacities for classical, private classical, and quantum communication, our tool is an inequality controlling the variation of output entropies of many copies of two nearby channels given the same initial state. By careful use of the Alicki-Fannes inequality [15], this bound is shown to be linear (not quadratic) in the number of copies. For the quantum capacity with two-way classical communication, and the quantum capacity with classical back communication, we also show continuity within an open set of nonzero quantum capacity channels. Our results in this setting build on [14], whose arguments are extended from the distillable entanglement of states to the capacity of channels.

The rest of the paper is organized as follows. Section II contains various definitions, concepts, and prior results used in this paper. Our main tool, the inequality controlling the variation of output entropies of many copies of two nearby channels given the same initial state is proved in Sec. III. This is used to show our main results, the continuity of the quantum, classical, and private classical capacity in Sec. IV. For simplicity throughout most of this paper, we focus on channels with finite dimensional inputs and outputs, although the results of Sec. IV can easily be seen to apply to channels with infinite dimensional inputs and finite outputs. One exception to this focus is in Sec. V, where we consider a family of pairs of infinite dimensional channels, parameterized by n . As n increases, each pair has decreasing distance, but their capacities differ by at least a constant, thereby showing that finite output dimension is needed for continuity. Continuity for the quantum capacities assisted by backward or two-way classical communication in the interior of the nonzero capacity region is proved in Sec. VI. We make a few concluding remarks in Sec. VII.

II. PRELIMINARIES

In this section, we introduce the concepts, notations, definitions, and background materials, focusing on finite dimensional quantum systems. Notations and discussion in the infinite dimensional case will be deferred to Sec. V.

A. Quantum States and Channels

Let \mathcal{H} be a complex Hilbert space, and $\mathcal{B}(\mathcal{H})$ be the set of bounded linear operators taking \mathcal{H} to itself. A quantum state is represented by a positive semidefinite operator $\rho \in \mathcal{B}(\mathcal{H})$ with unit trace. Except in Sec. V, we will be interested in finite-dimensional \mathcal{H} . A quantum channel \mathcal{N} that takes states from \mathcal{H}_{in} to \mathcal{H}_{out} is a linear map from $\mathcal{B}(\mathcal{H}_{\text{in}})$ to $\mathcal{B}(\mathcal{H}_{\text{out}})$ that is trace-preserving and completely-positive. In particular, when $\mathcal{H} = \mathcal{H}_{\text{in}} = \mathcal{H}_{\text{out}}$, we denote by \mathcal{I} the identity map from $\mathcal{B}(\mathcal{H})$ to itself. Recall the definition that \mathcal{N} is completely-positive if for any reference system with associated Hilbert space \mathcal{H}_{ref} , $\mathcal{I} \otimes \mathcal{N}$ maps the positive-semidefinite cone in $\mathcal{B}(\mathcal{H}_{\text{ref}} \otimes \mathcal{H}_{\text{in}})$ to that in $\mathcal{B}(\mathcal{H}_{\text{ref}} \otimes \mathcal{H}_{\text{out}})$. We also call channels, which are trace-preserving and completely-positive, ‘‘TCP maps.’’ They are exactly the physical operations on a state that are allowed by quantum mechanics. A quantum system is associated with a Hilbert space and its set of bounded operators. We also use the system name loosely. For example, we may say that a channel takes system A to system B , or write $\mathcal{N} : A \rightarrow B$.

We denote the trace, which is a simple example of a TCP map, by $\text{Tr}[\cdot]$. A partial trace on a composite system is simply the trace operation on one component. A pure state is a rank one projector, and is also represented by any vector it projects onto. For a quantum state $\rho \in \mathcal{B}(\mathcal{H})$, a purification is any pure state $|\psi\rangle\langle\psi| \in \mathcal{B}(\mathcal{H} \otimes \mathcal{H}')$ such that the partial trace over \mathcal{H}' gives ρ , and purifications always exist. Any channel \mathcal{N} can be represented as a conjugation by an isometry $U : \mathcal{H}_{\text{in}} \rightarrow \mathcal{H}_{\text{out}} \otimes \mathcal{H}_{\text{env}}$, followed by a partial trace: $\mathcal{N}(\rho) = \text{Tr}_{\text{env}} U\rho U^\dagger$.

We sometimes add subscripts to the symbols for quantum states and channels to emphasize what systems they act on, but we may omit these to avoid cluttering. However, for multipartite states, the reduced state on a subset of systems is always subscripted by the subset.

Throughout this paper, we use a distance measure between states given by the 1-norm of their difference:

$$\|\rho - \sigma\|_1 = \text{Tr} |\rho - \sigma| \tag{1}$$

Half of the above is called the trace distance, the quantum analogue of the total variation distance in the classical setting.

We use a distance measure between channels (mapping from $\mathcal{B}(\mathcal{H}_{\text{in}})$ to $\mathcal{B}(\mathcal{H}_{\text{out}})$) induced by the diamond norm:

$$\|\mathcal{N}_1 - \mathcal{N}_2\|_{\diamond} = \max\{\|(\mathcal{N}_1 - \mathcal{N}_2) \otimes \mathcal{I}(X)\|_1 : X \in \mathcal{B}(\mathcal{H}_{\text{in}} \otimes \mathcal{H}_{\text{ref}}), \|X\|_1 = 1\}. \quad (2)$$

The maximum can always be attained with X being a pure quantum state. Operationally, the diamond norm on the difference between the two channels characterizes the probability to distinguish them, if one can prepare an optimal state and feed part of it into the channel. The distance measure also has the nice property that, increasing the dimension of the reference system beyond $\dim(\mathcal{H}_{\text{in}})$ does not increase the distinguishability. This gives us control over the trace distance of the output states of different channels given the same input, and subsequently other quantities of interest to be defined in the next subsection.

The diamond norm of a channel is closely related to the family of completely bounded norms (cb-norms), and in fact is equal to the usual cb-norm of the adjoint channel as well as a generalized cb-norm of the original channel (for more on cb-norms and their relation to quantum information, see [17, 18]).

B. Entropic Quantities

For a classical random variable X with $\text{Prob}(X=x) = p_x$, the Shannon entropy of X is given by $H(X) = -\sum_x p_x \log p_x$ (or $H(\{p_x\})$). If X is binary with probabilities $p, 1-p$, $H(X)$ is written as $H(p)$. Here and throughout this paper, \log is in base 2.

For a quantum system A prepared in state ρ , the von Neumann entropy is written as $S(A)_{\rho}$ or $S(\rho) = -\text{Tr} \rho \log \rho = H(\{\lambda_k\})$ where λ_k is the k th eigenvalue of ρ . Throughout the paper, subscripts showing states on which entropies and other information theoretic quantities are evaluated are omitted when there is little risk of confusion.

For two systems AB in state ρ , we mention a few measures of correlation between A and B :

- the quantum mutual information is defined as $I(A; B)_{\rho} = S(A) + S(B) - S(AB)$ where entropies are evaluated on ρ and its partial traces.
- The conditional entropy is given by $S(A|B) = S(AB) - S(B)$.
- The coherent information $I^{\text{coh}}(A|B)_{\rho}$ is given by $S(B) - S(AB) = -S(A|B)$.

The entropy and conditional entropy, viewed as functions of the underlying states, are both continuous. The following, particularly Theorem 2, will be helpful tools for our task of showing the continuity of capacities.

Theorem 1 (Fannes Inequality [11]) *For any ρ and σ with $\|\rho - \sigma\|_1 \leq \epsilon$, $|S(\rho) - S(\sigma)| \leq \epsilon \log d + H(\epsilon)$.*

Theorem 2 (Alicki-Fannes Inequality [15]) *For any ρ_{AB} and σ_{AB} with $\|\rho - \sigma\|_1 \leq \epsilon$,*

$$|S(A|B)_{\rho} - S(A|B)_{\sigma}| \leq 4\epsilon \log d_A + 2H(\epsilon). \quad (3)$$

C. Capacities of a quantum channel

Consider a quantum channel $\mathcal{N} : A' \rightarrow B$. The channel \mathcal{N} has several different capacities for communication. The following quantities will play crucial roles in the various capacities.

- For an input ensemble $\{p_x, \phi_x\}$, let $\omega = \sum_x p_x |x\rangle\langle x|_X \otimes \mathcal{N}(\phi_x)$ and

$$\chi(\mathcal{N}) := \max_{p_x, \phi_x} I(X; B)_{\omega} \quad (4)$$

be the optimal Holevo information [19] of the output ensemble (after the channel acts on the input).

- For an input state $\rho_{AA'}$, where part of it will be fed into \mathcal{N} , let

$$I^{\text{coh}}(\mathcal{N}, \rho_{AA'}) = I^{\text{coh}}(A|B)_{\mathcal{I} \otimes \mathcal{N}(\rho_{AA'})} \quad (5)$$

be the coherent information generated. Maximizing over the input gives the coherent information of \mathcal{N} :

$$I^{\text{coh}}(\mathcal{N}) = \max_{\rho_{AA'}} I^{\text{coh}}(\mathcal{N}, \rho_{AA'}). \quad (6)$$

We remark that the maximizing state can be chosen to be pure.

• For an input ensemble $\{p_x, \phi_x\}$, let $\omega = \sum_x p_x |x\rangle\langle x|_X \otimes (U\phi_x U^\dagger)_{BE}$, where $U : \mathcal{H}_{A'} \rightarrow \mathcal{H}_B \otimes \mathcal{H}_E$ is an isometric extension of \mathcal{N} . Then,

$$I^{\text{priv}}(\mathcal{N}) = \max_{p_x, \phi_x} (I(X; B)_\omega - I(X; E)_\omega), \quad (7)$$

where the mutual information is evaluated on the reduced states.

To give the operational definitions of the different capacities of \mathcal{N} for communication, we need to consider n uses of the channel. We will use shorthands \mathcal{N}^n , A^n , B^n , and E^n to stand for $\mathcal{N}^{\otimes n}$, $A'^{\otimes n}$, $B^{\otimes n}$, and $E^{\otimes n}$.

Definition 3 *Classical Capacity.* We say that a rate R is ϵ -classically-achievable if there is an n_ϵ such that for all $n \geq n_\epsilon$ there is a classical code $\{\rho_k \in A^n\}_{k=1}^{K_n}$ and a decoding operation $\mathcal{D}_n : B^n \rightarrow \{|k\rangle\langle k|\}_{k=1}^{K_n}$ such that $\forall k$, $\|\mathcal{D}_n(\mathcal{N}^n(\rho_k)) - |k\rangle\langle k|\|_1 \leq \epsilon$ with $\log K_n \geq nR$. A rate is classically-achievable if it is ϵ -classically achievable for all $\epsilon > 0$. The classical capacity of \mathcal{N} , $C(\mathcal{N})$, is the supremum over classically-achievable rates.

Theorem 4 (HSW Theorem [1, 2]) *The classical capacity satisfies*

$$C(\mathcal{N}) = \lim_{n \rightarrow \infty} \frac{1}{n} \chi(\mathcal{N}^n). \quad (8)$$

Definition 5 *Quantum Capacity.* We say that a rate R is ϵ -achievable if there is an n_ϵ such that for all $n \geq n_\epsilon$ there is a quantum code, $C_n \subset A^n$ and decoding operation $\mathcal{D}_n : B^n \rightarrow C_n$ such that for all $\psi \in \mathcal{B}(C_n)$, $\|\mathcal{D}_n(\mathcal{N}^n(\psi)) - \psi\|_1 \leq \epsilon$ and $\log \dim \mathcal{H}_{C_n} \geq nR$. A rate R is achievable if it is ϵ -achievable for all $\epsilon > 0$. The quantum capacity of \mathcal{N} , $Q(\mathcal{N})$, is the supremum over achievable rates.

Theorem 6 (LSD Theorem [3, 4, 5]) *The quantum capacity satisfies*

$$Q(\mathcal{N}) = \lim_{n \rightarrow \infty} \frac{1}{n} I^{\text{coh}}(\mathcal{N}^n). \quad (9)$$

Definition 7 *Private Capacity.* The private capacity is the capacity of a channel for classical communication with the added requirement that an adversary with access to the environment of the channel is ignorant of the communication. More formally, we say that a rate R is ϵ -privately-achievable if there is an n_ϵ such that $\forall n \geq n_\epsilon$ there exists a classical code $\{\rho_k \in A^n\}_{k=1}^{K_n}$ with $\log K_n \geq nR$ and decoding operation $\mathcal{D}_n : B^n \rightarrow \{|k\rangle\langle k|\}_{k=1}^{K_n}$ such that for all k

$$\|\mathcal{D}_n(\mathcal{N}^n(\rho_k)) - |k\rangle\langle k|\|_1 \leq \epsilon \quad (10)$$

$$\text{and} \quad \|\rho_{E^n}^k - \sigma_{E^n}\|_1 \leq \epsilon. \quad (11)$$

Here $\rho_{E^n}^k = \widehat{\mathcal{N}}^n(\rho_k)$, where $\widehat{\mathcal{N}}(\rho) = \text{Tr}_B U \rho U^\dagger$, with $U : \mathcal{H}_{A'} \rightarrow \mathcal{H}_B \otimes \mathcal{H}_E$ an isometric extension of \mathcal{N} , and σ_{E^n} is a fixed state on E^n . If R is ϵ -privately-achievable for all $\epsilon > 0$, it is called privately achievable, and the supremum of privately-achievable rates is called the private capacity.

Theorem 8 ([3]) *The private capacity satisfies*

$$C_p(\mathcal{N}) = \lim_{n \rightarrow \infty} \frac{1}{n} I^{\text{priv}}(\mathcal{N}^n). \quad (12)$$

The three capacity definitions above are similar in structure, and differing only in the type of information being sent. The corresponding theorems, which give what are called “regularized capacity formulas” also seem to be parallel. In each case, the “regularization”, as the limit over n is called, prevents us from evaluating the capacity of a given channel explicitly, or even numerically. In the case of the quantum capacity [20, 21] and the private classical capacity [22] it is known for a while that the regularization cannot be removed in general. More recently, the regularization in the classical capacity was reported to be generally necessary [23].

While very little is known about the capacities above, even less is known about the capacity of a channel for quantum communication assisted by two-way classical communication. To define this capacity, we introduce the notion of an n -use protocol \mathcal{P}_n , where n denote the number of times the channel \mathcal{N} can be used. Just as in the definition of the unassisted quantum capacity, we consider a system C_n which holds the quantum information to be sent. We use the same symbol to denote Bob's quantum system which holds the quantum data in his possession at the end of the protocol. \mathcal{P}_n is a composition of the following steps (in order of being performed): $\mathcal{A}_0, \mathcal{M}_{\rightarrow 0}, \mathcal{N}, \mathcal{B}_1, \mathcal{M}_{\leftarrow 1}, \mathcal{A}_1, \mathcal{M}_{\rightarrow 1}, \mathcal{N}, \mathcal{B}_2, \mathcal{M}_{\leftarrow 2}, \dots, \mathcal{A}_{n-1}, \mathcal{M}_{\rightarrow(n-1)}, \mathcal{N}, \mathcal{B}_n, \mathcal{M}_{\leftarrow n}, \mathcal{A}_n$. Here, each \mathcal{A}_i is performed by the sender Alice on C_n and her auxiliary system after the i -th channel use, and each produces an extra system A' as an input to the $(i+1)$ -th channel use. Each $\mathcal{M}_{\rightarrow i}$ transmits classical communication from Alice to the receiver Bob. Each \mathcal{B}_i is performed by Bob on his auxiliary system and all i systems cumulated from the channel uses. Each generates some classical outcome to be sent to Alice in the step $\mathcal{M}_{\leftarrow i}$. Using the notion of a protocol, we can now define quantum capacity with two-way classical assistance.

Definition 9 *Quantum Capacity with two-way classical assistance.*

For any $\epsilon > 0$ we say that a rate R is ϵ -2-way-achievable if there is an n_ϵ such that for all $n \geq n_\epsilon$ there is an n -use protocol \mathcal{P}_n such that for any auxiliary reference system A , $\psi \in C_n \otimes A$, $\|\mathcal{P}_n \otimes \mathcal{I}(\psi) - \psi\|_1 \leq \epsilon$ and $\log \dim \mathcal{H}_{C_n} \geq nR$. In other words, \mathcal{P}_n and the identity map on the code space are ϵ -close in the diamond norm. A rate is achievable if it is ϵ -achievable for all $\epsilon > 0$. The quantum capacity of \mathcal{N} with two-way classical assistance, $Q_2(\mathcal{N})$, is the supremum over achievable rates.

Definition 10 *Quantum Capacity with back classical assistance $Q_B(\mathcal{N})$.*

An n -use protocol in this setting is similar to that with two-way assistance, except that $\mathcal{M}_{\rightarrow i}$ are omitted. The rest of the capacity definition is similar to that of $Q_2(\mathcal{N})$.

Little is known about these assisted capacities. One proven fact [24, 25] is that $Q_2(\mathcal{N})$ is equal to the *entanglement capacity* of \mathcal{N} (informally, that is the maximum amount of near perfect entanglement generated per use of \mathcal{N} , asymptotically). Clearly $Q(\mathcal{N}) \leq Q_B(\mathcal{N}) \leq Q_2(\mathcal{N})$, but beyond that, almost nothing is known about $Q_B(\mathcal{N})$. For instance, there is no known analogue of a connection to entanglement capacity.

III. CONTINUITY OF OUTPUT ENTROPY

The following theorem is one of our main technical tools.

Theorem 11 *Let $\mathcal{N} : A' \rightarrow B$ and $\mathcal{M} : A' \rightarrow B$ be quantum channels and d_B be the finite dimension of B . Let A be an auxiliary reference system. If $\|\mathcal{N} - \mathcal{M}\|_\diamond \leq \epsilon$, then, for any state $\phi \in \mathcal{B}(AA'^n)$,*

$$\left| S((\mathcal{I} \otimes \mathcal{N}^n)(\phi)) - S((\mathcal{I} \otimes \mathcal{M}^n)(\phi)) \right| \leq n(4\epsilon \log d_B + 2H(\epsilon)). \quad (13)$$

Proof Let

$$\rho_{AB^n}^k = \left(\mathcal{I}_A \otimes \mathcal{M}^{\otimes k} \otimes \mathcal{N}^{\otimes(n-k)} \right) (\phi_{AA'^n}). \quad (14)$$

In the above, we have explicitly labeled the auxiliary, the input and the output systems on the states. We omit these subscripts from now on. Setting $k = 0$ and then n , we have in particular $\rho_{AB^n}^0 = \mathcal{I} \otimes \mathcal{N}^n(\phi)$ and $\rho_{AB^n}^n = \mathcal{I} \otimes \mathcal{M}^n(\phi)$. Since ρ^{k-1} and ρ_k differs only in the k th output system,

$$S(AB_1 \dots B_{k-1} B_{k+1} \dots B_n)_{\rho^{k-1}} = S(AB_1 \dots B_{k-1} B_{k+1} \dots B_n)_{\rho^k}. \quad (15)$$

The quantity we are interested in is

$$\left| S(AB^n)_{\rho^0} - S(AB^n)_{\rho^n} \right|, \quad (16)$$

which satisfies

$$|S(AB^n)_{\rho^0} - S(AB^n)_{\rho^n}| = \left| \sum_{k=1}^n S(AB^n)_{\rho^{k-1}} - S(AB^n)_{\rho^k} \right| \quad (17)$$

$$\leq \sum_{k=1}^n |S(AB^n)_{\rho^{k-1}} - S(AB^n)_{\rho^k}|. \quad (18)$$

Applying Eq.(15) to a single term in this sum, we have

$$\begin{aligned} & |S(AB^n)_{\rho^{k-1}} - S(AB^n)_{\rho^k}| \\ &= |S(AB^n)_{\rho^{k-1}} - S(AB_1 \dots B_{k-1} B_{k+1} \dots B_n)_{\rho^{k-1}} - S(AB^n)_{\rho^k} + S(AB_1 \dots B_{k-1} B_{k+1} \dots B_n)_{\rho^k}| \\ &= |S(B_k | AB_1 \dots B_{k-1} B_{k+1} \dots B_n)_{\rho^{k-1}} - S(B_k | AB_1 \dots B_{k-1} B_{k+1} \dots B_n)_{\rho^k}|. \end{aligned} \quad (19)$$

Because $\|\mathcal{N} - \mathcal{M}\|_{\diamond} \leq \epsilon$, we also have $\|\rho^k - \rho^{k-1}\|_1 \leq \epsilon$, so by the Alicki-Fannes Inequality,

$$|S(B_k | AB_1 \dots B_{k-1} B_{k+1} \dots B_n)_{\rho^k} - S(B_k | AB_1 \dots B_{k-1} B_{k+1} \dots B_n)_{\rho^{k-1}}| \leq 4\epsilon \log d_B + 2H(\epsilon). \quad (20)$$

As a result, we find

$$|S(AB^n)_{\rho^0} - S(AB^n)_{\rho^n}| \leq n(4\epsilon \log d_B + 2H(\epsilon)), \quad (21)$$

which completes the proof. \square

IV. CONTINUITY OF CAPACITIES FOR CHANNELS WITH FINITE OUTPUT DIMENSION

We now apply Theorem 11 to show the continuity of $C(\mathcal{N})$, $Q(\mathcal{N})$, and $C_p(\mathcal{N})$. Each of these capacities has the form $F(\mathcal{N}) = \lim_{n \rightarrow \infty} \frac{1}{n} \max_{P^{(n)}} f_n(\mathcal{N}^n, P^{(n)})$ for some appropriate family of function $\{f_n\}$ and parameters $P^{(n)}$ to be optimized over. We make repeated use of the following Lemma.

Lemma 12 *If $F(\mathcal{N}) = \lim_{n \rightarrow \infty} \frac{1}{n} \sup_{P^{(n)}} f_n(\mathcal{N}^n, P^{(n)})$ and $\forall n, \forall P^{(n)}, |f_n(\mathcal{N}^n, P^{(n)}) - f_n(\mathcal{M}^n, P^{(n)})| \leq nc$, then $|F(\mathcal{N}) - F(\mathcal{M})| \leq c$.*

Proof Let $\epsilon > 0$ be arbitrary. Let $f_n(\mathcal{N}^n) = \sup_{P^{(n)}} f_n(\mathcal{N}^n, P^{(n)})$. Suppose $f_n(\mathcal{N}^n)$ and $f_n(\mathcal{M}^n)$ are ϵ -close to optimal at $P_1^{(n)}$ and $P_2^{(n)}$. Then,

$$f_n(\mathcal{N}^n) - \epsilon < f_n(\mathcal{N}^n, P_1^{(n)}) \leq f_n(\mathcal{M}^n, P_1^{(n)}) + nc \leq f_n(\mathcal{M}^n) + nc \quad (22)$$

$$f_n(\mathcal{M}^n) - \epsilon < f_n(\mathcal{M}^n, P_2^{(n)}) \leq f_n(\mathcal{N}^n, P_2^{(n)}) + nc \leq f_n(\mathcal{N}^n) + nc \quad (23)$$

Thus, $\forall \epsilon > 0, \forall n, |f_n(\mathcal{N}^n) - f_n(\mathcal{M}^n)| \leq nc + \epsilon$. Taking limits $\epsilon \rightarrow 0, n \rightarrow \infty, |F(\mathcal{N}) - F(\mathcal{M})| \leq c$.

Note that in particular, Lemma 12 holds with sup replaced by max, as needed in the following corollaries.

Corollary 13 *The classical capacity of a quantum channel with finite-dimensional output is continuous. Quantitatively, if $\mathcal{N}, \mathcal{M} : A' \rightarrow B$ where the dimension of B is d_B and $\|\mathcal{N} - \mathcal{M}\|_{\diamond} \leq \epsilon$, then*

$$|C(\mathcal{N}) - C(\mathcal{M})| \leq 8\epsilon \log d_B + 4H(\epsilon). \quad (24)$$

Proof From the HSW theorem

$$C(\mathcal{N}) = \lim_{n \rightarrow \infty} \frac{1}{n} \chi(\mathcal{N}^n) = \lim_{n \rightarrow \infty} \frac{1}{n} \max_{p_x, \phi_x^{(n)}} I(X; B^n)_{\omega^{(n)}}, \quad (25)$$

where $\omega^{(n)} = \sum_x p_x |x\rangle\langle x|_X \otimes \mathcal{N}^{\otimes n}(\phi_x^{(n)})$. For any $\mathcal{N} : A' \rightarrow B$ and $\mathcal{M} : A' \rightarrow B$ with $\|\mathcal{N} - \mathcal{M}\|_\diamond \leq \epsilon$, and for fixed n and $\{p_x, \phi_x^{(n)}\}$, letting $\omega = \sum_x p_x |x\rangle\langle x|_X \otimes \mathcal{N}^n(\phi_x^{(n)})$ and $\tilde{\omega} = \sum_x p_x |x\rangle\langle x|_X \otimes \mathcal{M}^n(\phi_x^{(n)})$, we have

$$|I(X; B^n)_\omega - I(X; B^n)_{\tilde{\omega}}| = |S(B^n)_\omega - S(B^n X)_\omega - S(B^n)_{\tilde{\omega}} + S(B^n X)_{\tilde{\omega}}| \quad (26)$$

$$\leq |S(B^n)_\omega - S(B^n)_{\tilde{\omega}}| + |S(B^n X)_{\tilde{\omega}} - S(B^n X)_\omega| \quad (27)$$

$$\leq 2n(4\epsilon \log d_B + 2H(\epsilon)). \quad (28)$$

Applying Lemma 12 gives the desired result $|C(\mathcal{N}) - C(\mathcal{M})| \leq 8\epsilon \log d_B + 4H(\epsilon)$. \square

Corollary 14 *The quantum capacity of a quantum channel with finite dimensional output is continuous. Quantitatively, if $\mathcal{N}, \mathcal{M} : A' \rightarrow B$ where the dimension of B is d_B and $\|\mathcal{N} - \mathcal{M}\|_\diamond \leq \epsilon$, then*

$$|Q(\mathcal{N}) - Q(\mathcal{M})| \leq 8\epsilon \log d_B + 4H(\epsilon). \quad (29)$$

Proof From the LSD Theorem,

$$Q(\mathcal{N}) = \lim_{n \rightarrow \infty} \frac{1}{n} I^{\text{coh}}(\mathcal{N}^n) = \lim_{n \rightarrow \infty} \frac{1}{n} \max_{\rho_{AA'^n}} I^{\text{coh}}(\mathcal{N}^n, \rho_{AA'^n}). \quad (30)$$

Let $\omega_{AB^n} = \mathcal{I} \otimes \mathcal{N}^n(\rho_{AA'^n})$ and $\tilde{\omega}_{AB^n} = \mathcal{I} \otimes \mathcal{M}^n(\rho_{AA'^n})$. Consider the difference of coherent informations

$$|I^{\text{coh}}(\mathcal{N}^n, \rho_{AA'^n}) - I^{\text{coh}}(\mathcal{M}^n, \rho_{AA'^n})| = |S(B^n)_\omega - S(AB^n)_\omega - S(B^n)_{\tilde{\omega}} + S(AB^n)_{\tilde{\omega}}| \quad (31)$$

$$\leq |S(B^n)_\omega - S(B^n)_{\tilde{\omega}}| + |S(AB^n)_\omega - S(AB^n)_{\tilde{\omega}}| \quad (32)$$

$$\leq 2n(4\epsilon \log d_B + 2H(\epsilon)). \quad (33)$$

Applying Lemma 12 gives the result. \square

Corollary 15 *The private classical capacity of a quantum channel with finite-dimensional output is continuous. Quantitatively, if $\mathcal{N}, \mathcal{M} : A' \rightarrow B$ where the dimension of B is d_B and $\|\mathcal{N} - \mathcal{M}\|_\diamond \leq \epsilon$, then*

$$|C_p(\mathcal{N}) - C_p(\mathcal{M})| \leq 16\epsilon \log d_B + 8H(\epsilon). \quad (34)$$

Proof Let U and W be the isometric extensions for \mathcal{N} and \mathcal{M} respectively.

$$C_p(\mathcal{N}) = \lim_{n \rightarrow \infty} \frac{1}{n} I^{\text{priv}}(\mathcal{N}^n) = \lim_{n \rightarrow \infty} \frac{1}{n} \max_{p_x, \phi_x} (I(X; B^n)_\omega - I(X; E^n)_\omega), \quad (35)$$

where ϕ_x lives in A'^n , $\omega_{XB^nE^n} = \sum_x p_x |x\rangle\langle x| \otimes U\phi_x U^\dagger$ and $|\omega\rangle_{XB^nE^nG}$ purifies it. Then,

$$I(X; B^n)_\omega - I(X; E^n)_\omega \quad (36)$$

$$= [S(B^n) - S(B^n X)]_\omega - [S(E^n) - S(E^n X)]_\omega \quad (37)$$

$$= [S(B^n) - S(B^n X)]_\omega - [S(XB^nG) - S(B^nG)]_{|\omega\rangle\langle\omega|} \quad (38)$$

Similarly, define $\tilde{\omega}_{XB^nE^n} = \sum_x p_x |x\rangle\langle x| \otimes W\phi_x W^\dagger$ for \mathcal{M} . Switching from Eq. (38) to that defined by $\tilde{\omega}$, the difference can be bounded by applying Theorem 11 to each of the four terms followed by Lemma 12, giving the stated result. \square

V. DISCONTINUITY OF CAPACITIES WITH INFINITE OUTPUT DIMENSION

In this section we provide simple examples to show that the classical and quantum capacities of channels with infinite output dimensions are not generally continuous. An earlier demonstration of the discontinuity of the classical capacity for infinite dimensional quantum channel was given by Shirokov [26].

For an infinite dimensional complex Hilbert space \mathcal{H} with bounded linear operators $\mathcal{B}(\mathcal{H})$, the space of all trace class operators (subset of $\mathcal{B}(\mathcal{H})$ with finite trace) is denoted $\mathfrak{T}(\mathcal{H})$, and its positive semidefinite subset is denoted $\mathfrak{T}_+(\mathcal{H})$. A quantum state is an element of $\mathfrak{T}_+(\mathcal{H})$ with unit trace. A quantum channel \mathcal{N} from \mathcal{H}_{in} to \mathcal{H}_{out} is a linear map from $\mathfrak{T}(\mathcal{H}_{\text{in}})$ to $\mathfrak{T}(\mathcal{H}_{\text{out}})$ that is trace-preserving and completely-positive.

A. Classical Capacity

Example Let $\mathcal{H} = \text{Span}\{|i\rangle\}_{i=0}^{\infty}$, and $\mathcal{H}_+ = \text{Span}\{|i\rangle\}_{i=1}^{\infty}$. Consider the channels \mathcal{N} and $\mathcal{M}_n : \mathfrak{T}(\mathcal{H}_+) \rightarrow \mathfrak{T}(\mathcal{H})$ with

$$\mathcal{N}(|i\rangle\langle j|) = \text{Tr}(|i\rangle\langle j|) |0\rangle\langle 0| \quad (39)$$

and

$$\mathcal{M}_n = \left(1 - \frac{1}{\log n}\right) \mathcal{N} + \frac{1}{\log n} \text{id}_n, \quad (40)$$

where

$$\text{id}_n(|i\rangle\langle j|) = |i\rangle\langle j| \quad \text{for } 1 \leq i, j \leq n \quad (41)$$

$$= \text{Tr}(|i\rangle\langle j|) |0\rangle\langle 0| \quad \text{otherwise.} \quad (42)$$

First of all, we have $C(\mathcal{N}) = 0$, since \mathcal{N} maps every state to $|0\rangle\langle 0|$. As for the capacity of \mathcal{M}_n , an easy lower bound can be obtained by using the codewords $|k\rangle\langle k|$ for $k = 1, \dots, n$, turning \mathcal{M}_n to a classical erasure channel in n -dimensions, with erasure probability $p_e = 1 - \frac{1}{\log n}$. The capacity of the latter is known [7] to be $(1 - p_e) \log n = 1$. Thus,

$$C(\mathcal{M}_n) \geq 1. \quad (43)$$

However,

$$\|\mathcal{N} - \mathcal{M}_n\|_{\diamond} = \left\| \frac{1}{\log n} (\mathcal{N} - \text{id}_n) \right\|_{\diamond} \quad (44)$$

$$= \frac{1}{\log n} \|\mathcal{N} - \text{id}_n\|_{\diamond} \leq \frac{2}{\log n}. \quad (45)$$

□

B. Quantum Capacity

Example Now let $\mathcal{N} : \mathfrak{T}(\mathcal{H}_+) \rightarrow \mathfrak{T}(\mathcal{H})$ be defined by

$$\mathcal{N}(\rho) = \frac{1}{2} \text{Tr}(\rho) |0\rangle\langle 0| + \frac{1}{2} \rho. \quad (46)$$

That is, \mathcal{N} is a 50% erasure channel, so that $Q(\mathcal{N}) = 0$. Let

$$\mathcal{M}_n = \left(1 - \frac{1}{\log n}\right) \mathcal{N} + \frac{1}{\log n} \text{id}_n. \quad (47)$$

A lower bound of the quantum capacity can be obtained by restricting each input to the span of $\{|i\rangle\}_{i=1, \dots, n}$, so that \mathcal{M}_n is effectively a quantum erasure channel with n -dimensional inputs and with erasure probability $p_e = \frac{1}{2} - \frac{1}{2 \log n}$. This quantum erasure channel has capacity [7] $(1 - 2p_e) \log n = 1$. Therefore,

$$Q(\mathcal{M}_n) \geq 1. \quad (48)$$

As before, we have $\|\mathcal{N} - \mathcal{M}_n\|_{\diamond} \leq \frac{2}{\log n}$, so that Q is also discontinuous. □

VI. TWO-WAY CAPACITY AND CAPACITY WITH BACK COMMUNICATION

For a general channel, these capacities are not known to have a closed form expression. In this setting, an argument similar to that for continuity of asymptotic entanglement measures in [14] can be used for the interior of the nonzero

capacity region. Q_2 and Q_B differ in the definition of the n -use protocol, and we will see that this difference does not affect the argument, and we only talk about Q_2 for clarity.

For any metric chosen for the space of channels, continuity of Q_2 at \mathcal{N} can be stated as $\forall \epsilon > 0, \exists \delta > 0$ such that $\forall \mathcal{N}' \in B(\mathcal{N}, \delta), |Q_2(\mathcal{N}') - Q_2(\mathcal{N})| \leq \epsilon$, where $B(\mathcal{N}, \delta)$ is an open ball of radius δ centered at \mathcal{N} . (Similarly for Q_B).

We consider the set of channels taking d_{in} to d_{out} dimensions.

A. Interior of $\{Q_2(\mathcal{N}) > 0\}$

Let us denote the interior of $\{Q_2(\mathcal{N}) > 0\}$ by \mathcal{Q}_2^+ . Suppose $\mathcal{N} \in \mathcal{Q}_2^+$. Using the definition of continuity stated above, we will derive δ as a function of ϵ and other relevant parameters, so that $\forall \epsilon > 0, \exists \delta > 0$ such that $\forall \mathcal{N}' \in B(\mathcal{N}, \delta), |Q_2(\mathcal{N}') - Q_2(\mathcal{N})| \leq \epsilon$.

First, consider $B(\mathcal{N}, \Delta)$ where Δ is small enough to ensure $B(\mathcal{N}, \Delta) \subset \mathcal{Q}_2^+$ (i.e., $Q_2 > 0$ on the entire $B(\mathcal{N}, \Delta)$). Second, for every \mathcal{M} on the boundary of $B(\mathcal{N}, \Delta)$, we specify two other channels \mathcal{M}_1 and \mathcal{M}_2 so that:

$$\mathcal{M} = p_1 \mathcal{M}_1 + (1 - p_1) \mathcal{N}, \quad (49)$$

$$\mathcal{N} = p_2 \mathcal{M}_2 + (1 - p_2) \mathcal{M}, \quad (50)$$

for some $p_1, p_2 \in [0, 1]$. $\mathcal{M}_1, \mathcal{M}_2$ need not be in \mathcal{Q}_2^+ but have to be TCP maps. Such $\mathcal{M}_1, \mathcal{M}_2$ always exists (for example, we can take them to be \mathcal{M} and its antipodal point on $B(\mathcal{N}, \Delta)$ respectively). We take $\mathcal{M}_1, \mathcal{M}_2$ to be on the boundary of the set of channels, as far from \mathcal{N}, \mathcal{M} as possible to minimize p_1, p_2 .

The concepts involved in the proof are summarized in the following diagram:

We show how to simulate \mathcal{M} by \mathcal{N} , from which we derive an upper bound on $Q_2(\mathcal{M})$, Eq. (51), in terms of $Q_2(\mathcal{N})$. A less ϵ - δ -loaded, more concise, and slightly more heuristic derivation in terms of resource inequalities [27] is given in [28].

(1) We start from the definition of $Q_2(\mathcal{N})$. Consider any $R_1 < Q_2(\mathcal{N})$, with $\delta_1 > 0$ such that $R_1 = Q_2(\mathcal{N}) - \delta_1$. For any $\epsilon > 0, \exists n_\epsilon$ such that $\forall n_1 \geq n_\epsilon$, there is a protocol \mathcal{P}_{n_1} with n_1 uses of \mathcal{N} and 2-way classical communication that simulates the identity map on an $2^{n_1 R_1}$ -dimensional system ϵ -close in diamond norm.

(2) Any channel can be trivially (and inefficiently) simulated by either one of the two following methods: Alice sends the input noiselessly to Bob who then locally applies the channel, or Alice applies the channel on the input and sends the resulting state to Bob via the noiseless channel. Thus, $\log d$ noiseless qubit channels are sufficient for simulating any channel where $d = \min(d_{\text{in}}, d_{\text{out}})$, in an exact and 1-shot manner.

(3) Using the assisting classical communication (only one of the forward or backward direction suffices), Alice and Bob can agree on n biased coins (with probabilities of the two outcomes being $p_1, 1-p_1$) and apply the channel \mathcal{N} or

\mathcal{M}_1 accordingly. Due to the Chernoff bound, $\forall \delta_{\text{Ch}}, \exists n_{\text{Ch}}$ such that the probability is less than ϵ that it requires more than $n(p_1 + \delta_{\text{Ch}})$ uses of \mathcal{M}_1 or more than $n(1 - p_1 + \delta_{\text{Ch}})$ uses of \mathcal{N} . In this unlikely event, Alice and Bob just run an inaccurate simulation.

We now put these 3 steps together. Let $n_1 = n(Q_2(\mathcal{N}) - \delta_1)^{-1}(p_1 + \delta_{\text{Ch}}) \log d$. We use an n_1 -use protocol of \mathcal{N} to simulate $n(p_1 + \delta_{\text{Ch}}) \log d$ identity channels (it will be ϵ -close in diamond norm if $n_1 \geq n_\epsilon$) which in turns simulates $n(p_1 + \delta_{\text{Ch}})$ uses of \mathcal{M}_1 with the same precision. In addition to the above, we use the coin tosses and $n(1 - p_1 + \delta_{\text{Ch}})$ direct uses of \mathcal{N} to simulate n uses of \mathcal{M} . This simulation is ϵ -close unless an atypical outcome of the coin tosses occurs. If n is large enough, then $n_1 \geq n_\epsilon$ and $n \geq n_{\text{Ch}}$, the simulation is 2ϵ -close in diamond norm. This takes a total of $n(1 - p_1 + \delta_{\text{Ch}}) + n(Q_2(\mathcal{N}) - \delta_1)^{-1}(p_1 + \delta_{\text{Ch}}) \log d$ uses of \mathcal{N} .

Now, $\forall \delta_2 > 0, R_2 = Q_2(\mathcal{M}) - \delta_2, \exists m_\epsilon$ such that $\forall n \geq m_\epsilon$, there is a protocol with n uses of \mathcal{M} that simulates the identity map on 2^{nR_2} dimensions ϵ -close in diamond norm. Substitute these n uses of \mathcal{M} by the 2ϵ -close simulation above. We have an 3ϵ -close simulation of the 2^{nR_2} -dim identity map with $n(1 - p_1 + \delta_{\text{Ch}}) + n/[Q_2(\mathcal{N}) - \delta_1] \times (p_1 + \delta_{\text{Ch}}) \log d$ uses of \mathcal{N} . Letting $\epsilon, \delta_1, \delta_2$, and $\delta_{\text{Ch}} \rightarrow 0$, we have

$$\left[p_1 \frac{\log d}{Q_2(\mathcal{N})} + (1 - p_1) \right] Q_2(\mathcal{N}) \geq Q_2(\mathcal{M}) \quad (51)$$

Running the same argument with \mathcal{N}, \mathcal{M} reversed and using Eq. (50) instead, we have

$$\left[p_2 \frac{\log d}{Q_2(\mathcal{M})} + (1 - p_2) \right] Q_2(\mathcal{M}) \geq Q_2(\mathcal{N}) \quad (52)$$

Together,

$$|Q_2(\mathcal{N}) - Q_2(\mathcal{M})| \leq \min[p_1(\log d - Q_2(\mathcal{N})), p_2(\log d - Q_2(\mathcal{M}))]. \quad (53)$$

We now consider \mathcal{N}' which is colinear with \mathcal{N} and \mathcal{M} , and is on the boundary of $B(\mathcal{N}, \delta)$. We can run the same argument with \mathcal{N}' in place of \mathcal{M} but with the same $\mathcal{M}_1, \mathcal{M}_2$. Here, $\mathcal{N}' = \frac{\delta}{\Delta} \mathcal{M} + (1 - \frac{\delta}{\Delta}) \mathcal{N}$. Eliminating \mathcal{M} from Eqs. (49) and (50), one can verify that the parameters change as

$$p_1 \rightarrow q_1 = p_1 \frac{\delta}{\Delta} \quad (54)$$

$$p_2 \rightarrow q_2 = p_2 \frac{\delta}{\Delta} \cdot \frac{1}{\frac{\delta}{\Delta} p_2 + (1 - p_2)} \leq p_2 \frac{\delta}{\Delta} \frac{1}{1 - p_2} \leq 2p_2 \frac{\delta}{\Delta}. \quad (55)$$

In the last inequality, we use the fact that $p_2 \leq 1/2$ by construction. Using Eq. (53) for \mathcal{N}' and substituting p_1, p_2 by q_1, q_2 , and for $\delta \leq \frac{\Delta \epsilon}{2 \log d}$,

$$|Q_2(\mathcal{N}) - Q_2(\mathcal{N}')| \leq \min[q_1(\log d - Q_2(\mathcal{N})), q_2(\log d - Q_2(\mathcal{N}'))] \leq \epsilon.$$

Note that δ depends on $\mathcal{N}' \in B(\mathcal{N}, \delta)$ via the dependence of \mathcal{M}' and Δ on \mathcal{N}' .

The continuity bound is not as tight as those derived for the unassisted capacities, but it has the merit of being independent of the metric used for the channels.

The same argument holds for continuity of Q_B in the interior of $Q_B(\mathcal{N}) > 0$ with the only modification in the definition of an n -use protocol.

B. Q_B of Erasure Channel

The erasure channel of erasure probability p acts on qubit states as follows: $\mathcal{E}_p(\rho) = (1 - p)\rho + p|2\rangle\langle 2|$, where $|2\rangle$ can be view as an error symbol. $Q_2(\mathcal{E}_p) = 1 - p$ but an expression for $Q_B(\mathcal{E}_p)$ is unknown, though it is known to be positive for $p < 1$.

Instead of the continuity of Q_2 or Q_B at \mathcal{E}_p , we can ask if these capacities are continuous as a function of p . In other word, we are considering the restriction of these functions to the 1-parameter family of channels \mathcal{E}_p .

In this restricted domain, $Q_2(\mathcal{E}_p) = 1 - p$ is clearly continuous. For $Q_B(\mathcal{E}_p)$, the previous proof now holds on the restricted domain for $p < 1$. For the point $p = 1$, continuity still holds because $Q_B(\mathcal{E}_p) \leq Q_2(\mathcal{E}_p) = 1 - p$ which is vanishing (converging towards $Q_B(\mathcal{E}_1)$) as $p \rightarrow 1$.

VII. DISCUSSION

We have shown that many of the communication capacities of a quantum channel are continuous. For unassisted capacities, such as private, quantum, and classical capacities we proved continuity using Theorem 11. In these cases, the capacities are near-Lipschitz when the distance between the channels is no less than the inverse of the single use output dimension. We obtained explicit bounds on the effective Lipschitz constants, typically finding variations of order $\epsilon \log d$ for channels that are distance ϵ apart. For the more involved case of two-way capacity, we have shown continuity of Q_2 on the interior of $\{Q(\mathcal{N}) > 0\}$, and similarly for Q_B by making use of an argument of Vidal[14].

In general, application of Theorem 11 will give continuity any time a regularized capacity formula is available. In particular, it can easily be used to show the continuity of the capacity region of multi-user channels such as the multiple access channel [29] and broadcast channels [30, 31].

Acknowledgements

We are grateful to Aram Harrow for discussions about continuity of the two-way and back-assisted capacities, and John Smolin for suggesting the example of discontinuity for the classical capacity of infinite-dimensional channels. We thank Bill Rosgen for a careful reading and many helpful corrections on an earlier version of the manuscript. DL was supported by CRC, CFI, ORF, NSERC, CIFAR, MITACS, ARO, and QuantumWorks.

- [28] We describe the proof in the language of resource inequalities[27]. Each resource inequality (RI) $S_1 + S_2 \cdots \geq R_1 + R_2 \cdots$ represents the fact that n units of LHS resources can be used to simulate n units of the RHS resources for asymptotically large n and with sufficient accuracy (say, in diamond norm of the operations involved in the RHS). If the simulation is sufficiently good, manipulating RIs as though they are usual algebraic inequalities can often be justified. In particular, the following can be rigorously proved in in many situations.
- (1) Multiplication by a positive scalar on both sides is allowed.
 - (2) Inequalities can be summed.
 - (3) The inequalities are transitive.
 - (4) Substitution that preserves the inequalities is allowed. Operationally, this requires that simulations are accuracy enough to be composable, so that recursive/concatenated simulation is possible. In a related manner, cancellation (or subtraction) is frequently possible.

Now, we give an argument for Eq. (51). By the definition of two-way assisted channel capacity,

$$\mathcal{N} + \infty \text{CC}_{\leftrightarrow} \geq Q_2(\mathcal{N}) \mathcal{I}, \quad (56)$$

where $\infty \text{CC}_{\leftrightarrow}$ denotes the assistance. Using $\log d$ qubit noiseless channels to simulate \mathcal{M}_1 (see main text),

$$\log d \mathcal{I} \geq \mathcal{M}_1. \quad (57)$$

Together

$$\mathcal{N} + \infty \text{CC}_{\leftrightarrow} \geq Q_2(\mathcal{N}) \mathcal{I} \geq \frac{Q_2(\mathcal{N})}{\log d} \mathcal{M}_1. \quad (58)$$

It means that we can use n copies of \mathcal{N} to transmit $n \frac{Q_2(\mathcal{N})}{\log d}$ inputs to the receiver, who then applies copies of \mathcal{M}_1 locally thereby giving a protocol to simulate \mathcal{M}_1 using \mathcal{N} . Equation (49) means that

$$p_1 \mathcal{M}_1 + (1 - p_1) \mathcal{N} + \infty \text{CC}_{\leftarrow} \geq \mathcal{M}. \quad (59)$$

Using free back communication to generate n biased coins (see main text)

$$\left[p_1 \frac{\log d}{Q_2(\mathcal{N})} + (1 - p_1) \right] \mathcal{N} + \infty \text{CC}_{\leftrightarrow} \geq \mathcal{M}. \quad (60)$$

This implies

$$\left[p_1 \frac{\log d}{Q_2(\mathcal{N})} + (1 - p_1) \right] Q_2(\mathcal{N}) \geq Q_2(\mathcal{M}) \quad (61)$$

as claimed.
