We use the non-equilibrium Green function (NEGF) method in the ballistic limit to provide a quantitative description of the conductance of graphene pn junctions - an important building block for graphene electronics devices. In this paper, recent experiments on graphene junctions are explained by a ballistic transport model, but only if the finite junction transition width, D_w , is accounted for. In particular, the experimentally observed anomalous increase in the resistance asymmetry between nn and np junctions under low source/drain charge density conditions is also quantitatively captured by our model. In light of the requirement for sharp junctions in applications such as electron focusing, we also examine the pn junction conductance in the regime where D_w is small and find that wavefunction mismatch (so-called pseudo-spin) plays a major role in sharp pn junctions.

I. INTRODUCTION

Graphene is a two-dimensional sheet of carbon atoms arranged in a honeycomb lattice with unique electronic properties due to its linear energy dispersion, with zero bandgap, and a spinor-like two-component wavefunction [1, 2, 3]. These characteristics give rise to interesting transport phenomena such as the absence of backscattering [4], anomalies in the quantum Hall regime [2, 5], weak anti-localization [6, 7], so-called Klein tunneling [8], and electron focusing analogous to optical effects that occur in negative refractive index materials [9]. As such, one expects that graphene pn junctions should differ from traditional semiconductor pn junctions. The pn junction is a basic building block for electronic devices. Developing a quantitative understanding of graphene pn junctions is an important step on the way to realizing novel devices such as graphene lenses [9, 10] and filters [8]. Our goal in this paper is to demonstrate that the non-equilibrium Green's function (NEGF) approach [11] quantitatively explains recent experiments on graphene pn junctions, including the critical role of the junction depletion width and the increased in the odd resistance observed under low source/drain charge density conditions [12].

Electron transmission across a graphene pn junction occurs by interband tunneling. A theoretical treatment for an abrupt, graphene pn junction predicts that for a symmetric pn junction (i.e. one in which the hole and electron densities on each side of the junction are equal) the transmission probability is given by $\cos^2\theta$, where θ is the angle between the electron's wave-vector and the normal to the junction interface [8]. Realistic pn junctions will have a transition region of finite width. For

a smooth junction transition region of width D_w , the Wentzel Kramers Brillouin (WKB) approximation can be used to show that the transmission probability for a symmetric pn junction is $e^{-\pi k_f D_w \sin^2(\theta)/2}$ [13], where k_f is the Fermi wave-vector. Whether the transition region is abrupt or graded, the transmission is perfect when $\theta=0$ (i.e. commonly referred to as Klein tunneling), but the transmission decreases as θ and D_w increase. This angular selectivity for electron transport across the pn junction serves as a filter, allowing states with $|\theta| \leq \sigma_\theta$ (where σ_θ is the spread of the angular distribution) to pass through more effectively. The quantity $2\sigma_\theta$ can be viewed as the bandwidth of this filter and is what gives rise to the larger resistance of a pn junction as compared to a uniform graphene sheet.

Several research groups have recently fabricated graphene pnp devices by using electrostatic gates to create p and n regions [12, 14, 15, 16]. The typical setup consists of a back-gate and top-gate, which are used to control the amount of charge density in the source/drain and channel regions respectively. For example, the back gates can be set to produce n-type source and drain regions and the top gate can be biased to change the middle (channel) region from n to p type. An asymmetry in the device's source to drain resistance as a function of top-gate voltage has been experimentally observed [12]. The amount of this resistance asymmetry is a measure of the intrinsic property of the pn junction, provided that the mean free path of carriers is larger than the transition length of the junction. One can theoretically compute the junction's transition length accounting for non-linear screening effects [17]. For recent experiments [12], typical transition lengths for pn junction are less than $100nm$. Recent experiments indicate that the carrier's mean free path is about $100nm$ under low temperature and moderate carrier density conditions of $10^{12}cm^{-2}$ [18]. In addition, there is experimental evidence of Fabry-Perot inter-

*Electronic address: tonyaslow@gmail.com

ference effects within the channel region in devices with channel lengths less than $100nm$ [19, 20], evidently a signature of phase coherent transport. Therefore, a ballistic transport model is sufficient for the study of the experimental pn junction devices reported in [12].

In this paper, we present a quantitative study of the near-equilibrium IV characteristics of graphene pn junctions. In particular, we present a systematic study of the impact of the junction transition width, D_w , on the transport properties of graphene pn junctions. We use the non-equilibrium Green function (NEGF) approach with a nearest neighbor tight-binding description of graphene. This method allows us to accurately simulate the pn junction conductance for both abrupt and graded junctions under different bias conditions. The value of D_w is not known a priori because it depends on charge screening and the gate potential as governed by the Poisson equation. In this work, we employ the analytical screening model derived in [17]. Our numerical result based on the assumption of ballistic transport is in reasonable quantitative agreement with the experiments reported in [12]. As has been noted previously, we also found that the conductance follows an inverse square root dependence on D_w when D_w is large [13], but we find strong deviations from this trend occur when D_w is sufficiently small. Understanding this regime of operation has practical importance because devices based on the electron focusing property of graphene pn junctions, i.e. graphene lenses [9, 10] and filters [8], are expected to operate in this regime.

II. GRAPHENE PN JUNCTIONS AND RESISTANCE ASYMMETRY

Before describing the simulation method used in this study, we define some terms that will be used in subsequent discussions, present a simple picture of the conductance of a graphene npn or pnp junction, and identify the issues that will be addressed in the numerical study. Figure 1(a,b) are depictions of the energy band diagram for the experiment, which shows the location of the intersection of the conduction and valence bands (the so-called Dirac point) vs. position. A back gate controls the location of the Fermi level, E_f , in the source/drain regions. For $E_f > 0$ (above the Dirac point), there is an increase of electrons with respect to $E_f = 0$, the electron density is greater than zero, $n_1 > 0$, and the material is n-type. If the back gate is biased negative so that $E_f < 0$, then $n_1 < 0$ and the source/drain regions are p-type. Similarly, the channel (middle) region can be biased by a top gate to be either p-type ($n_2 < 0$) or n-type ($n_2 > 0$). The top gate also controls the built-in potential, V_{pn} , of the np/nn junction. Thus, appropriate top and bottom gate voltages can produce npn, nnn, pnp, or ppp structures. Near equilibrium conditions are assumed, so that the source and drain Fermi energies are the same. In this paper, we shall assume that the channel length is greater than

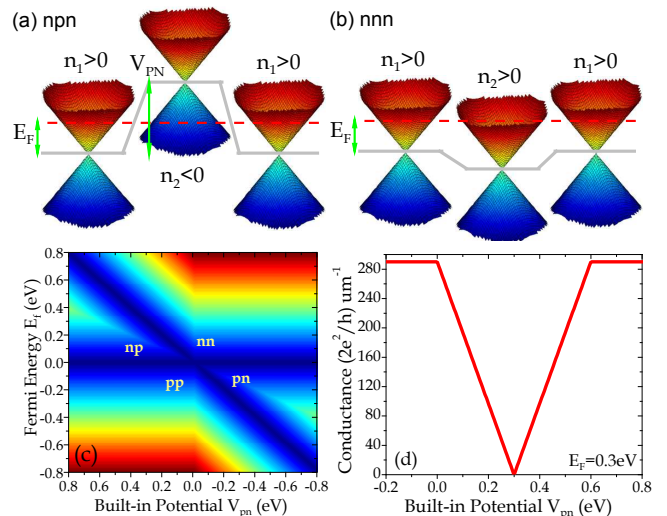

FIG. 1: The energy band diagram of graphene npn and nnn devices depicted in (a) and (b) respectively. (c) is an intensity plot of the pn junction conductance, σ_{pn} , as a function of E_f and V_{pn} using Eq. 1 and (d) plots σ_{pn} as a function of V_{pn} at $E_f = 0.3eV$ using Eq. 1.

the carrier's phase coherent length, allowing us to ignore wave interference effects within the channel. Therefore, we can reduce the problem by only studying the transport across a single pn junction.

As a first step to understanding the near-equilibrium conductance of a pn junction, σ_{pn} ($S/\mu m$), as a function of V_{pn} and E_f conditions, we adopt a simple density-of-states argument in the Landauer picture. In this simple analysis, σ_{pn} can be written in the following form,

$$\sigma_{pn} = \frac{2e^2}{Wh} \min(M_1, M_2) \quad (1)$$

where $M_{1/2}$ is the number of modes in the source/channel respectively and W is the device width. Eq. 1 mimics the matching of transverse momentum between the source and channel in a ballistic manner, such that the current will be limited by the region with the smaller number of modes. In this simple exercise, we assume a zero temperature treatment, so that $M_{1/2}$ refers to the number of modes at their respective E_f .

Figure 1(c) is an intensity plot of σ_{pn} computed using Eq. 1 versus V_{pn} and E_f . The dark blue lines are regions of low current. The horizontal line occurs when the source Fermi level is at the Dirac point. Since $n_1 = 0$, so no current flows. The diagonal black line described by $V_{pn} = E_f$ occurs when the channel region is adjusted to place the Dirac point in the channel at the Fermi energy of the carrier. Since $n_2 = 0$ along this diagonal line, no current flows. Very similar features are observed experimentally [12, 19]. Looking more closely, we can plot σ_{pn} vs. V_{pn} at a fixed $E_f = 0.3eV$. As shown in Fig. 1 (d), the conductance vs. V_{pn} is symmetrical about $V_{pn} = E_f$. In experiments, an asymmetry about $V_{pn} = E_f$ is observed [12, 19]. This asymmetry cannot be captured by simple density-of-states argument because its origin is quan-

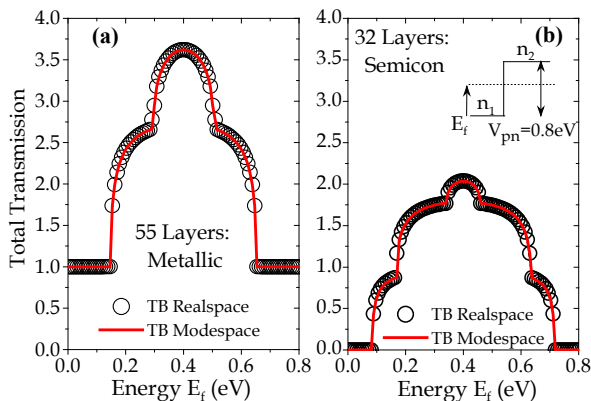

FIG. 2: Total transmission as a function of energy calculated for (a) 55 layers ($W \approx 13.7nm$) metallic armchair ribbons and (b) 32 layers ($W \approx 8nm$) semiconducting armchair ribbons transporting across a pn junction with a built-in potential of $V_{pn}=0.8eV$. In both cases, we compared the method outlined in our paper (solid line) with that of real-space tight-binding approach (open symbols).

tum mechanical in nature i.e. quantum tunneling and wavefunction mismatch. Our goal in this paper is to explain the role that quantum tunneling and wavefunction mismatch played in the observed asymmetry and then quantitatively explain the magnitude of the asymmetry observed in experiments.

III. SIMULATION METHODS

In this section, we briefly outline the NEGF formalism for quantum ballistic transport and describe its application to non-equilibrium transport [11, 21] through graphene pn junctions [36]. The central quantity in the theory is the retarded Green's function,

$$G(\epsilon, k_y) = [(\epsilon + i\delta)I - H(k_y) - U - \Sigma_l(\epsilon, k_y) - \Sigma_r(\epsilon, k_y)]^{-1} \quad (2)$$

where δ is an infinitesimal quantity in the channel region but is adjusted to provide a non-vanishing density-of-states at the Dirac point for the contact regions [22, 23]. The Hamiltonian is formulated by treating only nearest-neighbor interaction between the p_z orbitals [24, 25]. Assuming that the device width is large and homogeneous along the direction transverse to current flow, we can write the Hamiltonian as

$$H = \begin{bmatrix} \alpha & \beta_1 & & & \\ \beta_1^\dagger & \alpha & \beta_2 & & \\ & \beta_2^\dagger & \alpha & \ddots & \\ & & \ddots & \ddots & \ddots \end{bmatrix} \quad (3)$$

where α , β_1 and β_2 are all 2×2 matrices given by,

$$\alpha = \begin{bmatrix} 0 & t_c \\ t_c & 0 \end{bmatrix} \quad \beta_1 = \begin{bmatrix} 0 & 0 \\ t_y^\dagger & 0 \end{bmatrix} \quad \beta_2 = \begin{bmatrix} 0 & 0 \\ t_y & 0 \end{bmatrix} \quad (4)$$

where t_c is the nearest neighbor orbital coupling energy and $t_y = t_c + t_c e^{ik_y a_0}$. The lattice parameter, $a_0 = \sqrt{3}a_{cc}$

, where $a_{cc} = 1.44 \text{ \AA}$ is the c-c bond distance. The quantum number k_y is the quantized transverse momentum, to be elaborated upon in next paragraph. The contacts' self-energies, $\Sigma_i(\epsilon, k_y)$, are obtained by solving $\Sigma_i = \tau_i g_i \tau_i^\dagger$ where g_i is the surface green function associated with the contact. We should mention that for armchair ribbon an analytical closed form solution for g_i is possible, since the wavefunction is known, both in the tight-binding [26] and Dirac formalisms [27]. However, in our numerical treatment, we had employed a non-negligible δ in the contact regions, which prevent us from using the analytical closed form solution for g_i . Therefore, g_i is computed numerically with an iterative scheme proposed in [28]. Finally, the current through contact i can then be computed using,

$$I_i(\epsilon) = \frac{2q}{h} \sum_{k_y} \text{trace} \left[\Sigma_i^{in}(\epsilon) A(\epsilon) - \Gamma_i(\epsilon) G^n(\epsilon) \right] \quad (5)$$

where $A = i(G - G^\dagger)$ is the local density-of-states, $\Sigma_i^{in} = f_0(\epsilon) \Gamma_i(\epsilon)$ is the filling function (analogous to the in-scattering function for incoherent case), $f_0(\epsilon)$ is the Fermi function of the contacts, and $\Gamma_i = i(\Sigma_i - \Sigma_i^\dagger)$ is the contact broadening factor. In Eq. 5, $G^n(\epsilon)$ is the electron correlation function given by $G(\Sigma_l^{in} + \Sigma_r^{in})G^\dagger$. G and G^n are computed using the recursive green function algorithm through Dyson's equation [29], and making use of the fact that the Hamiltonian is tridiagonal in nature.

By assuming an armchair ribbon configuration and imposing a box-boundary condition and solving the Dirac equation, Brey and Fertig showed [27] that the transverse momentum is quantized according to

$$k_y = \left(\frac{2\pi}{3a_0} + \frac{2\pi n}{2W + a_0} \right) \pm \frac{2\pi}{3a_0} \quad (6)$$

for all integer n and W is the width of the device. The last term accounts for the momentum of the Dirac points, \vec{K} and \vec{K}' , where the upper/lower sign is used when n is even/odd respectively.

Treating the problem in terms of transverse modes greatly reduces the computation burden while still providing accurate results when the potential in the transverse direction is uniform [30, 31, 32]. This approach essentially translates a two-dimensional real space transport problem into m decoupled one-dimensional real space transport problem, where m is the number of relevant transverse modes. In the limit of large device width, W , we have $m \propto W\epsilon$. Fig. 2 compares this mode space method with two-dimensional real space NEGF calculations for a 55-layer metallic graphene ribbon and a 32-layer semiconducting ribbon. 'n-layer' refers to the number of layers of carbon atoms along the width direction, where $W = na_0$. In both cases, the two methods give nearly identical energy-resolved transmission functions for transport across a pn junction. The mode space approach has a computational burden that scales linearly with device width, which makes it possible to study typical experimental npn-type structures.

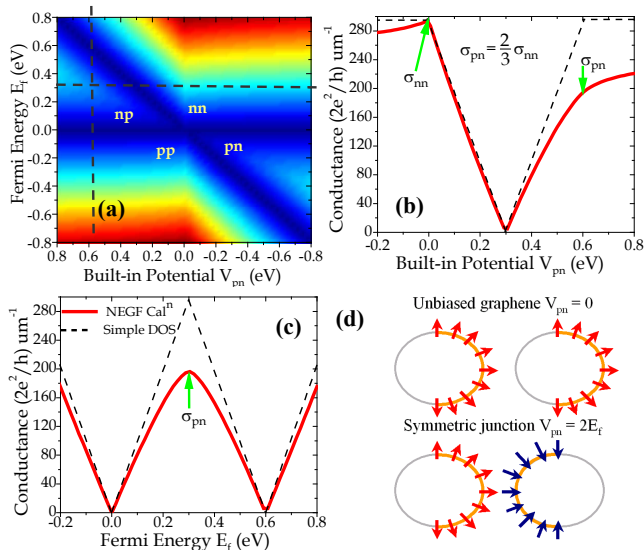

FIG. 3: Simulation results from NEGF calculation of an abrupt graphene pn junction with device width of $0.5\mu m$ at temperature of $4K$. (a) shows the intensity plot of conductance as function of built-in potential V_{pn} and Fermi energy E_f (see inset of figure 2(b) for definitions). Blue/red denotes low/high intensity respectively. (b) and (c) plots the conductance curves as function of V_{pn} (at $E_f=0.3eV$) and E_f (at $V_{pn}=0.6eV$) respectively. The dashed lines indicates the estimated conductance from a simple density-of-states argument (see text) for each case. In each case, the conductance of an unbiased graphene (σ_{nn}) and a symmetric pn junction (σ_{pn}) are indicated. (d) depicts the constant energy contour and its pseudo-spin alignment at each side of the junction for an unbiased graphene and a symmetric pn junction.

IV. RESULTS

As discussed in Sec. II, the experimental setup [12, 14, 15, 16] uses a back-gate and top-gate to control the source/drain contacts Fermi energy, E_f , and the potential difference across the pn junction, V_{pn} , respectively. The electron density in the source/drain regions is n_1 and in the channel, n_2 ; a negative value can be interpreted as a positive hole density. In this study, we assume that the applied source-drain bias is small, in accordance with experiments [12].

We shall also assume that the channel length is greater than the carrier's phase coherent length, allowing us to ignore any quantum interference effects within the channel i.e. Fabry Perot effects. On this premise, the transport process across a pn junction on one side of the channel would not be influenced by the presence of the pn junction on the other side of the channel. Hence, we shall focus only on the transport across a single pn junction. We begin by examining the pn junction's conductance (σ in units of $S/\mu m$) when the junction is abrupt i.e. $D_w \approx 0$.

A. Conductance for an Abrupt PN Junction

Fig. 3(a), which shows the computed conductance as function of E_f and V_{pn} for an abrupt pn junction, exhibits the features typically observed in experiments [12, 19]. The four distinctive regime of operations (i.e. nn, pp, np and pn) are partitioned by the $E_f=0$ and $E_f=V_{pn}$ lines, which correspond to conditions where either/both the contacts and channel are at zero equilibrium charge density as previously discussed in Se. II using simple density-of-states argument. Examining more closely, Fig. 3(b,c) plot the conductance as a function of V_{pn} ($E_f=0.3eV$) and E_f ($V_{pn}=0.6eV$) respectively. The red solid line is NEGF calculation while the dashed black line is calculated using Eq. 1. In Fig. 3(b), one can clearly see the conductance asymmetry with respect to the $V_{pn}=E_f$ point. This conductance asymmetry is an experimentally observed phenomena [12] which cannot be captured by a simple density-of-states argument.

Conductance asymmetry refers to the difference in conductance between a np junction and its nn counterpart. By 'counterpart', we mean that n_2 for np junction is $-n_2$ for nn junction, while n_1 is the same for both junctions. In Fig. 3(b), σ_{nn} is the conductance of an unbiased graphene (i.e. $V_{pn} = 0$), while σ_{pn} is the conductance of a symmetric np junction (i.e. $V_{pn} = 2E_f$). Clearly $\sigma_{nn} > \sigma_{pn}$, a feature that is observed experimentally and captured by our NEGF calculation. The asymmetry is due to wave-function mismatch at the junction interface.

Electrons in graphene have a two-component wave function, which is often referred to as pseudo-spin in analogy to the two-component wave function for spins. In the vicinity of the Dirac point, the two-dimensional Hamiltonian can be written in a form of Dirac equation [3, 4] i.e. $H = v_f \vec{\sigma} \cdot \vec{P}$, where $\vec{\sigma}$ and \vec{P} are the Pauli spin matrices and momentum operator respectively. By convention, the definition of pseudo-spin is such that its direction is parallel to the group velocity, since the group velocity operator is defined as $\vec{v}_G = \nabla_P H = v_f \vec{\sigma}$. Fig. 3(d) provides an illustration of the constant energy contour for an unbiased nn graphene and symmetric pn junction case. The arrows simultaneously represents the group velocity and pseudospin, which points inwards/outwards for the valence/conduction band respectively. For the nn case, the velocity vectors are similarly aligned for each side of the junction. For the pn case, \vec{v}_G changes sign across the junction. Analogous to spin, the wavefunction for the n and p regions can be expressed as $|\Psi_n\rangle = (1, e^{i\theta})/\sqrt{2}$ and $|\Psi_p\rangle = (1, e^{i(\theta+\pi)})/\sqrt{2}$ respectively (where $\theta = \tan^{-1}(k_y/k_f)$). The transmission probability across the junction for a particular mode can then be written simply as $|\langle \Psi_n | \Psi_p \rangle|^2$. For $k_y=0$, the wavefunction is perfectly matched i.e. $|\Psi_n\rangle = |\Psi_p\rangle$, so transmission is unity (i.e. Klein tunneling [8]). Through theoretical analysis, we derive $\sigma_{pn} = 2/3\sigma_{nn}$, where the factor of 2/3 is due to $\Sigma_{k_y}(1 - k_y^2/k_f^2)$. Similarly, it can also be shown that the conductance when $V_{pn} \rightarrow \infty$ would approach the asymptotic value of $\approx (1/2 + \pi/8)\sigma_{nn}$. Rig-

FIG. 4: **Analysis of the impact of junction width on conductance modulation of a symmetric pn junction.** (a) plots the energy-resolved local density-of-states (i.e. $G\Sigma^{in}G^\dagger$) for a $W=0.5\mu m$ pn junction device with a junction length of $D_w=50nm$ and a built-in potential $V_{pn}=0.5eV$. This is generated for the transverse mode with a transverse energy of $\epsilon_y \approx 0.075eV$, which yields an apparent ‘bandgap’ of $\approx 0.15eV$ as seen in the plot. $\epsilon = 0$ is set at the Dirac point of the source (b) is the intensity plot of the transmission as a function of incident angle θ and D_w . The device is a symmetric pn junction with $V_{pn}=2E_f$, where $E_f=0.3eV$. An illustration of the setup is shown in the inset. (c) plots the fraction of conductance contribution due to wavefunction mismatch, i.e. $\sigma_{pn}^{wf}/\sigma_{pn}$, for a symmetric pn junction (see Eq. 7).

orous NEGF calculations faithfully reproduces these features as shown in Fig. 3(b).

In summary, the conductance of an abrupt pn junction can be understood as being controlled by the region in which the number of conducting channels is smallest. Wavefunction mismatch reduces the current by a factor of $2/3$ in a symmetric np junction compared to an unbiased graphene. These features are captured by NEGF simulation, but realistic junctions have a finite transition width, D_w , which, as we emphasize in the following section, plays an important role.

B. Effect of Junction Width on Symmetric PN Junction Conductance

For realistic np junctions, the transition length across which the charge density changes monotonically from n-type to p-type is finite. The width of the junction transition region has a strong influence on the conductance of the junction. To understand these effects, it is instructive to consider each of the transverse modes individually. According to Eq. 6, for a wide graphene sheet, the transverse momentum with respect to the Dirac point is given by $k_y \approx n\pi/W$ where n is an integer. We can view each mode as a ray with an angle of incidence on the junction $\theta = \tan^{-1}[k_y(k_f^2 - k_y^2)^{-0.5}]$. Fig. 4(a) plots the energy-resolved local density-of-states ($G\Sigma^{in}G^\dagger$) for a pn junction with a transition length of $D_w=50nm$ and a built-in potential $V_{pn}=0.5eV$. Only one transverse mode with a transverse energy of $\hbar v_f k_y \approx 0.075eV$ is considered. The dark blue region correspond to a low density of states. Because of the quantization of transverse wavevectors, an apparent bandgap of $0.15eV$ is observed. Therefore, electrons at Fermi energy of $E_f < V_{pn}$ will have to quantum mechanically tunnel through this k_y -dependent

bandgap when moving from one side of the junction to the other. This problem is analogous to the classic band-to-band tunneling problem in direct band-gap semiconductors [33].

Based on this physical picture, Cheianov and Falko [13] worked out the WKB tunneling probability for a given transverse mode to be $e^{-\pi k_f D_w \sin^2(\theta)/2}$. This tunneling expression is derived by assuming a symmetric pn junction. In similar spirit to classic band-to-band tunneling treatment, the electric field across the pn junction is assumed to be linear, given by $2E_f/D_w$ in this work. Realistically, the potential energy landscape at the beginning/end of the pn junction would exhibit a more quadratic profile. However, only the details of the potential energy landscape within the tunneling region contributes to the WKB tunneling probability. In this linear electric field approximation, the tunneling distance is simply given by, $D_t = 2\hbar v_f k_y D_w / V_{pn}$. Fig. 4(b) shows the NEGF-computed electron transmission as a function of incident angle, θ , and transition length, D_w , for a symmetric pn junction with $E_f=0.3eV$. As expected, increasing D_w results in a decreased angular bandwidth ($2\sigma_\theta$) of the allowable transverse modes that can be transmitted across the pn junction, which subsequently leads to a decreased pn junction conductance. Based on the WKB tunneling formula, it can be shown that $\sigma_{pn} \propto \sqrt{k_f/D_w}$. This leads to the question of whether the junction rectification metric can be improved by using a larger D_w . Unfortunately, σ_{nn}/σ_{pn} which depends on D_w in an inverse square root manner, yields only a factor of 10 with $D_w \approx 100nm$ at a typical E_f of $0.3eV$.

Device concepts based on the electron focusing property of pn junction, i.e. graphene lenses [9, 10] and filters [8] operate best in a symmetric pn junction. These devices operate in a regime where σ_θ has to be as large as possible so as to reconstruct back a point source image

on the other side of the pn junction. This implies that D_w has to be sufficiently small to enhance tunneling at high incident angle. By accounting for both the wavefunction mismatch and tunneling factor in the following manner, $T(\theta) = \cos^2(\theta)e^{-\pi k_f D_w \sin^2(\theta)/2}$, we found that we are able reproduce the result of NEGF for arbitrary D_w (not shown). By integrating $T(\theta)$ over all transverse modes, we can arrive at a more general result for the conductance of a symmetric pn junction (in units of $2\frac{e^2}{h}$),

$$\sigma_{pn} = \frac{\sqrt{k_f}}{\sqrt{\pi\gamma D_w}} \text{erf}(\sqrt{\gamma D_w k_f}) + \frac{2}{\pi^2 D_w} e^{-\gamma D_w k_f} - \frac{\sqrt{2}}{\pi^2 \sqrt{k_f D_w^{1.5}}} \text{erf}(\sqrt{\gamma D_w k_f}) \quad (7)$$

where $\gamma = \pi/2$. The first term in Eq. 7 is due to the tunneling factor. The last two terms are corrections due to wavefunction mismatch. Eq. 7 can be written as $\sigma_{pn} = \sigma_{pn}^{tun} + \sigma_{pn}^{wfm}$. Fig. 4(c) is an intensity plot of $\sigma_{pn}^{wfm}/\sigma_{pn}$ as a function of E_f and D_w . The blue region represents $\sigma_{pn}^{tun} \gg \sigma_{pn}^{wfm}$ while the red regions indicate $\sigma_{pn}^{tun} \ll \sigma_{pn}^{wfm}$. Evidently, conductance modulation is predominantly due to wavefunction mismatch only when $\gamma D_w k_f < 1$, which suggests that for the tunneling component not to limit electron focusing applications, a $D_w < 5nm$ is required.

In summary, the conductance asymmetry of a graphene pn junction is due to two quantum mechanical processes, wavefunction mismatch and the need to tunnel through an apparent bandgap induced by the quantization of transverse momentum. Increasing D_w results in a decreased angular bandwidth ($2\sigma_\theta$) of the allowable transverse modes that can be transmitted across the pn junction. This leads to a decreased pn junction conductance and would eventually result in a larger magnitude of odd resistance R_{odd} .

C. Odd Resistance and Comparison With Experiments

Finally, we shall examine the odd resistance, R_{odd} , of pn junction devices and compare our NEGF result with the experimental data reported in [12]. Typically, the resistance asymmetry is characterized by analyzing the resistance of the device as a function of V_{pn} at a given E_f . A quantity known as odd resistance, R_{odd} , can be obtained by taking the difference between the resistance of the npn and its nnn **counterpart** device i.e. $R_{odd} = \frac{1}{2}[R_{nnpn} - R_{nnnn}]$, where the channel hole density for npn is equal to the electron density for nnn. Fig. 1(a,b) depicts the energy band of a typical npn device and its nnn **counterpart**. R_{odd} for a long channel device depends only on the odd resistance contribution from individual pn junctions. Essentially, R_{odd} simply reduces to $R_{odd} = [1/\sigma_{np} - 1/\sigma_{nn}]$ obtained by a simple sum of the resistance of the two adjacent pn junctions. As a first step, we shall investigate the contributions of wavefunction mismatch and quantum mechanical tunneling

FIG. 5: Theoretical resistance per unit width of a single pn junction as a function of V_{pn} at $E_f=0.1845eV$ under different D_w conditions (b) Comparison of NEGF and experimental odd resistance R_{odd} for different D_w plotting with respect to $n_2 - n_1$. Experimental device has $W=1.7\mu m$ with contacts Fermi energy also at $E_f=0.1845eV$.

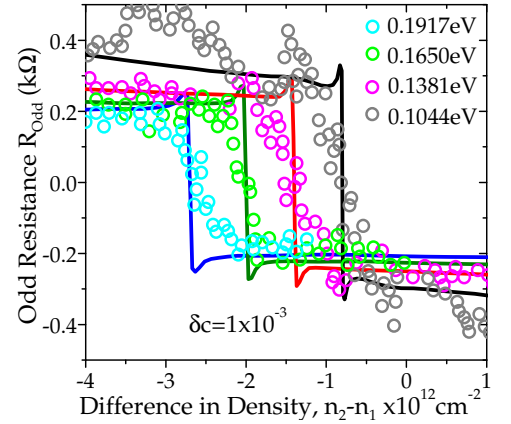

FIG. 6: Comparison of the NEGF simulated R_{Odd} with that of experimental results in [12] at different Fermi energies i.e. $E_f=0.1917, 0.165, 0.1381$ and $0.1044eV$. The device width is $1.7\mu m$ and operating temperature is $4K$. In the simulations, the contacts are assumed to have an energy broadening of $1meV$. The calculations assumed $\alpha=0.78$ due to a κ of 4.5 [12] and an oxide thickness of $T_{ox} \approx 80nm$ as a fitting parameter.

processes to the magnitude of R_{odd} . Fig. 5(a) shows the theoretical pn junction resistance as a function of V_{pn} at $E_f=0.1845eV$ under different D_w conditions. The odd resistance contribution due to wavefunction mismatch alone (i.e. $D_w=0$) does not adequately account for the R_{odd} observed in experiments as evident in Fig. 5(b). In fact, it only accounts for 10% of the R_{odd} . Accounting for finite D_w is essential to match the experimental data.

In our NEGF simulation, D_w is the parameter that we need to determine prior to our NEGF calculations. The determination of D_w is an electrostatics problem which is sensitive to the specific device geometry. In this work, we used the model presented in [17], which expresses D_w in terms of n_1 and n_2 as follows,

$$D_w \approx 0.196 \times \frac{V_{pn}}{\hbar v_f \alpha^{1/3}} \left(1 - \frac{n_2}{n_1}\right)^{4/3} \left|\frac{T_{ox}}{n_2}\right|^{2/3} \quad (8)$$

where $\alpha = e^2 / (\kappa \hbar v_f)$. κ and T_{ox} are the effective dielectric

constant and thickness of the oxide between the top gate and graphene device respectively[37].

Fig. 6 shows the computed R_{odd} at different E_f conditions as a function of $n_1 - n_2$ and its comparison with experimental data. The NEGF result achieves quantitative agreement with the experimentally observed odd resistance. In particular, the increase in odd resistance with decreasing E_f , a puzzling feature in the experiments [12], is captured by the simulations. This occurs because of the increasing D_w with decreasing E_f i.e. smaller n_1 which results in an increase of pn junction screening length. We note conductance oscillations at the smallest E_f . These oscillations are likely due to interference effects within the device channel, which are more pronounced at $E_f=0.1eV$ due to the large D_w which leads to an effectively shorter channel length. The ‘spikes’ observed in the NEGF simulations when R_{odd} crosses zero are due to the zero density-of-states at Dirac point. Such spikes are not observed in the experiments, probably due to the presence of spatial fluctuations (electron-hole puddles) when E_f approaches the Dirac point [34]. By construction, our NEGF model does not account for these electron/hole puddles.

V. CONCLUSIONS

In this paper we presented a numerical study of electron transport in graphene pn junctions. We first pre-

sented a very simple minimum density-of-states (or conducting channels) model to account for the overall shape of the conductance vs. source carrier density and junction potential. Such a simple model does not capture the resistance asymmetry observed experimentally. We then use NEGF simulation to explore in detail the role of wave-function mismatch (also called pseudo-spin) and quantum mechanical tunneling through the junction transition region. In particular, we examined deviations from the inverse square root dependence of σ_{pn} on D_w due to wave-function mismatch at small D_w . Finally, we compared the simulations to a recent experiment and showed that the numerical model is in reasonable agreement with experiments and explain the increase in odd resistance with decreasing carrier density in the source. The novel features of graphene’s electronic structure lead to interesting possibilities for new devices, and this study shows that NEGF simulation should provide a useful tool to explore and assess device concepts.

Acknowledgement We gratefully acknowledge support of the Nanoelectronic Research Initiative and the Network for Computational Nanotechnology. We also acknowledge Prof Jing Guo for useful discussions on NEGF simulation by mode-space methods [32] and Srikant Srinivasan for useful discussions and comments on this work.

- [36] Note that we are using the NEGF method in the ballistic limit where it is equivalent to the Landauer approach, as explained in chapter 8 of [11].
- [37] We shall also briefly discuss the validity of the analytical non-linear screening model of Eq. 8. As discussed in [17], the accuracy of the analytical model is dependent on the physical parameter α . The model would yield a possible deviation from numerical results of $\approx 25\%$ when $\alpha \approx 0.9$ at the charge neutrality point within the transition region. We emphasize that the error is of an oscillatory nature with the oscillation amplitude deteriorating when it moves away from the charge neutrality point. This would serve to alleviate the average error. While on the other limit, $\alpha \approx 0.1$ yields an excellent agreement with the numerical result. In the set of experiments we studied in this manuscript, $\alpha \approx 0.78$ due to a $\kappa \approx 4.5$. Therefore, the average error is intermediate of these two limits. However, when α is large (approaching 1), one would need to also account for electron exchange and correlation effects (see e.g. [35]), making the problem numerically non-tractable.
