# Combinatorial study on the group of parity alternating 

 permutationsShinji Tanimoto<br>Department of Mathematics, University of Kochi, Kochi 780-8515, Japan*.

#### Abstract

The combinatorial theory for the set of parity alternating permutations is expounded. In view of the numbers of ascents and inversions, several enumerative aspects of the set are investigated. In particular, it is shown that signed Eulerian numbers have intimate relationships to the set.

## 1. Introduction

Let $n$ be a positive integer. A permutation of the set $[n]=\{1,2, \ldots, n\}$ will be called a parity alternating permutation (PAP), if its entries assume even and odd integers alternately, such as 72581634 or 1452763 . It is readily checked that such permutations form a subgroup of the symmetric group, $\mathcal{S}_{n}$, of degree $n$ and it will be denoted by $\mathcal{P}_{n}$. The objective of this paper is to study combinatorial properties of permutations in $\mathcal{P}_{n}$ with respect to permutation statistics.

The extreme ends $a_{1}$ and $a_{n}$ in a PAP $\xi=a_{1} a_{2} \cdots a_{n}$ are both odd, when $n$ is odd. Hence the cardinality $\left|\mathcal{P}_{n}\right|$ is equal to

$$
\left(\frac{n+1}{2}\right)!\left(\frac{n-1}{2}\right)!=\frac{n+1}{2}\left(\left(\frac{n-1}{2}\right)!\right)^{2}
$$

when $n$ is odd, while it is equal to

$$
2\left(\left(\frac{n}{2}\right)!\right)^{2}
$$

when $n$ is even, because there are two possibilities; either even $a_{1}$ or odd $a_{1}$.
Let $\xi=a_{1} a_{2} \cdots a_{n}$ be a permutation of $[n]$. An ascent of $\xi$ is an adjacent pair such that $a_{i}<a_{i+1}$ for some $i(1 \leq i \leq n-1)$. Let $\mathcal{S}_{n, k}$ be the set of all permutations of [ $n$ ] with exactly $k$ ascents, where $0 \leq k \leq n-1$. Its cardinality, $\left|\mathcal{S}_{n, k}\right|$, is the classical Eulerian number (see [1] or [3]). In relation to it let us define the set of PAPs with $k$ ascents by

$$
\mathcal{P}_{n, k}=\mathcal{P}_{n} \cap \mathcal{S}_{n, k}
$$

For our study of $\mathcal{P}_{n, k}$ we will make use of an operator introduced in [4]. It is useful for a study of permutations in view of the ascent number (see [4-7]). The operator $\sigma$ is defined by adding one to all entries of a permutation $a_{1} a_{2} \cdots a_{n}$ of $[n]$, but by changing $n+1$ into one. However, when $n$ appears at either end of a permutation, it is removed and one is put at the other end. To be more precise, we define as follows.

[^0](a) $\sigma\left(a_{1} a_{2} \cdots a_{n}\right)=b_{1} b_{2} \cdots b_{n}$, where $b_{i}=a_{i}+1$ for $1 \leq i \leq n$ and $n+1$ is replaced by one at the position, i.e., $b_{i}=1$, when $a_{i}=n$ for $2 \leq i \leq n-1$.
(b) $\sigma\left(a_{1} \cdots a_{n-1} n\right)=1 b_{1} b_{2} \cdots b_{n-1}$, where $b_{i}=a_{i}+1$ for $1 \leq i \leq n-1$.
(c) $\sigma\left(n a_{1} \cdots a_{n-1}\right)=b_{1} b_{2} \cdots b_{n-1} 1$, where $b_{i}=a_{i}+1$ for $1 \leq i \leq n-1$.

This operator is a bijection on $\mathcal{S}_{n}$ and preserves the number of ascents of permutations, as is easily observed. Hence it becomes a bijection on $\mathcal{S}_{n, k}$ onto itself for each ascent number $k$. For a permutation $\xi$ and a positive integer $\ell$, we denote successive applications of $\sigma$ by $\sigma^{\ell} \xi=\sigma\left(\sigma^{\ell-1} \xi\right), \sigma^{0}$ being the identity operator on permutations.

It is easy to see that in the case of even $n$ the operator $\sigma$ is also a bijection on $\mathcal{P}_{n, k}$ onto itself. When $n$ is odd, however, this is not the case. Taking a PAP $\xi=1476523$, for example, $\sigma \xi=2517634$ is not a PAP. The following table shows the cardinalities $\left|\mathcal{P}_{n, k}\right|$ for small $n$, the top row being the ascent number $k$.

| $\left\|\mathcal{P}_{n, k}\right\|$ | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
| :--- | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: | ---: |
| $n=2$ | 1 | 1 |  |  |  |  |  |  |  |  |
| $n=3$ | 1 | 0 | 1 |  |  |  |  |  |  |  |
| $n=4$ | 1 | 3 | 3 | 1 |  |  |  |  |  |  |
| $n=5$ | 1 | 2 | 6 | 2 | 1 |  |  |  |  |  |
| $n=6$ | 1 | 9 | 26 | 26 | 9 | 1 |  |  |  |  |
| $n=7$ | 1 | 8 | 39 | 48 | 39 | 8 | 1 |  |  |  |
| $n=8$ | 1 | 23 | 165 | 387 | 387 | 165 | 23 | 1 |  |  |
| $n=9$ | 1 | 22 | 228 | 674 | 1030 | 674 | 228 | 22 | 1 |  |
| $n=10$ | 1 | 53 | 860 | 4292 | 9194 | 9194 | 4292 | 860 | 53 | 1 |

For permutations $\xi=a_{1} a_{2} \cdots a_{n}$ we can define an involution operator by $\xi^{*}=a_{n} \cdots a_{2} a_{1}$, i.e., $\xi^{* *}=\xi$. If $\xi$ has $k$ ascents, then $\xi^{*}$ has $n-1-k$ ascents, for $\xi$ has $n-1$ adjacent pairs.

An inversion of a permutation $\xi=a_{1} a_{2} \cdots a_{n}$ is a pair $(i, j)$ such that $1 \leq i<j \leq n$ and $a_{i}>a_{j}$. Let us denote by $\operatorname{inv}(\xi)$ the number of inversions in $\xi$. A permutation is called even or odd if it has an even or odd number of inversions, respectively. We observe the number of inversions of a permutation when $\sigma$ is applied. When $n$ appears at either end of a permutation $\xi$ as in (b) or (c), it is evident that

$$
\operatorname{inv}(\sigma \xi)=\operatorname{inv}(\xi)
$$

As for the case (a), i.e., $a_{i}=n$ for some $i(2 \leq i \leq n-1)$, we get $\sigma\left(a_{1} a_{2} \cdots a_{n}\right)=b_{1} b_{2} \cdots b_{n}$ and $b_{i}=1$. In this case, $n-i$ inversions $(i, i+1), \ldots,(i, n)$ of $\xi$ vanish and, in turn, $i-1$ inversions $(1, i), \ldots,(i-1, i)$ of $\sigma \xi$ occur. Hence the difference between the numbers of inversions is given by

$$
\begin{equation*}
\operatorname{inv}(\sigma \xi)-\operatorname{inv}(\xi)=(i-1)-(n-i)=2 i-(n+1) . \tag{1}
\end{equation*}
$$

This means that, when $n$ is even, each application of the operator $\sigma$ changes the parity of permutations as long as $n$ remains in the interior of permutations. If $n$ is odd, however, the operator also preserves the parity of all permutations of $[n]$.

A signed Eulerian number is the difference of the numbers of even permutations and odd ones in $\mathcal{S}_{n, k}$, which is denoted by $d_{n, k}$. Namely, letting $\mathcal{S}_{n, k}^{\mathrm{e}}$ and $\mathcal{S}_{n, k}^{\circ}$ be the sets of even permutations and odd ones in $\mathcal{S}_{n, k}$, respectively, it is defined by

$$
d_{n, k}=\left|\mathcal{S}_{n, k}^{e}\right|-\left|\mathcal{S}_{n, k}^{\circ}\right| .
$$

As was shown in [2], the recurrence relation for signed Eulerian numbers is given by

$$
d_{n, k}= \begin{cases}(n-k) d_{n-1, k-1}+(k+1) d_{n-1, k}, & \text { if } n \text { is odd, }  \tag{2}\\ d_{n-1, k-1}-d_{n-1, k}, & \text { if } n \text { is even }\end{cases}
$$

with initial condition $d_{1,0}=1$.

## 2. Enumerative properties of $\mathcal{P}_{n}$ for even $n$

In this section we assume that $n$ is an even positive integer and we derive several enumerative properties of $\mathcal{P}_{n, k}$ of parity alternating permutations with $k$ ascents. We subdivide the set $\mathcal{P}_{n, k}$ into the following four classes. We denote by $\mathcal{E}_{n, k}^{\uparrow}\left(\right.$ or $\left.\mathcal{E}_{n, k}^{\downarrow}\right)$ the set of permutations $a_{1} a_{2} \cdots a_{n} \in \mathcal{P}_{n, k}$ such that $a_{1}$ is even and $a_{n}>a_{1}$ (or $a_{n}<a_{1}$ ). Similarly we denote by $\mathcal{O}_{n, k}^{\uparrow}$ (or $\mathcal{O}_{n, k}^{\downarrow}$ ) the set of permutations $a_{1} a_{2} \cdots a_{n} \in \mathcal{P}_{n, k}$ such that $a_{1}$ is odd and $a_{n}>a_{1}$ (or $a_{n}<a_{1}$ ).

According to (a)-(c) it is easily shown that $\sigma$ maps $\mathcal{P}_{n, k}^{\uparrow}=\mathcal{O}_{n, k}^{\uparrow} \cup \mathcal{E}_{n, k}^{\uparrow}$ onto $\mathcal{P}_{n, k}^{\uparrow}$. It also maps $\mathcal{P}_{n, k}^{\downarrow}=\mathcal{O}_{n, k}^{\downarrow} \cup \mathcal{E}_{n, k}^{\downarrow}$ onto $\mathcal{P}_{n, k}^{\downarrow}$. Note that $\mathcal{P}_{n, k}=\mathcal{P}_{n, k}^{\uparrow} \cup \mathcal{P}_{n, k}^{\downarrow}$, whose cardinality is denoted by $\left|\mathcal{P}_{n, k}\right|$.

As was shown in [4], to each permutation $\xi$ of $[n]$ there corresponds a smallest positive integer $\ell$ such that $\sigma^{\ell} \xi=\xi$, which is the period of $\xi$ and denoted by $\pi(\xi)$. Its trace

$$
\left\{\sigma \xi, \sigma^{2} \xi, \ldots, \sigma^{\pi(\xi)} \xi=\xi\right\}
$$

is called the orbit of $\xi$.
For an even $n, \xi \in \mathcal{P}_{n, k}^{\uparrow}$ holds if and only if $\sigma \xi \in \mathcal{P}_{n, k}^{\uparrow}$, and $\xi \in \mathcal{P}_{n, k}^{\downarrow}$ holds if and only if $\sigma \xi \in \mathcal{P}_{n, k}^{\downarrow}$. Therefore, we can consider orbits both in $\mathcal{P}_{n, k}^{\uparrow}$ and in $\mathcal{P}_{n, k}^{\downarrow}$ under $\sigma$. Permutations of the form $a_{1} a_{2} \cdots a_{n-1} n \in \mathcal{P}_{n, k}^{\uparrow}$ are called canonical. Similarly, permutations of the form $n a_{1} a_{2} \cdots a_{n-1} \in \mathcal{P}_{n, k}^{\downarrow}$ are also called canonical. Alternatively though equivalently, in view of (a)-(c), we could call those permutations of the forms $1 a_{1} a_{2} \cdots a_{n-1}$ and $a_{1} a_{2} \cdots a_{n-1} 1$ canonical as in [4]. It is proved in [4, Theorem 6] that the period $\pi(\xi)$ satisfies the relation

$$
\begin{equation*}
\pi(\xi)=(n-k) \operatorname{gcd}(n, \pi(\xi)), \tag{3}
\end{equation*}
$$

for $\xi \in \mathcal{P}_{n, k}^{\uparrow}$.
From the properties (a) and (b) of $\sigma$ we see that orbits of permutations of $\mathcal{P}_{n, k}^{\uparrow}$ contain canonical ones $a_{1} a_{2} \cdots a_{n-1} n$, where $a_{1} a_{2} \cdots a_{n-1}$ are permutations of $[n-1]$. The next theorem plays a fundamental role in enumerating PAPs with given ascent number. The procedure is analogous to [5], where classical Eulerian numbers $\left|\mathcal{S}_{n, k}\right|$ are discussed.

Theorem 1. Let $n$ be an even integer and $k$ be such that $1 \leq k \leq n-1$. Then it follows that

$$
\begin{gathered}
\left|\mathcal{P}_{n, k}^{\uparrow}\right|=(n-k)\left|\mathcal{P}_{n-1, k-1}\right|, \quad\left|\mathcal{P}_{n, k}^{\downarrow}\right|=(k+1)\left|\mathcal{P}_{n-1, k}\right| ; \\
\left|\mathcal{P}_{n, k}\right|=(n-k)\left|\mathcal{P}_{n-1, k-1}\right|+(k+1)\left|\mathcal{P}_{n-1, k}\right| .
\end{gathered}
$$

Proof. Considering the orbit of $\xi \in \mathcal{P}_{n, k}^{\uparrow}$ under $\sigma$, it follows from (3) that its period is of the
form $d(n-k)$, where $d=\operatorname{gcd}(n, \pi(\xi))$ is a divisor of $n$. For a divisor $d$ of $n$, we denote by $\alpha_{d}^{k}$ the number of orbits with period $d(n-k)$ in $\mathcal{P}_{n, k}^{\uparrow}$. There exist $n$ canonical permutations in $\left\{\sigma \xi, \sigma^{2} \xi, \ldots, \sigma^{n(n-k)} \xi=\xi\right\}$ due to [4, Corollary 2], and hence each orbit

$$
\left\{\sigma \xi, \sigma^{2} \xi, \ldots, \sigma^{d(n-k)} \xi=\xi\right\}
$$

of $\xi$ with period $d(n-k)$ contains exactly $d$ canonical permutations. This follows from the fact that the latter repeats itself $n / d$ times in the former. The number of all canonical permutations in $\mathcal{P}_{n, k}^{\uparrow}$ is equal to $\left|\mathcal{P}_{n-1, k-1}\right|$, since canonical permutations are represented as $a_{1} a_{2} \cdots a_{n-1} n$, where $a_{1} a_{2} \cdots a_{n-1}$ are permutations of $\mathcal{P}_{n-1, k-1}$. Since there exist $\alpha_{d}^{k}$ orbits with period $d(n-k)$ for each divisor $d$ of $n$, classifying all canonical permutations of $\mathcal{P}_{n, k}^{\uparrow}$ into orbits leads us to

$$
\begin{equation*}
\left|\mathcal{P}_{n-1, k-1}\right|=\sum_{d \mid n} d \alpha_{d}^{k} \tag{4}
\end{equation*}
$$

Using the numbers of orbits and periods, we see that the cardinality of $\mathcal{P}_{n, k}^{\uparrow}$ is given by

$$
\begin{equation*}
\left|\mathcal{P}_{n, k}^{\uparrow}\right|=\sum_{d \mid n} d(n-k) \alpha_{d}^{k}=(n-k) \sum_{d \mid n} d \alpha_{d}^{k}=(n-k)\left|\mathcal{P}_{n-1, k-1}\right| . \tag{5}
\end{equation*}
$$

Next consider the set of all permutations $\xi=a_{1} a_{2} \cdots a_{n} \in \mathcal{P}_{n, k}^{\downarrow}$, i.e., $a_{1}>a_{n}$. For such $\xi=a_{1} a_{2} \cdots a_{n}$ let us define the involution $\xi^{*}=a_{n} \cdots a_{2} a_{1}$. Then the set $\mathcal{P}_{n, k}^{\downarrow}$ is converted to $\mathcal{P}_{n, n-k-1}^{\uparrow}$ by the involution. Therefore, using (5), its cardinality is

$$
\begin{equation*}
\left|\mathcal{P}_{n, k}^{\downarrow}\right|=\left|\mathcal{P}_{n, n-k-1}^{\uparrow}\right|=(k+1)\left|\mathcal{P}_{n-1, n-k-2}\right|=(k+1)\left|\mathcal{P}_{n-1, k}\right|, \tag{6}
\end{equation*}
$$

since the involution operator $*$ is a bijection from $\mathcal{P}_{n-1, n-k-2}$ into $\mathcal{P}_{n-1, k}$.
Since all permutations $a_{1} a_{2} \cdots a_{n}$ of $\mathcal{P}_{n, k}$ are divided in two classes according to $a_{1}<a_{n}$ or $a_{1}>a_{n}$. Therefore, by adding (5) and (6), we obtain

$$
\left|\mathcal{P}_{n, k}\right|=(n-k)\left|\mathcal{P}_{n-1, k-1}\right|+(k+1)\left|\mathcal{P}_{n-1, k}\right| .
$$

This completes the proof.
It is interesting to observe that the last recurrence relation holds only for even $n$, although such a relation is valid for classical Eulerian numbers $\left|\mathcal{S}_{n, k}\right|$ independently of the parity of $n$ (see $[1,3])$.

Theorem 2. Let $n$ be an even integer and $k$ be such that $1 \leq k \leq n-1$. Then it follows that

$$
\left|\mathcal{O}_{n, k}^{\uparrow}\right|=\left|\mathcal{E}_{n, k}^{\uparrow}\right|+\left|\mathcal{P}_{n-1, k-1}\right|, \quad\left|\mathcal{E}_{n, k}^{\downarrow}\right|=\left|\mathcal{O}_{n, k}^{\downarrow}\right|+\left|\mathcal{P}_{n-1, k}\right|
$$

Proof. We consider the image of $\mathcal{O}_{n, k}^{\uparrow}$ under the operator $\sigma$. Permutations $\xi=a_{1} a_{2} \cdots a_{n}$ in $\mathcal{O}_{n, k}^{\uparrow}$ begin with odd entries $a_{1}$ and end with $a_{n}\left(>a_{1}\right)$. Since $\sigma$ preserves the ascent number, property (a) of $\sigma$ implies that the image includes all permutations of $\mathcal{E}_{n, k}^{\uparrow}$ that begin with even entries. Moreover, it also includes permutations of the form $1 b_{1} b_{2} \cdots b_{n-1}$, which are images of $a_{1} a_{2} \cdots a_{n-1} n \in \mathcal{O}_{n, k}^{\uparrow}$ by $\sigma$ (see (b) of Section 1). Then the permutation $\left(b_{1}-1\right)\left(b_{2}-1\right) \cdots\left(b_{n-1}-1\right)$ that is obtained
by subtracting one from each entry of $b_{1} b_{2} \cdots b_{n-1}$ is a PAP of $[n-1]$ and has ascents $k-1$. The number of such permutations is equal to $\left|\mathcal{P}_{n-1, k-1}\right|$. Hence we have

$$
\left|\mathcal{O}_{n, k}^{\uparrow}\right|=\left|\mathcal{E}_{n, k}^{\uparrow}\right|+\left|\mathcal{P}_{n-1, k-1}\right|
$$

Similarly, we consider the image of $\mathcal{E}_{n, k}^{\downarrow}$ under the operator $\sigma$. Permutations $\xi=a_{1} a_{2} \cdots a_{n}$ in $\mathcal{E}_{n, k}^{\downarrow}$ begin with even entries $a_{1}$ and end with $a_{n}\left(<a_{1}\right)$. Since $\sigma$ preserves the ascent number, property (a) of $\sigma$ implies that the image includes all permutations of $\mathcal{O}_{n, k}^{\downarrow}$ that begin with odd entries. Moreover, it also includes permutations of the form $b_{1} b_{2} \cdots b_{n-1} 1$, which are images of $n a_{1} a_{2} \cdots a_{n-1} \in \mathcal{E}_{n, k}^{\downarrow}$ by $\sigma$ (see (c) of Section 1$)$. Then the permutation $\left(b_{1}-1\right)\left(b_{2}-1\right) \cdots\left(b_{n-1}-1\right)$ is a PAP of $[n-1]$ and has the same ascents $k$. The number of such permutations is equal to $\left|\mathcal{P}_{n-1, k}\right|$. Hence we have

$$
\left|\mathcal{E}_{n, k}^{\downarrow}\right|=\left|\mathcal{O}_{n, k}^{\downarrow}\right|+\left|\mathcal{P}_{n-1, k}\right|
$$

This completes the proof.

Combining Theorems 1 and 2 yields the following Corollary.

Corollary 3. The cardinalities of the above four sets are given by

$$
\begin{aligned}
\left|\mathcal{O}_{n, k}^{\uparrow}\right|=\frac{(n-k+1)\left|\mathcal{P}_{n-1, k-1}\right|}{2}, & \left|\mathcal{E}_{n, k}^{\uparrow}\right|=\frac{(n-k-1)\left|\mathcal{P}_{n-1, k-1}\right|}{2} \\
\left|\mathcal{E}_{n, k}^{\downarrow}\right|=\frac{(k+2)\left|\mathcal{P}_{n-1, k}\right|}{2}, & \left|\mathcal{O}_{n, k}^{\downarrow}\right|=\frac{k\left|\mathcal{P}_{n-1, k}\right|}{2}
\end{aligned}
$$

Proof. Since $\left|\mathcal{P}_{n, k}^{\uparrow}\right|=\left|\mathcal{O}_{n, k}^{\uparrow}\right|+\left|\mathcal{E}_{n, k}^{\uparrow}\right|=(n-k)\left|\mathcal{P}_{n-1, k-1}\right|$ by Theorem 1, we obtain

$$
(n-k)\left|\mathcal{P}_{n-1, k-1}\right|=2\left|\mathcal{E}_{n, k}^{\uparrow}\right|+\left|\mathcal{P}_{n-1, k-1}\right|
$$

by Theorem 2 , which leads us to

$$
\left|\mathcal{E}_{n, k}^{\uparrow}\right|=\frac{(n-k-1)\left|\mathcal{P}_{n-1, k-1}\right|}{2}, \quad\left|\mathcal{O}_{n, k}^{\uparrow}\right|=\frac{(n-k+1)\left|\mathcal{P}_{n-1, k-1}\right|}{2}
$$

Similarly, Since $\left|\mathcal{P}_{n, k}^{\downarrow}\right|=\left|\mathcal{E}_{n, k}^{\downarrow}\right|+\left|\mathcal{O}_{n, k}^{\downarrow}\right|=(k+1)\left|\mathcal{P}_{n-1, k}\right|$ by Theorem 1, we obtain

$$
(k+1)\left|\mathcal{P}_{n-1, k}\right|=2\left|\mathcal{O}_{n, k}^{\downarrow}\right|+\left|\mathcal{P}_{n-1, k}\right|
$$

by Theorem 2, which implies

$$
\left|\mathcal{O}_{n, k}^{\downarrow}\right|=\frac{k\left|\mathcal{P}_{n-1, k}\right|}{2}, \quad\left|\mathcal{E}_{n, k}^{\downarrow}\right|=\frac{(k+2)\left|\mathcal{P}_{n-1, k}\right|}{2}
$$

This completes the proof.

Just as classical Eulerian numbers $\left|\mathcal{S}_{n, k}\right|$ are divisible by some prime powers under certain conditions (see [5, Theorem 7]), we will show that several cardinalities related to $\mathcal{P}_{n, k}$ or $\mathcal{P}_{n-1, k}$ can be divided by some prime powers under the same conditions.

Theorem 4. Suppose that $p$ is a prime and an even integer $n$ is divisible by $p^{m}$ for a positive integer $m$. If $k$ is divisible by $p$, then $\left|\mathcal{P}_{n-1, k-1}\right|$ is divisible by $p^{m}$ and $\left|\mathcal{P}_{n, k}^{\uparrow}\right|$ is divisible by $p^{m+1}$. If $k+1$ is divisible by $p$, then $\left|\mathcal{P}_{n, k}^{\downarrow}\right|$ is divisible by $p^{m+1}$.

Proof. We denote by $\alpha_{d}^{k}$ the number of orbits with period $d(n-k)$ in $\mathcal{P}_{n, k}^{\uparrow}$, as in the proof of Theorem 1. Without loss of generality we can assume that $m$ is the largest integer for which $p^{m}$ divides $n$. Suppose $k$ is a multiple of $p$. From (3) the period of a permutation $\xi \in \mathcal{P}_{n, k}^{\uparrow}$ satisfies $\pi(\xi)=d(n-k)$, where $d=\operatorname{gcd}(n, \pi(\xi))$. Hence we get $d=\operatorname{gcd}(n, d(n-k))$ and $\operatorname{gcd}(n / d, n-k)=1$. This implies that $\operatorname{gcd}(k, n / d)=1$ holds. In other words, $\alpha_{d}^{k}=0$ for any divisor $d$ of $n$ such that $\operatorname{gcd}(k, n / d)>1$. Moreover, a divisor $d$ with $\operatorname{gcd}(k, n / d)=1$ must be a multiple of $p^{m}$, since $k$ is a multiple of $p$. Therefore, equality (4) implies that $\left|\mathcal{P}_{n-1, k-1}\right|$ is divisible by $p^{m}$. Theorem 1 tells us that $\left|\mathcal{P}_{n, k}^{\uparrow}\right|=(n-k)\left|\mathcal{P}_{n-1, k-1}\right|$. Since $n$ and $k$ are multiples of $p$ by the assumption, $\left|\mathcal{P}_{n, k}^{\uparrow}\right|$ is divisibles by $p^{m+1}$. Since $\left|\mathcal{P}_{n, k}^{\downarrow}\right|=(k+1)\left|\mathcal{P}_{n-1, k}\right|$ holds from Theorem 1, it is also divisible by $p^{m+1}$, when $k+1$ is a multiple of $p$. This follows from the fact that $\left|\mathcal{P}_{n-1, k}\right|$ is divisible by $p^{m}$ when $k+1$ is a multiple of $p$.

Using Corollary 3 , similar arguments imply the following result.
Corollary 5. Suppose that $p$ is an odd prime and an even integer $n$ is divisible by $p^{m}$ for a positive integer $m$. If $k$ is divisible by $p$, then $\left|\mathcal{O}_{n, k}^{\uparrow}\right|$ and $\left|\mathcal{E}_{n, k}^{\uparrow}\right|$ are divisible by $p^{m}$. If $k+1$ is divisible by $p$, then $\left|\mathcal{O}_{n, k}^{\downarrow}\right|$ and $\left|\mathcal{E}_{n, k}^{\downarrow}\right|$ are divisible by $p^{m}$.

## 3. Signed Eulerian numbers

Let $\mathcal{P}_{n, k}^{\mathrm{e}}$ and $\mathcal{P}_{n, k}^{\mathrm{o}}$ be the sets of even permuations and odd ones in $\mathcal{P}_{n, k}$, respectively. The signed Eulerian number introduced in Section 1 is defined by the difference of classical Eulerian numbers

$$
d_{n, k}=\left|\mathcal{S}_{n, k}^{\mathrm{e}}\right|-\left|\mathcal{S}_{n, k}^{\mathrm{o}}\right| .
$$

In this section we prove that they have an alternative expression as

$$
d_{n, k}=\left|\mathcal{P}_{n, k}^{\mathrm{e}}\right|-\left|\mathcal{P}_{n, k}^{\mathrm{o}}\right| .
$$

In other words, the numbers of even permutations and odd ones are the same in the set of permutations that are not parity alternating in $\mathcal{S}_{n, k}$. So defining

$$
\mathcal{N}_{n, k}=\mathcal{S}_{n, k} \backslash \mathcal{P}_{n, k},
$$

the set of all permutations that are not parity alternating in $\mathcal{S}_{n, k}$, we show that the numbers of even permutations and odd ones are equal in $\mathcal{N}_{n, k}$. This assertion was proved in [7] by using the recurrence relation (2). The present proof is self-contained and more elementary.

In order to do so, we introduce another operator based on $\sigma$. Let us define an operator $\tau$ on canonical permutations of $\mathcal{S}_{n, k}$ by

$$
\begin{equation*}
\tau\left(a_{1} a_{2} \cdots a_{n-1} n\right)=\sigma^{n-a_{n-1}}\left(a_{1} a_{2} \cdots a_{n-1} n\right)=b_{1} b_{2} \cdots b_{n-1} n, \tag{7}
\end{equation*}
$$

where $b_{1}=n-a_{n-1}$ and $b_{i}=a_{i-1}+\left(n-a_{n-1}\right)(\bmod n)$ for $i(2 \leq i \leq n-1)$. Since $\sigma$ preserves the ascent number of a permutation, so does $\tau$. Notice that $\tau^{n} \xi=\xi$ holds for a canonical permutation
$\xi$, since the differences between adjacent entries remain constant throughout, and every entry of $\xi$ returns to the original position after $n$ applications of $\tau$.

It is easy to see that in the case of even $n$ the operator $\tau$ maps canonical permutations of $\mathcal{P}_{n, k}$ onto themselves and similarly for $\mathcal{N}_{n, k}$. On the other hand, when $n$ is odd, this is not true; $\xi=1436527$, for example, is a canonical PAP, but $\tau \xi=5621437$ is not a PAP. So at first we assume $n$ is an even positive integer.

A PAP sequence $a_{i+1} \cdots a_{j}$ of a permutation $a_{1} a_{2} \cdots a_{n}$ means a consecutive subsequence in which even and odd integers appear alternately. A PAP sequence $a_{i+1} \cdots a_{j}$ is called maximal, if neither $a_{i} a_{i+1} \cdots a_{j}$ nor $a_{i+1} \cdots a_{j} a_{j+1}$ is no longer a PAP sequence.

Lemma 6. Let $n$ be an even positive integer. Suppose that $\xi=a_{1} \cdots a_{i} a_{i+1} \cdots a_{n-1} n$ is not $a$ PAP, while $a_{i+1} \cdots a_{n-1} n$ is a maximal PAP sequence. Then all of $\left\{\xi, \tau \xi, \ldots, \tau^{n-i-1} \xi\right\}$ have the same parity and the first entries of the permutations in $\left\{\tau \xi, \tau^{2} \xi, \ldots, \tau^{n-i-1} \xi\right\}$ are all odd, but $\tau^{n-i} \xi$ has a different parity from that of $\left\{\xi, \tau \xi, \ldots, \tau^{n-i-1} \xi\right\}$ and the first entry of $\tau^{n-i} \xi$ is even.

Proof. First we examine the parity of $\tau \xi$. Remark that $\operatorname{inv}(\sigma \xi)=\operatorname{inv}(\xi)$, because $\xi$ is canonical. However, each additional application of $\sigma$ changes the parity of permutations as long as $n$ lies in the interior of permutations, as shown in Section 1. Therefore, after the entry $a_{n-1}$ of $\xi$ becomes $n$ at the right end of $\tau \xi$ by the application of $\sigma^{n-a_{n-1}}$, the parity of $\xi$ has changed $n-a_{n-1}-1$ times. Hence, when $a_{n-1}$ is even, the parity of $\tau \xi$ is different from that of $\xi$ and the first entry of $\tau \xi$ is an even $n-a_{n-1}$. On the other hand, when $a_{n-1}$ is odd, the parity of $\tau \xi$ is the same as that of $\xi$ and the first entry of $\tau \xi$ is odd.

In the latter case, let $\tau \xi=b_{1} b_{2} \cdots b_{n-1} n$, where $b_{n-1}=a_{n-2}+\left(n-a_{n-1}\right)(\bmod n)$. If $a_{n-2}$ is even, then $b_{n-1}$ is odd. So the above argument can be applied to $\tau \xi$, implying that $\left\{\tau \xi, \tau^{2} \xi\right\}$ have the same parity. Hence all of $\left\{\xi, \tau \xi, \tau^{2} \xi\right\}$ have the same parity. Moreover, the first entry of $\tau^{2} \xi$ is odd. But if $a_{n-2}$ is odd, then $b_{n-1}$ is even and $\tau^{2} \xi$ has a different parity from that of $\{\xi, \tau \xi\}$. Moreover, the first entry of $\tau^{2} \xi$ is even. If $a_{i+1} \cdots a_{n-1} n$ is a maximal PAP sequence, we see that the lemma follows, by employing this argument $n-i$ times.

By Lemma 6, when $\xi$ is not a PAP, it eventually changes the parity by repeated applications of $\tau$. If $\xi=a_{1} \cdots a_{n-1} n$ is a PAP (hence $a_{1}$ is automatically an odd entry), however, then the parity of $\left\{\xi, \tau \xi, \ldots, \tau^{n-1} \xi\right\}$ remains the same and their first entries are all odd.

When $\xi$ is canonical but not a PAP, it can be written as

$$
\begin{equation*}
\xi=a_{1} \cdots a_{j} a_{j+1} \cdots a_{i} a_{i+1} \cdots a_{n-1} n=A \cdot B \cdot C, \tag{8}
\end{equation*}
$$

where $A=a_{1} \cdots a_{j}$ and $C=a_{i+1} \cdots a_{n-1} n$ are maximal PAP sequences and $B=a_{j+1} \cdots a_{i}$ is not necessarily a PAP sequence and may be empty. $A$ (or $C$ ) will be called the first (or last) maximal PAP sequence of $\xi$. A permutation 45316278 , for example, is expressed by $\xi=45 \cdot 316 \cdot 278$. The length of the sequence $A$, which is equal to $j$, is denoted by $\langle A\rangle$, similarly for the lengths of $B$ and $C$.

Lemma 7. In addition to the assumptions of Lemma 6, suppose that the first entry $a_{1}$ of $\xi=a_{1} \cdots a_{i} a_{i+1} \cdots a_{n-1} n$ is even and let $\tau^{n-i} \xi=c_{1} \cdots c_{n-i} c_{n-i+1} \cdots c_{n-1} n$. Then $c_{1} \cdots c_{n-i}$ is a maximal PAP sequence.

Proof. Let us put $\xi=a_{1} \cdots a_{i} a_{i+1} \cdots a_{n-1} n=A \cdot B \cdot C$ and $\tau \xi=b_{1} b_{2} \cdots b_{n-1} n$, where $C=$ $a_{i+1} \cdots a_{n-1} n$ is the last maximal PAP sequence of $\xi$. If $a_{n-1}$ is even, or $\langle C\rangle=1$, then both $b_{1}=n-a_{n-1}$ and $b_{2}=a_{1}+\left(n-a_{n-1}\right)(\bmod n)$ are even, because $a_{1}$ is even. If $a_{n-1}$ is odd, or
$\langle C\rangle \geq 2$, then both $b_{1}$ and $b_{2}$ are odd. This implies that the first PAP sequence of $\tau \xi$ necessarily has a length of one.

By each application of $\tau$ to $\xi$, the entries $\left\{n, a_{n-1}, \ldots, a_{i+1}\right\}$ of $C$ move to the left end of permutations one by one in this order. If we put $\tau^{n-i} \xi=c_{1} \cdots c_{n-i} c_{n-i+1} \cdots c_{n-1} n$, then $c_{1} \cdots c_{n-i}$ is a PAP sequence and it is maximal. This follows from the facts that $a_{i+1} \cdots a_{n-1} n$ is a PAP sequence of $\xi$ and that the parity of $c_{n-i}$ and $c_{n-i+1}$ is the same, because $\tau^{n-i} \xi=\tau^{n-i-1}(\tau \xi)$ holds and both $b_{1}$ and $b_{2}$ of $\tau \xi$ have the same parity.

Lemma 7, together with Lemma 6, states that applying $\tau^{n-i}$ to $\xi$ of (8) moves the last maximal PAP sequence, $C$, of $\xi$ to the first maximal PAP sequence of a permutation $\tau^{n-i} \xi$ with opposite parity and both sequences have the same length. Furthermore, all entries of $A$ and $B$ move to the right by $n-i$ positions by means of an application of $\tau^{n-i}$, although their values have changed. In particular, the last entry of $B, a_{i}$, turns to $n$ at the right end of a permutation, when $B$ is not empty.

As an illustrative example, applying $\tau^{3}$ to an odd permutation $\xi=45 \cdot 316 \cdot 278$ yields an even permutation $412 \cdot 675 \cdot 38$. Thus the last maximal PAP sequence 278 of $\xi$ moves to the first maximal one 412 of $\tau^{3} \xi$, and the remaining sequence 45316 of $\xi$ moves to the right as 67538 in $\tau^{3} \xi$.

Theorem 8. In $\mathcal{N}_{n, k}$ the total number of even permutations is equal to that of odd ones.
Proof. Part I (the case of odd $n$ ).
For odd $n$ let us introduce the set of all canonical permutations in $\mathcal{N}_{n+1, k+1}$, which we denote by $\mathcal{N}_{n+1, k+1}^{\mathrm{c}}$ and on which we will apply the operator $\tau$ of (7). Then it is possible to correspond $\bar{\xi}=a_{1} a_{2} \cdots a_{n}(n+1)$ in $\mathcal{N}_{n+1, k+1}^{\mathrm{c}}$ to each $\xi=a_{1} a_{2} \cdots a_{n}$ in $\mathcal{N}_{n, k}$. Note that $\operatorname{inv}(\xi)=\operatorname{inv}(\bar{\xi})$ and the correspondence $\xi \rightarrow \bar{\xi}$ is a bijection from $\mathcal{N}_{n, k}$ to $\mathcal{N}_{n+1, k+1}^{\mathrm{c}}$. Therefore, the number of even permutations in the latter is equal to that in the former and similarly for odd permutations. Since $n+1$ is even, we can apply Lemmas 6 and 7 to canonical permutations of $\mathcal{N}_{n+1, k+1}^{c}$, in which it is possible to find those beginning with even $a_{1}$. We denote by $\mathcal{N}_{n+1, k+1}^{c \dagger}$ the set of such canonical ones having the even first entry.

A permutation $\bar{\xi}=a_{1} a_{2} \cdots a_{n}(n+1)$ in $\mathcal{N}_{n+1, k+1}^{c}$ can be written as $\bar{\xi}=A \cdot B \cdot C$ by using maximal PAP sequences $A=a_{1} \cdots a_{j}$ and $C=a_{i+1} \cdots(n+1)$, as in (8). So we have $n+1=\langle A\rangle+\langle B\rangle+\langle C\rangle$. The sequence $B$ needs not be a PAP sequence and may be empty. As was proved in Lemma 6, until the operator $\tau$ is applied $\langle C\rangle$ times to $\bar{\xi}$, the parity does not change.

Suppose that $\bar{\xi}_{1}, \bar{\xi}_{2}, \ldots, \bar{\xi}_{m}$ are all of even canonical permutations in $\mathcal{N}_{n+1, k+1}^{c \dagger}$, i.e., even permutations beginning with even integers and ending with $n+1$. For each $i(1 \leq i \leq m)$ let us define $\ell_{i}$ as the smallest positive integer such that $\bar{\eta}_{i}=\tau^{\ell} \bar{\xi}_{i}$ becomes an odd permutation in $\mathcal{N}_{n+1, k+1}^{\mathrm{c}}$, which indeed belongs to $\mathcal{N}_{n+1, k+1}^{c \dagger}$ by Lemma 6 . The correspondence between $\bar{\xi}_{i}$ and $\bar{\eta}_{i}$ is a bijection and thus we get all of odd ones $\bar{\eta}_{1}, \bar{\eta}_{2}, \ldots, \bar{\eta}_{m}$ in $\mathcal{N}_{n+1, k+1}^{c \dagger}$ by this procedure. For $i(1 \leq i \leq m)$ let $\bar{\xi}_{i}=A_{i} \cdot B_{i} \cdot C_{i}$ and $\bar{\eta}_{i}=A_{i}^{\natural} \cdot B_{i}^{\natural} \cdot C_{i}^{\natural}$ be the expressions using maximal first and last PAP sequences. Then it follows that the PAP sequence $C_{i}$ of $\bar{\xi}_{i}$ moves into the PAP sequence $A_{i}^{\natural}$ of $\bar{\eta}_{i}$ by $\tau^{\ell_{i}}$, and $\ell_{i}=\left\langle C_{i}\right\rangle=\left\langle A_{i}^{\natural}\right\rangle$ from Lemma 7. So we have

$$
\begin{equation*}
\sum_{i=1}^{m}\left\langle A_{i}^{\natural}\right\rangle=\sum_{i=1}^{m}\left\langle C_{i}\right\rangle . \tag{9}
\end{equation*}
$$

Since each odd $\bar{\eta}_{i}=A_{i}^{\natural} \cdot B_{i}^{\natural} \cdot C_{i}^{\natural}$ is, in turn, changed into a certain even permutation $\bar{\xi}_{j}=A_{j} \cdot B_{j} \cdot C_{j}$
in $\mathcal{N}_{n+1, k+1}^{c \dagger}$ in a similar way, we obtain an analogous equality

$$
\begin{equation*}
\sum_{i=1}^{m}\left\langle A_{i}\right\rangle=\sum_{i=1}^{m}\left\langle C_{i}^{\natural}\right\rangle \tag{10}
\end{equation*}
$$

Moreover, the PAP sequence $C_{i}^{\natural}$ of $\bar{\eta}_{i}$ moves into the PAP sequence $A_{j}$ of $\bar{\xi}_{j}$. From the above equalities we also have

$$
\sum_{i=1}^{m}\left\langle B_{i}\right\rangle=\sum_{i=1}^{m}\left\langle B_{i}^{\natural}\right\rangle .
$$

For each $i(1 \leq i \leq m)$ the permutation $\tau^{\ell} \bar{\xi}_{i}$ remains even, whenever $\ell<\left\langle C_{i}\right\rangle$. Noting $\tau^{0} \bar{\xi}_{i}=\bar{\xi}_{i}$, the number of all even permutations in $\mathcal{N}_{n+1, k+1}^{c}$ is given by the sum (9). Similarly, the number of all odd permutations in $\mathcal{N}_{n+1, k+1}^{\mathrm{c}}$ is given by the sum (10).

Now we know that the last maximal PAP sequence $C_{i}$ of $\bar{\xi}_{i}$ moves into the first maximal PAP sequence $A_{i}^{\natural}$ of $\bar{\eta}_{i}$ and that the last maximal PAP sequence $C_{i}^{\natural}$ of $\bar{\eta}_{i}$ moves into the first maximal PAP sequence $A_{j}$ of some even $\bar{\xi}_{j}$. Thus we obtain

$$
\sum_{i=1}^{m}\left\langle C_{i}\right\rangle=\sum_{i=1}^{m}\left\langle C_{i}^{\natural}\right\rangle,
$$

and hence the values of (9) and (10) are equal; $\sum_{i=1}^{m}\left\langle A_{i}\right\rangle=\sum_{i=1}^{m}\left\langle C_{i}\right\rangle$.
This implies that, among $\mathcal{N}_{n+1, k+1}^{c}$, the number of even permutations is equal to that of odd ones. In other words, the number of even permutations in $\mathcal{N}_{n, k}$ is equal to that of odd ones in it, which completes the proof of Part I.

Part II (the case of even $n$ ).
The case of even $n$ can easily be proved from the former part. Notice that in this case $\xi \in \mathcal{N}_{n, k}$ if and only if $\sigma \xi \in \mathcal{N}_{n, k}$. We divide all even permutations $a_{1} a_{2} \cdots a_{n}$ of $\mathcal{N}_{n, k}$ into the three types by the position of $n$ :
(i) $a_{i}=n$ for some $i(2 \leq i \leq n-1)$;
(ii) $a_{n}=n$;
(iii) $a_{1}=n$.

On the other hand, we divide all odd permutations $a_{1} a_{2} \cdots a_{n}$ of $\mathcal{N}_{n, k}$ into the following three types by the position of one:
(i') $a_{i}=1$ for some $i(2 \leq i \leq n-1)$;
(ii') $a_{1}=1$;
(iii') $a_{n}=1$.
Let $\xi=a_{1} a_{2} \cdots a_{n}$ be an even permutation of type (i). Then, using property (a) of $\sigma$, we see that $\sigma \xi$ is an odd one of type ( $\mathrm{i}^{\prime}$ ), because the difference of the numbers of inversions between $\xi$ and $\sigma \xi$ is $|2 i-(n+1)|$ by (1) and it is odd by assumption. Since $\sigma$ is a bijection, we see that to each even permutation $\xi$ of type (i) in $\mathcal{N}_{n, k}$ corresponds an odd one of type (i') in $\mathcal{N}_{n, k}$. Therefore,
both types have the same cardinality.
Let $\xi=a_{1} a_{2} \cdots a_{n-1} n$ be of type (ii), where $a_{1} a_{2} \cdots a_{n-1}$ is a permutation of $[n-1]$. Since $\xi$ is an even permutation, the permutation $a_{1} a_{2} \cdots a_{n-1} \in \mathcal{N}_{n-1, k-1}$ is also even. Hence the number of elements in $\mathcal{N}(n, k)$ of type (ii) is the cardinality of all even permutations of $\mathcal{N}(n-1, k-1)$. On the other hand, the set $\mathcal{N}_{n, k}$ of type (ii') consists of all odd $\xi=1 a_{2} a_{3} \cdots a_{n}$ and hence the permutations $\left(a_{2}-1\right)\left(a_{3}-1\right) \cdots\left(a_{n}-1\right)$, that are obtained by subtracting one from the entries $a_{2} a_{3} \cdots a_{n}$, are all odd in $\mathcal{N}_{n-1, k-1}$. Using Part I, we see that both cardinalities are the same.

Similar arguments can be applied to types (iii) and (iii'). Let $\xi=n a_{1} a_{2} \cdots a_{n-1}$ be of type (iii). Since $n-1$ is odd and $\xi$ is an even permutation, we see that the permutation $a_{1} a_{2} \cdots a_{n-1}$ is odd in $\mathcal{N}_{n-1, k}$. Hence the number of even permutations in $\mathcal{N}_{n, k}$ of type (iii) is equal to that of all odd permutations of $\mathcal{N}_{n-1, k}$. On the other hand, the set $\mathcal{N}_{n, k}$ of type (iii') consists of all odd $\xi=a_{2} a_{3} \cdots a_{n} 1$, where $\left(a_{2}-1\right)\left(a_{3}-1\right) \cdots\left(a_{n}-1\right)$ are all even in $\mathcal{N}_{n-1, k}$. Hence it follows from Part I that both cardinalities are the same. Thus we see that the cardinality of even permutations in $\mathcal{N}_{n, k}$ is equal to that of odd ones, which completes the proof.

Finally we leave an unsolved problem, which is a counterpart of Theorem 1; is it possible to express $\left|\mathcal{P}_{n, k}\right|$ for odd $n$ by means of $\left|\mathcal{P}_{n-1, k}\right|$ etc. in a relatively simple manner?
