# Towards a dynamical theory of observation 

George Jaroszkiewicz<br>University of Nottingham, UK

February 26, 2019

#### Abstract

We present a model of observation in physics, based on power sets of classical bits. The four elements of each power set are given physical significance: two elements represent the usual yes and no states of a detector whilst the other two represent the absence of that detector and the faulty state of that detector respectively. We show how operators on the power sets can be used to describe a range of physical scenarios in the laboratory, such as the construction of physical devices in otherwise empty laboratories, the dynamics of signal states over those detectors and the extraction of information from those states. We also discuss the possibility of describing multiple observers within this formalism and show how it is readily modified to give a description of quantum experiments in signal detector terms.

## Introduction

Despite the many triumphs of quantum mechanics, the physics of observation is still not well understood. There are many subtleties concerning the concepts of observer and system under observation (SUO) which are not universally agreed upon. For instance, the endo-versus-exo debate considers whether it is valid to regard observers as standing in isolation from SUOs or whether the unity of the laws of physics requires observers to be considered as SUOs themselves. On this topic, Feynman wrote: "...we have an illusion that we can do any experiment that we want. We all, however, come from the same universe, have evolved with it, and don't really have any "real" freedom. For we obey certain laws and have come from a certain past." [1]. This line of thinking is consistent with the notion that the universe is some sort of grand computational process, in which observers, apparatus and SUOs are all transient manifestations of patterns of energy and matter [2].

Related to this is the debate between classical and quantum mechanics: the former postulates that SUOs and their properties exist independently of any observers, apparatus and observation, whereas the latter does not make much sense without observers and observables. There are still those who adhere to the precepts of Bohmian mechanics [3] whilst within the quantum community, there are

## Towards a dynamical theory of observation

well-known significant disagreements concerning the interpretation of the wavefunction and its relation to the observer.

Regardless of how observers are defined and whether classical or quantum issues are involved, it is implicit in the terminology used consistently throughout all branches of physics that physicists believe that some element of classical information is extracted from SUOs in actual physics experiments. Experimentalists talk of measuring an electron's spin, or the mass of a new particle, and so on. Whilst this point of view is of immense practical value, it may be a monumental conceptual error. We can do no better than to quote Heisenberg: "I believe that one can fruitfully formulate the origin of the classical 'orbit' in this way: the 'orbit' comes into being only when we observe it." [4].

Is it possible that apparatus defines reality in some way? Such an idea motivated Feynman in his doctoral thesis to discuss photons as a reflection of the properties of apparatus, rather than of SUOs [5]. We should look more carefully at what goes on in actual experiments and model only what we can be really sure about, cutting out as much of the rest as possible.

It seems reasonable therefore to explore more precisely what happens when SUOs are observed. In this article we develop an approach to classical mechanics which departs from tradition and focuses on the classical observer and their apparatus from the outset. This approach is parallel to one we have been developing for quantum mechanics [6].

In our approach, SUOs are discussed in terms of equivalence classes defined by the physics and context of observation. This was an approach used by Ludwig [7] and Kraus [8] in their work on the quantum measurement problem which led to the positive operator valued measure (POVM) formalism in quantum mechanics, an enhancement of von Neumann's projection valued measure (PVM) formulation of quantum measurement [9].

We define relative external context to be that information about the state of an SUO which is washed out in the definition of an equivalence class, whilst relative internal context refers to the defining properties of those equivalence classes associated with a given experiment. For example, in the measurement of electron spin in the Stern-Gerlach experiment [10], the momentum and position of the electron plus whatever is happening in the rest of the universe represent the relative external context whereas whether the electron is in its spin up or down state is internal context, relative to that particular experiment. The equivalence class approach is based on an assumption implicit in all theories of observation: relative external context can be completely ignored. This is true of state preparation as well as outcome detection: Peres made the point that a prepared quantum state of a system carries no memory of how it was prepared [12].

Contextuality goes a long way in answering the endo-versus-exo question. It may be true that observers are themselves SUOs, but only in the context of other observers observing them. As far as any observer of an SUO is concerned, they themselves and their apparatus represent relative external context and so can be

## Towards a dynamical theory of observation

ignored in their own description of that SUO.
Another point in favour of the equivalence class perspective is that it ties in closely with the spirit of Heisenberg's remark quoted above, since it is clearly the apparatus which defines the equivalence classes being observed.

## Classical bits

The notion of a classical bit is central to our approach, as it is used to represent the processes of observation in its simplest possible form. A classical bit $B \equiv\{0,1\}$ is a set with two distinct elements, denoted 0 and 1 respectively, called classical bit states. We shall drop the adjective classical, so from now on, all references to a bit will mean a classical bit.

Bits are used to define equivalence classes of SUOs for those situations where only two alternatives exist as far as the observer is concerned at that time. For example, in the case of the Stern-Gerlach experiment, electrons with arbitrary momentum and position but with spin $u p$ are identified with bit state 0 , whilst electrons with arbitrary momentum and position but with spin down are identified with bit state 1 . The two equivalence classes so formed are characterized by 0 and 1 respectively.

In recent years, the quantum analogue of a bit, known as a qubit, has found many uses, such as in quantum computation. A qubit is altogether a more complicated mathematical object than a bit. One important difference is that whereas bits are not vector spaces, qubits are complex vector spaces, which means that elements of a qubit can be multiplied by complex numbers and can be added together. Another important difference is that a qubit contains a zero vector, which a bit does not. We will use the power set of a bit to get around that particular point.

It will be useful to us later to briefly review some basics aspects of a qubit now. Elements of a qubit $Q$ and its dual $Q^{*}$ are denoted by ket $|\psi\rangle$ and bra $\langle\phi|$ vectors respectively. Given orthonormal bases $\{|0\rangle,|1\rangle\},\{\langle 0|,\langle 1|\}$ for a qubit and its dual respectively, we define the projection operators $p^{0} \equiv|0\rangle\langle 0|, p^{1} \equiv|1\rangle\langle 1|$ and the transition operators $a \equiv|0\rangle\langle 1|, a^{+} \equiv|1\rangle\langle 0|$. These operators satisfy the product rules given in Table 1.

Our strategy is not to think of the SUOs as if they were "there" but to discuss only that information which an observer can extract from elementary signal detectors, or ESDs. Each ESD has only two possible normal states, known as the ground state and the signal state respectively. Whenever an observer looks at a normally functioning ESD, they will find it only in one of these two possible states, denoted by 0 for the ground state and 1 for the signal state.

## Towards a dynamical theory of observation

Table 1: The product table for the four basic qubit operators, where 0 represents the zero operator. Entries in the main square represent products of left-most column elements with top row elements in that order.

|  | $p^{0}$ | $p^{1}$ | $a$ | $a^{+}$ |
| :---: | :---: | :---: | :---: | :---: |
| $p^{0}$ | $p^{0}$ | 0 | $a$ | 0 |
| $p^{1}$ | 0 | $p^{1}$ | 0 | $a^{+}$ |
| $a$ | 0 | $a$ | 0 | $p^{0}$ |
| $a^{+}$ | $a^{+}$ | 0 | $p^{1}$ | 0 |

## Elementary signal detectors

Our approach assumes that any observation can be described in terms on ESDs. These are not necessarily related to position in space and we may need a vast number of them to represent the physical reality that we think we are observing. Although an ESD is any process of observation which will return either a yes or a no answer, an ESD could involve a great deal of spatially extended physical equipment operated over a long period of time. For example, real detectors such as those discussed by Glauber in quantum optics generally involve probability rates of signal production stimulated by finite wave-trains of various kinds of quantum states, such as incoherent or coherent beams of particles [11]. Yet whatever the nature of the process or its details, at the end of the day, it ends with an observer deciding whether the state of an ESD in a collection of ESDs corresponds to a yes answer or a no answer.

The physical interpretation of ESD states is important. A typical experiment will involve a collection of ESDs. It would normally be assumed that prior to any run (or repetition) of the experiment, each ESD would have been set in its characteristic ground state. This has nothing to do with energy. The ground state of an ESD is simply whatever condition the observer regards the ESD as having in the absence of a response to any external stimulus.

If subsequently during the act of observation an ESD were found still in its ground state, that would be taken as indicating that nothing had happened at that ESD. If on the other hand an ESD were found in its signal state, then something must have happened there, such as a particle impacting on a detector.

There are two important caveats to this interpretation which play a crucial role in the formalism. These will be discussed in detail below.

## Towards a dynamical theory of observation

## Bit power sets

We will identify the two possible normal signal states of a functioning ESD as the two elements of a bit. As we have mentioned, however, bits are not vector spaces and there seems to be no meaning to the addition of bit state 0 to bit state 1 , or even of the multiplication of a bit state by a real or complex number.

There is in fact a way of defining bit state addition, of a kind, in terms of set theory. We recall that the power set $\mathcal{P}(S)$ of a set is the set of all possible subsets of $S$ including the empty set $\emptyset$ and $S$ itself. The power set $\mathcal{P}(\mathrm{B})$ of a bit B therefore has four distinct elements:

$$
\begin{equation*}
\mathcal{P}(\mathrm{B})=\{\mid 0), \mid 1), \mid \mathrm{B}), \mid \emptyset)\}, \tag{1}
\end{equation*}
$$

where we define $\mid 0) \equiv\{0\},|1| \equiv\{1\}, \mid B) \equiv\{0,1\}$ and $|\emptyset| \equiv\{\emptyset\}$. In this scheme, $|\emptyset|$ is a non-trivial element of $\mathcal{P}(B)$ and counts as one element of the power set.

We shall work in terms of the elements of $\mathcal{P}(B)$ rather than with the elements of $B$ itself, identifying elements $\mid 0)$ and $\mid 1)$ of $\mathcal{P}(B)$ as synonymous with bit states 0 and 1 of $B$. The value of using $\mathcal{P}(B)$ rather than $B$ itself is that the elements of the former are sets, so we can use the set properties of union and intersection to make some interesting constructions analogous to those found in qubit theory.

## Interpretation

Before we proceed further however, we need to resolve the following problem: the power set $\mathcal{P}(B)$ of a bit $B$ appears to have too many elements. This problem arises because logic suggests that only the elements $\mid 0)$ and $\mid 1$ ) of the power set are actually needed. What do the elements $|B|$ and $|\emptyset|$ represent?

We turn to the physics of observation to answer this question. An observation of an ESD can be regarded as the acquisition of an answer to a binary question, such a question being one with a yes or no answer. For example, we could ask the question $Q_{1} \equiv$ is this ESD in its signal state? If we looked and found it was in that state, the answer would be yes and so the state of the ESD would be represented by the element 1 of the corresponding bit. Conversely, if the ESD was not found in its signal state, we would normally assume it was in its ground state and therefore we would represent that situation by the element 0 .

The matter is not as straightforward as it seems, however. First, a subtle issue arises concerning two-valued logic as it applies to physics. Given an ESD, there are generally two related binary questions. One is $Q_{1}$ and the other is $Q_{2} \equiv$ is this ESD in its ground state? Logically, we would assume $Q_{1}$ and $Q_{2}$ were conjugate questions, but physically this need not be true. In an experiment, we could not always be certain that an answer no to $Q_{1}$ implies an answer yes to $Q_{2}$. The reason is that in a real experiment, $Q_{1}$ and $Q_{2}$ would be questions asked at different physical

## Towards a dynamical theory of observation

locations, as in the Stern-Gerlach experiment [10]. We should be careful not to introduce unwarranted counterfactuality into any discussion concerned with the theory of observation, even when applied in the classical domain. Therefore, we shall adhere as much as possible to the quantum principle advocated by Wheeler [13] and Peres [12] that an observation not made does not count ${ }^{11}$.

A second issue is that there is always the possibility that the detector could be faulty and not register anything for both $Q_{1}$ and $Q_{2}$, or give false positive readings for $Q_{1}$ and $Q_{2}$.

The Stern-Gerlach experiment provides a good example of what we mean. When an electron passes through the main magnetic field, it normally appears in one of two impact sites, which are spatially separated. If the observer looked at only one of these sites and noticed that the electron had not landed there, would they be justified in assuming that the electron had inevitably landed on the other site? In a real experiment, this could not be always guaranteed. For instance, there could be some blockage in the channel that led to the second impact site which prevented electrons from landing there. In related experiments involving photons, the possibility of parametric down conversion could result in the production of two photons, each of which triggers a signal in what would otherwise be assumed were mutually exclusive detector channels.

Yet another fundamental issue concerns the existence of the ESDs themselves. Consider what happens in a real laboratory in the execution of a given run of an experiment. Before any observation of an ESD could be made for that run, the observer would have had to make a decision to perform a reading on $\mathrm{it}{ }^{2}$. Suppose the observer did make such a decision, but was unaware that the ESD no longer existed, or that it did exist but had broken down or was now inaccessible. In such a case, even if the observer had decided to make an observation, no possible answer 0 or 1 could be found. This scenario will be interpreted as corresponding to the empty set element $\mid \emptyset)$ of the power set $\mathcal{P}(B)$. In words, $\mid \emptyset)$ represents the answer "no" to the binary question "does the ESD actually exist?". We shall call the element $\mid \emptyset)$ the empty state.

With this possibility and the two "normal" elements $\mid 0)$ and $\mid 1)$, we have accounted for three of the four elements of the power set $\mathcal{P}(B)$. We account for the fourth element $\mid \mathrm{B})$ as follows. Suppose that the ESD did exist and was accessible to the observer, but had a technical problem. Not all physical equipment works perfectly all the time. The element $|B| \equiv \mid 0) \cup \mid 1)=\{0,1\}$ will be taken to represent such a scenario. Essentially, any answer that the observer obtained when the ESD was in state $\mid B$ ) would be known to the observer to be uncertain or ambiguous and therefore unreliable. We shall call the element $\mid \mathrm{B})$ the faulty state.

[^0]
## Union and intersection

Now that we have an interpretation of all four elements of the power set $\mathcal{P}(B)$ we will explore the consequences of this line of thinking.

The elements of the power set $\mathcal{P}(B)$ are sets and therefore union and intersection are defined. Taking union first, the elements of the power set satisfy the following rules:
$\mid 0) \cup \mid 0)=\mid 0)$,
$\mid 0) \cup \mid 1)=|B|$,
|0) $\cup(B)=\mid B)$,
$\mid 0) \cup|(\mid)=| 0)$,
$\mid 1) \cup \mid 0)=\mid B)$,
$\mid 1) \cup \mid 1)=\mid 1)$,
| 1$) \cup(B)=\mid B)$,
$\mid 1) \cup|\emptyset|=\mid 1)$,
$\mid B) \cup(0)=\mid B)$,
$\mid B) \cup(1)=(B)$,
$\mid B) \cup(B)=\mid B)$,
$\mid B) \cup|\emptyset|=\mid B)$,
$\mid \emptyset) \cup(0)=\mid 0)$,
$\mid \emptyset) \cup \mid 1)=\mid 1)$,
$\mid \emptyset) \cup(B)=\mid B)$,
$\mid \emptyset) \cup(\emptyset)=\mid \emptyset)$.

In the case of intersection, the elements of the power set $\mathcal{P}(B)$ satisfy the following rules:
$\mid 0) \cap \mid 0)=\mid 0)$,
$\mid 0) \cap \mid 1)=\mid \emptyset)$,
$\mid 0) \cap(B)=\mid 0)$,
$\mid 0) \cap|\emptyset|=\mid \emptyset)$,
$\mid 1) \cap \mid 0)=\mid \emptyset)$,
$\mid 1) \cap \mid 1)=\mid 1)$,
$\mid 1) \cap(B)=\mid 1)$,
$\mid 1) \cap|\emptyset|=\mid \emptyset)$,
$\mid B) \cap \mid 0)=\mid 0)$,
$\mid B) \cap \mid 1)=\mid 1)$,
$\mid B) \cap(B)=\mid B)$,
$\mid B) \cap|\emptyset\rangle=\mid \emptyset)$,
$\mid \emptyset) \cap(0)=\mid \emptyset)$,
$\mid \emptyset) \cap(1)=\mid \emptyset)$,
$\mid \emptyset) \cap(B)=\mid \emptyset)$,
$\mid \emptyset) \cap(\emptyset)=\mid \emptyset)$.

These are the rules of a Boolean algebra, with $|\emptyset|$ playing the role of the Boolean element $O$ and $\mid \mathrm{B})$ playing the role of the Boolean element $I$ whilst the union $\cup$ and intersection $\cap$ play the roles of the idempotent, associative and commutative operations normally denoted by $\vee$ and $\wedge$ respectively. We note that every element $t$ of a Boolean algebra has a complement $\bar{t}$, such that $t \vee \bar{t}=I$ and $t \wedge \bar{t}=O$. In our case, $|\overline{\bar{\emptyset}}\rangle=\mid \mathrm{B}), \mid \overline{\mathrm{B}})=|\emptyset|,(\overline{0})=\mid 1)$ and $|\overline{1}|=\mid 0)$.

## Questions and answers

We introduced the elements of a bit as representing the answers to a binary question. Given $(0) \equiv\{0\}$ represents "no" and $\mid 1) \equiv\{1\}$ represents "yes", we denote the particular binary question involved by ( $1 \mid$ and write

$$
\begin{equation*}
(1 \mid 0)=0, \quad(1 \mid 1)=1 . \tag{2}
\end{equation*}
$$

In words, (1| is the compound question: "does this ESD exist, and if so, is it working normally, and if so, is it in its signal state?" The bit state |1) returns a simultaneous "yes" to all three component sub-questions.

We noted above that the Boolean algebra of the power set $\mathcal{P}(B)$ consists of elements each of which has a complement. Likewise, binary questions have their

## Towards a dynamical theory of observation

complements. The complement of the question ( $1 \mid$ will be denoted by ( $0 \mid$, which is the binary question: "does this ESD exist, and if so, is it working normally, and if so, is it in its ground state?" Then we have the relations

$$
\begin{equation*}
(0 \mid 0)=1, \quad(0 \mid 1)=0 . \tag{3}
\end{equation*}
$$

By analogy we may introduce the questions (B| and ( $\emptyset \mid$, which have corresponding properties. We interpret ( $\mathrm{B} \mid$ as the question: "does this detector exist and if so, is it faulty?". In the case of the empty state, it is more convenient to ask about non-existence rather than existence, so we define ( $\emptyset \mid$ as the question: "is it true that the detector does not exist?"

The situation has now become more complicated than expected, because now we have four binary questions asked of four power set states. A change of notation is called for. We define $\left.\left|s_{1}\right\rangle \equiv|0|,\left|s_{2}\right\rangle=|1|,\left|s_{3}\right\rangle \equiv \mid \mathrm{B}\right)$ and $\left|s_{4}\right\rangle \equiv|\emptyset|$, whilst $\left(s_{1} \mid \equiv\left(0 \mid,\left(s_{2} \mid \equiv\left(1 \mid,\left(s_{3} \mid \equiv\left(\mathrm{B} \mid\right.\right.\right.\right.\right.\right.$ and $\left(s_{4} \mid \equiv(\emptyset \mid\right.$. Then all sixteen question and answer relations are given by the rule

$$
\begin{equation*}
\left(s_{i} \mid s_{j}\right)=\delta_{i j} \tag{4}
\end{equation*}
$$

where $\delta_{i j}$ is the Kronecker delta.
We should comment on relations such as $\left(s_{1} \mid s_{4}\right) \equiv(0 \mid \emptyset)=0$, which is a physical question asked of the empty state. In such cases, the zero value has to be interpreted not as a definite "no" answer but as the absence of a definite "yes" answer.

We note also that according to our conventions, the statement $\left(s_{4} \mid s_{4}\right)=1$ is interpreted as the answer "yes" to the question "is it true that there is no ESD here?" in the context that that is actually the case. Similarly, the relation $\left(s_{3} \mid s_{3}\right)=1$ is interpreted as the answer "yes" to the question "is it true that this ESD exists and is faulty?".

At this point the four questions ( $s_{i} \mid$ look very much like the basis elements of a dual vector space $V^{*}$ with the four answers $\mid s_{j}$ ) looking like the basis elements of a vector space $V$. For this reason we shall call the elements ( $s_{i} \mid$ the duals of the $\left.\mid s_{i}\right)$. However, there are significant differences. The power set $\mathcal{P}(V)$ is a Boolean algebra not a vector space whilst the set $\left\{\left(s_{i} \mid: i=1,2,3,4\right\}\right.$ does not have an obvious interpretation as a Boolean algebra. Simply put, questions do not have the same status as answers: there is usually a temporal ordering ${ }^{3}$, with questions being asked before answers can be obtained.

Another difference between bit questions and answers is that whilst ( $s_{1} \mid$ and ( $s_{2} \mid$ can be thought of as mutual complements on account of their physical interpretation, the same is not obviously the case as far as the physics of $\left(s_{3} \mid\right.$ and $\left(s_{4} \mid\right.$ are concerned, apart from the fact that an answer "yes" to either tells us that the ESD can be ignored.

[^1]
## Towards a dynamical theory of observation

## Bit operators

A bit operator is any mapping from the power set $\mathcal{P}(B)$ back into the power set. Given an element $\mid s)$ of $\mathcal{P}(\mathrm{B})$ and a bit operator $O$ then we denote the value of the operator's action on $\mid s)$ by $O \mid s)$. There is a total of $4^{4}=256$ different possible operators and only a few will be of use to us.

## Matrix representation

A useful way of representing bit operators is via matrices. Using the relabelling $\left.\left.\mid 0) \rightarrow\left|s_{1}\right|,|1\rangle \rightarrow\left|s_{2}\right|, \mid \mathrm{B}\right) \rightarrow\left|s_{3}\right|,|\emptyset| \rightarrow \mid s_{4}\right)$ as before, we represent the action of bit operator $O$ on $s_{i}$ ) by the action of a bit matrix $[O]$ on a column matrix $\left[s_{i}\right]$, such that

$$
\begin{equation*}
\left.\left.O \mid s_{i}\right) \equiv \mid O s_{i}\right) \rightleftharpoons[O]\left[s_{i}\right] . \tag{5}
\end{equation*}
$$

If each element $\mid s_{i}$ ) of the power set $\mathcal{P}(\mathrm{B})$ is represented by a column matrix $\left[s_{i}\right]$ such that

$$
\left[s_{1}\right] \equiv\left[\begin{array}{l}
1  \tag{6}\\
0 \\
0 \\
0
\end{array}\right], \quad\left[s_{2}\right] \equiv\left[\begin{array}{l}
0 \\
1 \\
0 \\
0
\end{array}\right], \quad\left[s_{3}\right] \equiv\left[\begin{array}{l}
0 \\
0 \\
1 \\
0
\end{array}\right], \quad\left[s_{4}\right] \equiv\left[\begin{array}{l}
0 \\
0 \\
0 \\
1
\end{array}\right]
$$

then every column of a bit matrix consists of zeros except for one element which is one.

In this matrix representation, the dual elements ( $s_{i} \mid$ are represented by the row matrices

$$
\begin{align*}
& \left(s_{1} \left\lvert\, \rightleftharpoons\left[\begin{array}{llll}
1 & 0 & 0 & 0
\end{array}\right]\right., \quad\left(s_{2} \left\lvert\, \rightleftharpoons\left[\begin{array}{llll}
0 & 1 & 0 & 0
\end{array}\right]\right.,\right.\right. \\
& \left(s_{3} \left\lvert\, \rightleftharpoons\left[\begin{array}{llll}
0 & 0 & 1 & 0
\end{array}\right]\right., \quad\left(s_{4} \left\lvert\, \rightleftharpoons\left[\begin{array}{llll}
0 & 0 & 0 & 1
\end{array}\right] .\right.\right.\right. \tag{7}
\end{align*}
$$

This is consistent with the question and answer relations (4).
We can use the bit matrix representation to define the operational meaning of the dyadics $\left.\mid s_{i}\right)\left(s_{j} \mid\right.$. These can then serve as formal basis elements in the expansion of bit operators. Given a bit operator (5), we can write it in the formal expression

$$
\begin{equation*}
\left.O=\mid O s_{i}\right)\left(s_{i} \mid\right. \tag{8}
\end{equation*}
$$

using the summation convention.

## Bit operator products

Products of bit operators are defined in the natural way: given bit operators $O_{1}$, $O_{2}$, we define their 'product' $O_{2} O_{1}$ by its action on any element $\mid s_{i}$ ) of the power set $\mathcal{P}(B)$ according to the rule

$$
\begin{equation*}
\left.\left.O_{2} O_{1} \mid s_{i}\right) \equiv O_{2}\left\{O_{1} \mid s_{i}\right)\right\} . \tag{9}
\end{equation*}
$$

## Towards a dynamical theory of observation

This product rule is associative but not commutative. To see this we note that products of two bit matrices are also bit matrices, with the operator $O_{2} O_{1}$ being represented in the matrix representation by the matrix product rule $\left[O_{2} O_{1}\right]=\left[O_{2}\right]\left[O_{1}\right]$. The result follows because matrix multiplication is associative but not commutative.

## Useful bit operators

The following bit operators turn out to be useful:

1. The identity I maps every element back into itself, i.e., $\left.I \mid s_{i}\right)=\mid s_{i}$ ). Its matrix elements are given by the Kronecker delta, viz., $[I]_{i j}=\delta_{i j}$.
2. The annihilator $Z$ maps any element $\left.\mid s_{i}\right)$ of the power set $\mathcal{P}(\mathrm{B})$ into the empty state $\mid \emptyset)$, viz., $\left.Z \mid s_{i}\right)=\mid \emptyset$ ), so its matrix representation is

$$
[Z]=\left[\begin{array}{llll}
0 & 0 & 0 & 0  \tag{10}\\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
1 & 1 & 1 & 1
\end{array}\right]
$$

3. The projection operators $P^{0}$ and $P^{1}$ have the action

$$
\left.\begin{array}{lll}
\left.\left.P^{0} \mid 0\right)=\mid 0\right), & \left.P^{0}|1|=\mid \emptyset\right), & \left.\left.P^{0} \mid \mathrm{B}\right)=\mid \emptyset\right),
\end{array} \quad P^{0}|\emptyset|=\mid \emptyset\right),
$$

Their matrix representations are

$$
\left[P^{0}\right]=\left[\begin{array}{llll}
1 & 0 & 0 & 0  \tag{12}\\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 1 & 1 & 1
\end{array}\right], \quad\left[P^{1}\right]=\left[\begin{array}{llll}
0 & 0 & 0 & 0 \\
0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 \\
1 & 0 & 1 & 1
\end{array}\right]
$$

These operators are idempotent, viz., $P^{0} P^{0}=P^{0}, \quad P^{1} P^{1}=P^{1}$ and orthogonal, viz. $P^{0} P^{1}=P^{1} P^{0}=Z$.
4. The signal creation and signal annihilation operators $\bar{A}, A$ are defined principally by their action on the normal states $\mid 0)$ and $\mid 1)$ :

$$
\begin{align*}
& \bar{A} \mid 0)=\mid 1), \quad \bar{A}(1)=\mid \emptyset), \quad \bar{A} \mid \mathrm{B})=\mid \emptyset), \quad \bar{A} \mid \emptyset)=\mid \emptyset), \\
& A \mid 0)=\mid \emptyset), \quad A|1|=\mid 0), \quad A|\mathrm{~B}\rangle=\mid \emptyset), \quad A|\emptyset\rangle=\mid \emptyset) . \tag{13}
\end{align*}
$$

This gives the matrix representations

$$
[\bar{A}]=\left[\begin{array}{llll}
0 & 0 & 0 & 0  \tag{14}\\
1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 1 & 1 & 1
\end{array}\right], \quad[A]=\left[\begin{array}{llll}
0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
1 & 0 & 1 & 1
\end{array}\right]
$$

## Towards a dynamical theory of observation

These operators are nilpotent, viz. $A A=\bar{A} \bar{A}=Z$.
The product rules for the operators $P^{0}, P^{1}, A, \bar{A}$ are given in Table 2. Comparison with Table 1 shows that these tables are essentially isomorphic, provided the zero operator in Table 1 is identified with the annihilator $Z$ in Table 2.

Table 2: The product table for the four basic bit operators, where $Z$ represents the annihilator. Entries in the main square represent products of left-most column elements with top row elements in that order.

|  | $P^{0}$ | $P^{1}$ | $A$ | $\bar{A}$ |
| :---: | :---: | :---: | :---: | :---: |
| $P^{0}$ | $P^{0}$ | $Z$ | $A$ | $Z$ |
| $P^{1}$ | $Z$ | $P^{1}$ | $Z$ | $\bar{A}$ |
| $A$ | $Z$ | $A$ | $Z$ | $P^{0}$ |
| $\bar{A}$ | $\bar{A}$ | $Z$ | $P^{1}$ | $Z$ |
|  |  |  |  |  |

5. The construction operator $C$ acts on every element $\left.\mid s_{i}\right)$ of the power set and sets it to the ground state, in readiness for observation, i.e., $\left.C \mid s_{i}\right)=\mid 0$ ). There are two scenarios. If the bit is in its empty state, then its ESD does not exist, so the action of the construction operator represents the physical construction of a standard ESD in its ground state in the laboratory, prior to any experiment. It is assumed that facilities exist in the laboratory for this. Alternatively, if the ESD already exists, then the construction operator resets it to its ground state if it is normal or repairs it and sets it to its ground state if it is faulty. This operator is represented by the matrix

$$
[C]=\left[\begin{array}{llll}
1 & 1 & 1 & 1  \tag{15}\\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0
\end{array}\right]
$$

## Discrete time and space

Classical mechanics generally assumes that SUOs move around continuous space continuously. Our approach to the subject requires a different perspective on this. We can still believe in the continuity of time and space, but how the observer interacts with SUOs is here always described in discrete terms. This reflects the fact that real experiments always involve observations taken at discrete times on finite numbers of ESDs. There are no true continuous observations, either spatially or temporally. This does not imply however that ensemble averages cannot be discussed in continuous terms.

A typical experiment described by our formalism involves an observer interacting with a time-dependent number $r_{n}$ of ESDs at a countable number of times $t_{n}$, where the integer $n$ runs from some initial integer $M$ to some final integer $N>M$.

## Towards a dynamical theory of observation

There is no need to assume that $t_{n+1}-t_{n}$ always has the same value, or that $r_{n}$ is independent of $n$. The formalism allows for the creation and destruction of ESDs, something which happens in the real world.

## The laboratory and the universal register

In our theory, it is assumed that the observer exists in a physical environment referred to as the laboratory, $\Lambda$. This will have the facilities for the construction or introduction of apparatus consisting of a number of ESDs. At any given discrete time $n$, the observer will assign a state known as the labstate to the collection of ESDs at that time. The labstate carries information as to whether various ESDs exist in the first place, and if so, whether they are functioning normally and either in their ground or signal states, or whether they are faulty.

The power set approach to ESDs allows us to think of an absence of an ESD in $\Lambda$ as an observable fact which can be representable mathematically. The state corresponding to an absent or non-functioning $\mathrm{ESD}^{4}$ is represented by the element $\mid \emptyset)$ of its associated power set. Therefore, we can represent a complete absence of any ESDs whatsoever by an infinite collection of such elements. This corresponds to an observer without any apparatus, i.e., an empty laboratory. We denote this labstate by the symbol $\mid \Omega$ ) and call it the void state. It represents a potential for existence, relative to a given observer.

If the observer's laboratory $\Lambda$ is in its void state $\mid \Omega)$, that does not mean that $\Lambda$ or the observer do not exist, or that there are no SUOs in $\Lambda$. It means simply that the observer has no current means of acquiring any information.

The void can be thought of as one element in an infinite "product" of bit power sets called the universal register $\mho$. We write

$$
\begin{equation*}
\left.\mid \Omega) \equiv \prod_{i}^{\infty} \mid \emptyset_{i}\right) \in \mathcal{V} \equiv \prod_{i}^{\infty} \mathcal{P}\left(\mathrm{B}^{i}\right), \tag{16}
\end{equation*}
$$

where the index $i$ could in principle be discrete, continuous or a combination of both. The cardinality of the universal register as a measure of how many power sets belong to it may be assumed to be infinity, but precisely what sort of Cantorian cardinality it should be is not clear. If we thought in terms of $\Lambda$ sitting in continuous space, then we expect at least the cardinality of the continuum, c . However, that is a metaphysical statement, because there would not be enough energy in the universe to create a continuum of ESDs 5 . Fortunately, because real observers can only ever deal with finite numbers of ESDs in practice, we can safely ignore the question of how many potential ESDs could there be. In other words, that question concerns the relative external context in any experiment and so can be ignored.

[^2]
## Towards a dynamical theory of observation

The product notation is not essential but has been chosen to reflect the relationship between collections of power sets and the tensor products of qubit spaces that we encounter in the quantum version of this approach, discussed later. In our products, ordering is not significant, since labels keep track of the various terms. An arbitrary labstate $\mid \Psi)$ in the universal register $\mho$ will be of the form $\left.\prod_{i}^{\infty} \mid s_{k_{i}}\right)$, where $\left.\mid s_{k_{i}}\right)$ is one of the four elements of $\mathcal{P}\left(\mathrm{B}^{i}\right)$.

Operators acting on universal register states will be denoted in blackboard bold font and act as follows. If $O^{i}$ is a bit operator acting on elements of $\mathcal{P}\left(B^{i}\right)$, then $\mathbb{O} \equiv$ $\prod_{i}^{\infty} O^{i}$ acts on an arbitrary state $\left.|\Psi\rangle \equiv \prod_{i}^{\infty} \mid s_{k_{i}}\right)$ according to the rule

$$
\begin{equation*}
\left.\mathbb{O} \mid \Psi) \equiv \prod_{i}^{\infty} O^{i} \mid s_{k_{i}}\right) \tag{17}
\end{equation*}
$$

For every register state $|\Psi\rangle \equiv \prod_{i}^{\infty}\left|s_{k_{i}}\right\rangle$ there will be a corresponding dual register state $\left(\Psi \mid \equiv \prod_{i}^{\infty}\left(s_{k_{i}} \mid\right.\right.$, where $\left(s_{k_{i}} \mid\right.$ is dual to $\left.\mid s_{k_{i}}\right)$. All register states including the void satisfy the normality condition

$$
\begin{equation*}
(\Psi \mid \Psi) \equiv \prod_{i}^{\infty} \prod_{j}^{\infty}\left(s_{k_{i}} \mid s_{k_{j}}\right)=\prod_{i}^{\infty} \prod_{j}^{\infty} \delta_{i j}=1 \tag{18}
\end{equation*}
$$

Register states $\mid \Phi), \mid \Psi)$ which differ in at least one bit power set element satisfy the rule $(\Phi \mid \Psi)=(\Psi \mid \Phi)=0$.

## Classical vacua

In conventional classical mechanics or Schrödinger-Dirac quantum mechanics, empty space is generally not represented by any specific mathematical object. In quantum field theory, however, empty space is represented by the vacuum, a normalized vector in a Hilbert space. It has physical properties such as zero total momentum, zero total electric charge, etc., which although bland are physically significant attributes nevertheless.

In our approach we encounter an analogous concept. Starting with the void $\mid \Omega)$, we represent the construction of a collection of ESDs in the laboratory $\Lambda$ by the application of a corresponding number of construction operators $C^{i}$ to their respective power states $\mid \emptyset_{i}$ ). For example, a labstate consisting of a single ESD $i$ in its ground state is given by

$$
\begin{equation*}
\left.\left.|\Psi\rangle=\mathbb{C}^{i} \mid \Omega\right)=\left\{\prod_{j \neq i}^{\infty} \mid \emptyset_{j}\right)\right\} \times\left(0_{i}\right) \tag{19}
\end{equation*}
$$

where $\mathbb{C}^{i}$ is the register operator

$$
\begin{equation*}
\mathbb{C}^{i} \equiv\left\{\prod_{j \neq i}^{\infty} I^{j}\right\} \times C^{i} \tag{20}
\end{equation*}
$$

## Towards a dynamical theory of observation

More generally, a state consisting of a number $r$ of ESDs each in its ground state is given by

$$
\begin{equation*}
\left.\left.\mid \Psi_{0}^{r}\right)=\mathbb{C}^{1} \mathbb{C}^{2} \ldots \mathbb{C}^{r} \mid \Omega\right) \tag{21}
\end{equation*}
$$

where without loss of generality we label the ESDs involved from 1 to $r$. Such a state will be said to be a rank-r ground state.

We can now draw an analogy between the vacuum of quantum field theory and the rank-r ground states in our formalism. The physical three-dimensional space of conventional physics would correspond to a ground state of extremely large rank, if physical space were relevant to the experiment. This would be the case for discussions involving particle scattering or gravitation, for example. For many experiments however, such as the Stern-Gerlach experiment and quantum optics networks, physical space would be considered part of the relative external context and therefore could be ignored for the purposes of those experiments. It all depends on what the observer is trying to do.

## Multiple observers and the void

In the real world there is more than one observer, so a theory of observation should take account of that fact. That is readily done in our theory. For example, the ground state for two or more distinct observers for which some commonality of time had been established would be represented by elements in $\mho$ of the form

$$
\begin{equation*}
\left.\left.\mid \Psi_{1}, \Psi_{2}\right) \equiv \mathbb{C}_{1}^{1} \mathbb{C}_{1}^{2} \ldots \mathbb{C}_{1}^{r_{1}} \mathbb{C}_{2}^{1} \mathbb{C}_{2}^{2} \ldots \mathbb{C}_{2}^{r_{2}} \mid \Omega\right) \tag{22}
\end{equation*}
$$

and so on, where the subscripts on the construction operators refer to the different observers. If subsequent dynamics was such that the ESDs of observer 1 never sent signals to those of observer 2 and vice versa, then to all intents and purposes we could discuss each observer as if they were alone. If on the other hand some signals did pass between them, then that would be equivalent to having only one observer.

If no commonality of time or other context has been established, then there can be no physical meaning to the above expression. This is an important point in cosmology, where there are frequent discussions about multiple universe "bubbles" beyond the limits of observation. The mere fact that astronomers have received light from extremely distant galaxies establishes a context between the signal preparation ESDs associated with those galaxies and the ESDs associated with the astronomers now and validates the use of General Relativity for those regions of spacetime. If no such signals have been received, then there is no such context. Therefore, relative to astronomers today, the universe beyond the horizon of observation can be meaningfully represented only by the void. Something may be there, but we should not discuss it as if we had access to any form of information about it, such as its spacetime structure.

Much the same concern must be raised about the loss of information question in black hole physics. The answer to that question can come only from a care-

## Towards a dynamical theory of observation

ful understanding of the contextual relation between observers outside the critical radius and those that were assumed to be inside it.

## Experiments

Long before any experiment can begin, the observer starts off with a laboratory $\Lambda$ in its void state $\mid \Omega$ ). Then at some time $t_{-1}$ before any runs can be taken, specific apparatus consisting of a finite number $r$ of ESDs has to be constructed in $\Lambda$. We will assume without loss of generality that these are all functioning normally and in their ground state, so the labstate $\left.\mid \Psi_{-1}\right)$ at that point is given by the the righthand side of (21). All of this is necessary before state preparation.

According to what we said earlier, external context involving ESDs in their empty state can be ignored. Therefore, we need only discuss those ESDs which subsequently are in states $\mid 0), \mid 1)$ or $\mid \mathrm{B})$. A further simplification is that in real experiments, observers generally filter out observations from faulty ESDs (assuming these have been identified) by post-selecting only those labstates which contain the normal bit states $\mid 0$ ) or $\mid 1)$. Henceforth, we shall confine our attention to such normal labstates.

Given this condition, we can restrict our discussion at any given time $t_{n}$ to the physical register $\mathcal{R}_{n}$, a subset of the universal register $\mho$ consisting of $2^{r_{n}}$ normal states, each of the form

$$
\begin{equation*}
\left.\left.\left.\mid i_{1} i_{2} \ldots i_{r_{n}}\right) \equiv\left|i_{1}\right| \mid i_{2}\right) \ldots \mid i_{r_{n}}\right) \tag{23}
\end{equation*}
$$

where $i_{j}=0$ or 1 for $j=1,2, \ldots, r_{n}$, such that $\left.\mid i_{j}\right)$ is in $\mathcal{P}\left(\mathrm{B}_{n}^{j}\right)$. The physical register $\mathcal{R}_{n}$ represents all those ESDs in the laboratory $\Lambda$ at time $n$ which exist and are not faulty.

Given the set of bits $\left.\mathrm{B}_{n}^{j} \equiv\left\{\mid 0_{j}\right),\left|1_{j}\right|\right\}$ associated with $\mathcal{R}_{n}$, the label $j$ gives an ordering, so $\mathcal{R}_{n}$ can be regarded as the Cartesian product $\mathrm{B}_{n}^{1} \times \mathrm{B}_{n}^{2} \times \ldots \times \mathrm{B}_{n}^{i_{n}}$. When we come to discuss quantization towards the end of this paper, every labstate (23) in $\mathcal{R}_{n}$ will be identified with a qubit tensor product state $\left|i_{1}\right\rangle \otimes\left|i_{2}\right\rangle \otimes \ldots \otimes\left|i_{r_{n}}\right\rangle$, an element of a preferred basis for a qubit register.

The notation (23) will be referred to as the oссирапсу notation, as the integers $i_{j}$ can be interpreted as the answer to the question whether the $j^{\text {th }}$ ESD $\Delta_{j}$ contains a signal or is in its ground state. An occupancy value 0 means $\Delta_{j}$ is in its ground state whilst the occupancy value 1 means that $\Delta_{j}$ is in its signal state. These states satisfy the orthonormality conditions

$$
\begin{equation*}
\left(i_{1} i_{2} \ldots i_{r_{n}} \mid j_{1} j_{2} \ldots j_{r_{n}}\right)=\delta_{i_{1} j_{1}} \delta_{i_{2} j_{2}} \ldots \delta_{i_{r_{n}} j_{r_{n}}} \tag{24}
\end{equation*}
$$

We define the signality of a given state in $\mathcal{R}_{n}$ to be the number of ones in the occupancy representation of that state. For example, the state |00101101) is a signality-four state in a rank-8 physical register. Signality allows us to partition

## Towards a dynamical theory of observation

the $2^{r_{n}}$ states in $\mathcal{R}_{n}$ into a number of signal classes $\mathcal{S}^{0}, \mathcal{S}^{1}, \ldots, \mathcal{S}^{r_{n}}$. These are equivalence classes of states in $\mathcal{R}_{n}$ defined by the same signality.

Signality has physical significance. The zero-signal class $\mathcal{S}^{0}$ consists of one state only, the ground state $\mid 000 \ldots 0)$ of the physical register. States in the one-signal class $\mathcal{S}^{1}$ correspond to what would normally be called a one-particle state, states in $\mathcal{S}^{2}$ correspond to two-particle states, and so on.

There is a total of $r_{n}+1$ distinct signal classes. The $d^{\text {th }}-$ signal class $\mathcal{S}^{d}$ contains $C_{d}^{r_{n}} \equiv r_{n}!/ d!\left(r_{n}-d\right)!$ distinct states. The $r_{n}$-signal class $\mathcal{S}^{r_{n}}$ consists of only one state, the fully saturated state $\left.\left.\left|1_{1}\right| \mid 1_{2}\right) \ldots \mid 1_{r_{n}}\right)$.

Given a rank-r physical register $\mathcal{R}_{r} \equiv \mathrm{~B}^{1} \mathrm{~B}^{2} \ldots \mathrm{~B}^{r}$ we define the $r$ signal creation operators

$$
\begin{equation*}
\overline{\mathbb{A}}_{i} \equiv\left\{\prod_{j \neq i}^{\infty} I^{j}\right\} \times \bar{A}_{i}, \quad 1 \leqslant i \leqslant r, \tag{25}
\end{equation*}
$$

and the $r$ signal annihilation operators

$$
\begin{equation*}
\mathbb{A}_{i} \equiv\left\{\prod_{j \neq i}^{\infty} I^{j}\right\} \times A_{i}, \quad 1 \leqslant i \leqslant r \tag{26}
\end{equation*}
$$

Then an application of the operator $\mathbb{A}_{i}$ on the rank-r ground state $\mathbb{C}_{1} \mathbb{C}_{2} \ldots \mathbb{C}_{r} \Omega$ gives the rank- $(r-1)$ ground state

$$
\begin{equation*}
\mathbb{A}_{i} \mathbb{C}_{1} \mathbb{C}_{2} \ldots \mathbb{C}_{r} \Omega=\mathbb{C}_{1} \mathbb{C}_{2} \ldots \mathbb{C}_{i-1} \mathbb{C}_{i+1} \ldots \mathbb{C}_{r} \Omega \tag{27}
\end{equation*}
$$

This is a non-zero labstate in $\mho$, but is not an element of the original physical register $\mathcal{R}_{r} \equiv \mathrm{~B}^{1} \mathrm{~B}^{2} \ldots \mathrm{~B}^{r}$. This is the formal analogue of the convention qubit register result

$$
\begin{equation*}
a_{i}\left\{\left|0_{1}\right\rangle \otimes\left|0_{2}\right\rangle \otimes \ldots \otimes\left|0_{r}\right\rangle\right\}=0 . \tag{28}
\end{equation*}
$$

In our case, we do not get zero, but the equivalent of it: the action of $\mathbb{A}_{i}$ on the ground state $\mathbb{C}_{1} \mathbb{C}_{2} \ldots \mathbb{C}_{r} \Omega$ of $\mathcal{R}_{r}$ maps it into the ground state of a different physical register, one of rank $r-1$, i.e., into a state orthogonal to every state in $\mathcal{R}_{r}$.

The signal creation operators $\overline{\mathbb{A}}_{i}$ can be used to create the various signal classes discussed above, as follows. We start from the signality-zero class $\mathcal{S}^{0}$, which consists of no application of any $\overline{\mathbb{A}}_{i}$ to the ground state $\left.\mid 0\right) \equiv \mathbb{C}_{1} \mathbb{C}_{2} \ldots \mathbb{C}_{r} \Omega$.

The signality-one class $\mathcal{S}^{1}$ consists of states of the form $\left.\left.\mid 2^{i-1}\right) \equiv \overline{\mathbb{A}}_{i} \mid 0\right)$ for $i=$ $1,2, \ldots, r$, the signality-two class consists of all states of the form $\left.\mid 2^{i-1}+2^{j-1}\right) \equiv$ $\left.\overline{\mathbb{A}}_{i} \overline{\mathbb{A}}_{j} \mid 0\right)$ for $1 \leqslant i<j \leqslant r$, and so on. Finally, the signality- $r$ signal class consists of the single state $\left.\left.\mid 2^{r-1}-1\right) \equiv \overline{\mathbb{A}}_{1} \overline{\mathbb{A}}_{2} \ldots \overline{\mathbb{A}}_{r} \mid 0\right)$.

In the following discussion, we shall use the notation $\mid k), k=0,1, \ldots, 2^{r-1}-1$ introduced above for the $2^{r}$ states in $\mathcal{R}^{r}$. We shall refer to it as the computation basis.

## Towards a dynamical theory of observation

## Particle signal mechanics

In this section, we discuss a physical register $\mathcal{R}^{r}$ of sufficiently large fixed rank $r$ such that it can serve as a model for a region of physical space over which particles can move. In this approach, particle motion is discussed in terms of the tracking of signals with time over a vast collection of ESDs. A particularly useful feature of this approach is that signality need not be conserved, which means that classical particle creation and annihilation is readily incorporated into the formalism.

There are several distinct forms of temporal evolution which could be discussed in such a scenario; the laws of mechanics for a given SUO could change with time or not, the SUO could be autonomous or interact with external forces, and signality could be conserved or not. We shall restrict our attention to autonomous SUOs with time-independent laws of dynamics, as these are generally of interest. In principle, there should be no problem in dealing with other forms of dynamics, including those where the rank of the physical register changes with time.

In the following, all states are elements in the universal register $\mho$ which also belong to $\mathcal{R}^{r}$, i.e., they represent the labstates of a fixed collection of normal ESDs, each of which can be found only in either its ground state or signal state.

We shall use the computational basis $\left.\{\mid k): k=0,1, \ldots, 2^{r}-1\right\}$ to represent the $2^{r}$ states in $\mathcal{R}^{r}$. Consider the temporal evolution of a system from state $\left.\mid k\right)$ at time $t$ to state $\mid U k)$ after one elementary time-step, where $k$ and $U k$ are integers in the interval $\left[0,2^{r}-1\right]$. Denoting this transition as the action of some temporal evolution operator $\mathbb{U}$ acting on the initial state $\mid k)$, we write

$$
\begin{equation*}
\mathbb{U} \mid k)=\mid U k), \quad 0 \leqslant k, U k<2^{r} . \tag{29}
\end{equation*}
$$

For a given $k$, there are in principle $2^{r}$ possible states $\left.\mid U k\right)$ into which it could be mapped, and because there are $2^{r}$ values of $k$, we conclude that for a rank- $r$ classical register, there are $\left(2^{r}\right)^{2^{r}}$ distinct possible evolution operators in this form of mechanics. Even for very low rank physical registers, the number of possible operators is impressive. For example, a rank-2 register can have 256 different forms of autonomous, time-independent dynamics whilst a rank-3 register has 16, 777, 216 different forms.

## Permutation flows

Most of the possible evolution operators over a physical register will not be useful. Many of them will correspond to irreversible and/or unphysical dynamical evolution and only a small subset will be of interest. We need to find some principles to guide us in our choice of evolution operator.

Recall that in standard classical mechanics, Hamilton's equations of motion

## Towards a dynamical theory of observation

lead to Liouville's theorem. This tells us that as we track a small volume element along a classical trajectory, this volume remains constant in magnitude though not necessarily constant in shape or orientation. This leads to the idea that a system of many non-interacting particles moving along classical trajectories in phase-space behaves like an incompressible fluid, such a phenomenon being referred to as a Hamiltonian flow.

An important characteristic of Hamiltonian flows is that flow lines never cross. We shall encode this idea into our approach to signal mechanics. There are two versions of this mechanics, one of which does not necessarily conserve signality whilst the other does. We consider the first one now.

## Permutation dynamics

The physical register $\mathcal{R}^{r}$ contains $2^{r}$ labstates denoted by $\left.\mid k\right), k=0,1,2, \ldots, 2^{r}-1$. Consider a permutation $P$ of the integers $k$, such that under $P, k \rightarrow P k \in\left[0,2^{r}-1\right]$. Define the evolution of the labstate $|k|$ over one time step by

$$
\begin{equation*}
\mid k) \rightarrow \mathbb{U} \mid k)=\mid P k) . \tag{30}
\end{equation*}
$$

Such a process is reversible and will be referred to as a permutation flow.
There is a total of $n$ ! distinct permutations of n objects, so there are $\left(2^{r}\right)$ ! possible distinct permutation flow processes. For large $r$, the number of permutation flows is a rapidly decreasing fraction of the number $\left(2^{r}\right)^{2^{r}}$ of all possible forms of register processes.

## Signal conserving flows

Most permutation flows will not conserve signality. We can readily identify the subset of the permutation flows which do conserve signality by using the occupancy notation. Consider a physical register state $\left.\mid \Psi_{n}\right)$ at time $t_{n}$ given by $\left|\Psi_{n}\right\rangle=$ $\left.\mid i_{1} i_{2} \ldots i_{r}\right)$ in the occupancy notation, where $i_{j}=0$ or else 1 for $1 \leqslant j \leqslant r$.

Now let $P^{*}$ be some permutation of the numbers $1,2, \ldots, r$ and write $P^{*} j$ to represent the number that $j$ changes to under this permutation. Now suppose that $\left.\mid \Psi_{n}\right)$ evolves into the labstate $\left.\mid \Psi_{n+1}\right)$ at time $t_{n+1}$ given by

$$
\begin{equation*}
\left.\left.\left.\left.\mid \Psi_{n}\right) \rightarrow \Psi_{n+1}\right) \equiv \mathbb{U} \mid \psi\right)=\mid i_{P^{*} 1} i_{P^{*} 2} \ldots i_{P^{*} r}\right) . \tag{31}
\end{equation*}
$$

To determine the new occupancy of the $j^{\text {th }}$ bit, we just look at the occupancy of the $\left(P^{*} j\right)^{t h}$ bit. This may be summarized as the dynamical rule $i_{j} \rightarrow i_{j}^{\prime} \equiv i_{P^{*} j}$. We shall call this form of signal mechanics signal permutation dynamics.

In this form of dynamics, signality is automatically conserved. Another way of seeing this is to use the signal creation operators and note that if $\left.\mid \Psi_{n}\right)$ has signality $d$, then we can write

$$
\begin{equation*}
\left.\left.\mid \Psi_{n}\right)=\overline{\mathbb{A}}_{j_{1}} \overline{\mathbb{A}}_{j_{2}} \ldots \overline{\mathbb{A}}_{j_{d}} \mid 0\right) \tag{32}
\end{equation*}
$$

## Towards a dynamical theory of observation

where $1 \leqslant j_{1}<j_{2}<\ldots<j_{d} \leqslant r$. Then under the above permutation $P^{*}$ of the integers $1,2, \ldots, r$ the new state at time $t_{n+1}$ takes the form

$$
\begin{equation*}
\left.\left.\left.\mid \Psi_{n+1}\right) \equiv \mathbb{U} \mid \Psi_{n}\right)=\overline{\mathbb{A}}_{P^{*} j_{1}} \overline{\mathbb{A}}_{P^{*} j_{2}} \ldots \overline{\mathbb{A}}_{P^{*} j_{d}} \mid 0\right) \tag{33}
\end{equation*}
$$

Then clearly signality is conserved.
The total number of distinct permutations of $r$ objects is $r$ !, so there are that many distinct forms of signal permutation dynamics for a rank- $r$ classical register. Since there are $\left(2^{r}\right)$ ! distinct forms of permutation dynamics, the set of signal permutation dynamics forms a rapidly decreasing fraction of the set of all possible permutation dynamics.

Permutation flows have a number of features which have analogues in standard classical mechanics. First, permutation flows are reversible. Given a permutation $P$, then its inverse $P^{-1}$ always exists, because permutations form a group.

Another feature of permutation dynamics is the existence of orbits or cycles. A permutation of $2^{r}$ objects will in general contain cycles, which are subsets of the objects such that only elements within a given cycle replace each other under the permutation. This is relevant here because we have chosen to discuss timeindependent autonomous systems, the evolution of which is given by repeated applications of the same permutation. Therefore, the structure of the cycles does not change and so each cycle consisting of $p$ elements has a dynamical period $p$. For example, the identity permutation gives a trivial form of mechanics where nothing changes. It has $2^{r}$ cycles each of period 1 . At the other end of the spectrum, the permutation denoted by $\left(0 \rightarrow 1 \rightarrow 2 \rightarrow \ldots \rightarrow 2^{2}-1 \rightarrow 0\right)$ has no cycles except itself and has period $2^{r}$. Therefore, any physical register evolving under time independent, autonomous permutation mechanics must return to its initial labstate no later than after $2^{r}$ time steps. This is the analogue of the Poincare recurrence theorem [14].

## Evolution and measurement

Any experiment consists of several distinct phases. We have discussed the creation of the apparatus and the evolution of the labstates. Now we turn to the process of measurement itself, which denotes the extraction of classical information from an SUO. Typically this will be in the form of real numbers.

Context plays a vital role here. When for example an observer reports that a particle has been observed at position $x=1.5$, what they mean is that positive signals have been detected at some normal ESD or ESDs associated with the number $x=1.5$. This assignment is based on the context of the experiment: the observer will know on the basis of theoretical knowledge what those ESDs mean in terms of the physics of the SUO concerned, and therefore, what "values" of some measurable quantity they represent.

## Towards a dynamical theory of observation

So far we have discussed the evolution on labstates. For each run or repetition of the experiment, this is modelled by the action of an evolution operator $\mathbb{U}_{N}$ mapping initial labstates at time $t_{0}$ into final labstates at time $t_{N}$. We need now to discuss how numbers are extracted at the end of of an experiment consisting of a number of runs.

With reference to the position measurement discussed immediately above, we model the measurement process in terms of weighted relevant questions. What this means is this. Suppose the final physical register $\mathcal{R}_{N}$ has rank $r_{N}$. Assuming the experimentalist has established that each ESD is normal, then there will be a total of $d_{N} \equiv 2^{r_{N}}$ possible normal labstates in this register. Therefore, the observer could ask a total of $\mathrm{d}_{N}$ normal questions. These questions are represented by the dual labstates $\left\{\left(k \mid: k=0,1, \ldots, d_{N}-1\right\}\right.$. Given a final labstate $\left.\mid \Psi_{N}\right)$, the answer yes or no to each question $\left(k \mid \equiv\right.$ "is it true that $\left.\mid \Psi_{N}\right)$ is $\left.\mid k\right)$ ?" is represented by the number one or zero respectively, and given by the bracket $\left(k \mid \Psi_{N}\right)$.

Now the observer will generally have some theory as to what each answer $\mid k)$ means physically. In many experiments, this will be some real number $X_{k}$. Therefore, the actual number $\langle X\rangle_{\Psi_{N}}$ obtained at time $t_{N}$ at end of a single run of the experiment can be written in the form

$$
\begin{equation*}
\langle X\rangle_{\Psi_{N}}=\left(\Psi_{N}\left|\mathbb{X}_{N}\right| \Psi_{N}\right), \tag{34}
\end{equation*}
$$

where

$$
\begin{equation*}
\left.\mathbb{X}_{N} \equiv \sum_{k=0}^{d_{N}-1} \mid k\right) X_{k}(k \mid \tag{35}
\end{equation*}
$$

is an observable, a sum of dyadics representing a weighted relevant question.
Two comments are relevant. First, despite appearances, this is still a classical theory at this point. The final labstate $\left.\mid \Psi_{N}\right)$ is a single element in the final physical register, $\mathcal{R}_{N}$, not a superposition of elements. Second, there is nothing in classical mechanics which rules out weighted sums of dyadics. For any element in $\mathcal{R}_{N}$, all the possible answers $\left(k \mid \Psi_{N}\right)$ are zero except for one of them, so (34) returns a physically sensible value for $X_{\Psi_{N}}$.

A further refinement, anticipating the possibility of random variations in the initial state and the extension of these ideas to quantum mechanics is to write

$$
\begin{equation*}
\langle X\rangle_{\Psi_{N}}=\operatorname{Tr}\left\{\mathbb{X}_{N} \rho_{N}\right\} \tag{36}
\end{equation*}
$$

where $\operatorname{Tr}$ represents the familiar trace process and $\rho_{N}$ is the dyadic $\left.\mid \Psi_{N}\right)\left(\Psi_{N} \mid\right.$ analogous to a pure state density matrix in quantum mechanics.

We note that $\left.\left.\mid \Psi_{N}\right)=\mathbb{U}_{N, 0} \mid \Psi_{0}\right)$ and $\left(\Psi_{N} \mid=\left(\Psi_{N} \mid \overline{\mathbb{U}}_{N, 0}\right.\right.$, where the evolution operator $\mathbb{U}_{N, 0}$ maps elements of $\mathcal{R}_{0}$ into elements of $\mathcal{R}_{N}$ and similarly for the dual evolution operator $\overline{\mathbb{U}}_{N, 0}$. In general, it will be true that

$$
\begin{equation*}
\overline{\mathbb{U}}_{N, 0} \mathbb{U}_{N, 0}=\mathbb{I}_{\mathcal{R}_{0}} \tag{37}
\end{equation*}
$$

the identity operator for $\mathcal{R}_{0}$. However, because there is no requirement formally in this approach for the rank $r_{N}$ of the final physical register $\mathcal{R}_{N}$ to equal the rank

## Towards a dynamical theory of observation

$r_{0}$ of the initial physical register $\mathcal{R}_{0}$, it is possible that $\mathbb{U}_{N, 0} \overline{\mathbb{U}}_{N, 0}$ does not equal $\mathbb{I}_{\mathcal{R}_{N}}$. This corresponds to irreversible dynamics. In the analogous quantum formalism we have developed [6], such evolution operators are referred to as semi-unitary.

Using (37) in (36), we may write

$$
\begin{equation*}
\langle X\rangle_{\Psi_{N}}=\operatorname{Tr}\left\{\mathbb{X}_{N} \mathbb{U}_{N, 0} \rho_{0} \overline{\mathbb{U}}_{N, 0}\right\}, \tag{38}
\end{equation*}
$$

where $\rho_{0}$ is the initial dyadic $\left.\mid \Psi_{0}\right)\left(\Psi_{0} \mid\right.$.

## Random initial states

Real experiments normally consist of a large number of repetitions or runs of a basic process. However, it cannot always be guaranteed that the initial labstate is always the same. In principle, we could start with any one of $d_{0} \equiv 2^{r_{0}}$ initial labstates. In such a case, a statistical approach can be taken.

Consider a very large number $R$ of runs, such that there is a total of $R_{k}$ runs starting with initial labstate $\mid k)$, for $k=0,1, \ldots, d_{0}-1$. Clearly, $\sum_{k=0}^{d_{0}-1} R_{k}=R$. Then in the limit of $R$ tending to infinity, we would assign a probability $\omega_{k} \equiv$ $\lim _{R \rightarrow \infty} R_{k} / R$ for the initial labstate to be in state $\left.\mid k\right)$.

In such a scenario, we define

$$
\begin{equation*}
\left.\rho_{0} \equiv \sum_{k=0}^{d_{0}-1} \omega_{k} \mid k, 0\right)(k, 0 \mid, \tag{39}
\end{equation*}
$$

where $\mid k, 0)$ is any one of the $d_{0}$ elements of the initial physical register $\mathcal{R}_{0}$ and the $\omega_{k}$ are probabilities summing to unity.

## Quantization

The formalism we have developed is readily extended to the quantum scenario, for which different principles hold concerning the interpretation and usage of the physical register. In this scenario, a rank $r_{n}$ physical register $\mathcal{R}_{n}$ at time $n$ is identified with a preferred orthonormal basis $\left\{|k\rangle: k=0,1, \ldots, d_{n}-1\right\}$ for a quantum register $\mathcal{Q}_{n} \equiv Q^{1} \otimes Q^{2} \otimes \ldots \otimes Q^{r_{n}}$, where now the $Q^{i}$ are qubits. This is the tensor product of $r_{n}$ qubits, each of which is identified with one ESD. We make the formal identification

$$
\begin{equation*}
\left|\varepsilon_{i}\right\rangle \rightleftharpoons\left|\varepsilon_{i}\right\rangle, \quad i=1,2, \ldots, r_{n} \tag{40}
\end{equation*}
$$

where $\mid \varepsilon_{i}$ ) is an element of classical bit $\mathrm{B}^{i}$ and $\left|\varepsilon_{i}\right\rangle$ is an element of the preferred basis $\mathrm{B}\left(Q^{i}\right)$ of qubit $Q^{i}$.

A quantum register is a complex Hilbert space of dimension $2^{d_{n}}$, so now labstates can be multiplied by complex numbers and added together, unlike the classical scenario. Most of the formulae developed in the previous section can be taken

## Towards a dynamical theory of observation

wholesale into the quantum scenario. For example, (34) now corresponds to the the expectation value of Hermitian operator $\hat{X} \equiv \sum_{k=0}^{d_{N}-1}|k\rangle X_{k}\langle k|$ relative to the pure quantum state $|\Psi\rangle=\sum_{k=0}^{d_{N}-1} \Psi_{k}|k\rangle$, where $\sum_{k=0}^{d_{N}-1}\left|\Psi_{k}\right|^{2}=1$.

In applications to quantum optics, this approach has been extended to include SUO attributes such as internal spin [15, 16] in a generalization of the LudwigKraus POVM formalism.

## Implications and Comments

The quantized version of our classical model of observation throws up a surprising possibility. We introduced the notion early on in this paper that an absence of an ESD in a laboratory or the presence of a faulty ESD were physically observable states in a laboratory. Therefore, we can contemplate the possibility of setting up labstates which are superpositions of states of devices actually in the laboratory and states of devices not in the laboratory. Such an exotic possibility would appear to be analogous to the "interaction-free measurement" experiments discussed by Elitzur and Vaidman [17].

This paper was motivated by the question "does quantum mechanics give a complete description of physics?", which was behind the famous paper of Einstein, Podolsky and Rosen [18]. Our view is that the answer is contextual. If the question refers to the description of the outcomes of a given experiment, then yes, quantum mechanics is as complete a description as you can get. If on the other hand we start to ask questions as to why we did that experiment in the first place, then we cannot get any answers from quantum mechanics as it is currently formulated.

It appears that there is still something deep still missing in physics: a comprehensive theory of observation. Such a theory should be able to clarify the relationship between the SUO, observer and apparatus concepts. Certainly, Feynman seemed to suggest that this was a legitimate physics question [1]. Unfortunately, there is no real understanding on this front currently. We hope that our paper, whilst it represents no more than a few comments and observations on what looks like an impossible challenge, may be of some value in suggesting new lines of research in this area.
