Draft, in preparation

#### ABSTRACT

In 2004, McLaughlin et al. discovered a phenomenon in the radio emission of PSR J0737−3039B (B) that resembles drifting sub-pulses. The repeat rate of the sub-pulses is equal to the spin frequency of PSR J0737−3039A (A); this led to the suggestion that they are caused by incidence upon B's magnetosphere of electromagnetic radiation from A. Here we describe a geometrical model which predicts the delay of B's sub-pulses relative to A's radio pulses. We show that measuring these delays is equivalent to tracking A's rotation from the point of view of an hypothetical observer located near B. This has three main astrophysical applications: (a) to determine the sense of rotation of A relative to its orbital plane; (b) to estimate where in B's magnetosphere the radio sub-pulses are modulated and (c) to provide an independent estimate of the mass ratio of A and B. The latter might improve existing tests of gravitational theories using this system.

### 1 INTRODUCTION

The discovery of the double pulsar system PSR J0737–3039 [\(Burgay et al. 2003;](#page-8-0) [Lyne et al. 2004\)](#page-8-1) has led to important advances in the study of radio pulsars and their associated phenomenology. The independent determination of the orbit of both neutron stars, and the recent measurement of five post-Keplerian parameters from the timing of A [\(Kramer et al. 2006](#page-8-2)) and a sixth one from eclipse observations of A [\(Breton et al. 2008\)](#page-7-1) has made this the most over-constrained system known, allowing five tests of general relativity.

PSR J0737−3039B (henceforth <sup>B</sup>) has many unique features. It emits pulsed radio waves during most of the orbit, but it becomes much brighter at two distinct orbital phases [\(Lyne et al. 2004](#page-8-1)). Furthermore, its pulse profile changes strongly with orbital phase and with time [\(Burgay et al. 2005](#page-8-3)). Though instructive in other ways, this behaviour has made it difficult to measure times of arrival accurately and obtain a precise estimate of the semi-major axis of the orbit of B, limiting the precision of our knowledge of the pulsar mass ratio  $R = m_A/m_B$  and the precision of some of the tests of general relativity in this system (see, e.g., Kramer & Stairs 2008 for a recent review).

This paper is motivated by another unique feature of B: for certain orbital phases its radio emission is clearly modulated by electromagnetic emission from A [\(McLaughlin et al. 2004\)](#page-8-4); the phenomenon superficially resembles drifting sub-pulses (e.g. Lorimer & Kramer 2005). In this work, we discuss the *timing* of this phenomenon. In  $\S$  [2,](#page-1-0) we present a theoretical calculation of the delay in the arrival at the Earth of the sub-pulses of B relative to the radio pulses of A responsible for the

<span id="page-1-1"></span>Figure 1. Sequence of events in A, looking down the pulsar's spin axis. We assume that the plane of the drawing is the orbital plane. Left: at  $t_0$  the radio beam is pointing at the Earth (outside of the orbital plane), producing a maximum of radio emission. At this time,  $\mathbf{A}$ 's EM beam is not necessarily pointing at B. *Center, top*: at  $t'_0$  **A** is emitting the EM signal that will produce the response. Locally, the wavefront (light line) is a plane perpendicular to the direction of propagation of the EM signal. Between  $t_0$  and  $t'_0$ , A rotated by  $\theta = \lambda_b + \pi/2 - \phi_e$  if the pulsar is rotating in the same sense of the orbit (clockwise here), or  $\theta = 2\pi - (\lambda_b + \pi/2 - \phi_e)$  if the pulsar is rotating in the opposite sense of the orbit. *Right, bottom* at time  $t'_{1}$ , the EM wavefront arrives at B's position. Soon after that, at time  $t_1$ , the wavefront arrives at point E, where the Earth-bound radio emission of B originates. This is located at a fixed distance  $\epsilon$  from B on that pulsar's line of sight to Earth, it is at a small distance from the orbital plane  $\epsilon \cos i$  (see text). The arrival of the wavefront at point E at time  $t_1$  produces the response in B's emission, which then follows to Earth.  $\lambda_a$  is the longitude of A as seen from E at  $t_1$ ; so  $\lambda_b = \lambda_a + \pi$  is the longitude at which A's EM beam transmits towards B.

drift. We name this simply the "response delay". In  $\S$  [3,](#page-5-0) we discuss how we can compare the predicted and measured response delays. In § [4,](#page-7-2) we highlight the astrophysical knowledge that can be gained from the timing of the response delays.

### <span id="page-1-2"></span><span id="page-1-0"></span>2 CALCULATING RESPONSE DELAYS

#### 2.1 Time between emission of A's radio pulse and B's response

The time between the emission of A's radio pulse and B's response can be divided in three parts, which we discuss below.

(i) The sub-pulses of B are spaced by 22.7 ms, which is the same as the spin period of A [\(McLaughlin et al. 2004](#page-8-4)). Therefore, we can think of the maximum intensity of the sub-pulses of B (the "response") as being caused by the impact upon B's radio emitting region of a co-rotating beam of electromagnetic radiation from A. We henceforth refer to this as the EM beam. Since the EM beam is not necessarily aligned in rotational phase with A's radio beam, as shown in Fig. [1,](#page-1-1) we introduce a phase offset  $\phi_e$  between the two beams. We define A's zero longitude to be the point where the radio emission towards the Earth reaches maximum intensity. As we show later, one of the applications of our model would be the direct determination of  $\phi_e$ .

One of the simplifying assumptions in Fig. [1](#page-1-1) is that the spin axis of A is perpendicular to the orbital plane. This has been suggested [\(Manchester et al. 2005](#page-8-5)) as the most plausible explanation for the lack of change in the pulse profile of A; Ferdman

(2008) set an upper limit of about 14◦ for the misalignment between the orbital angular momentum and the spin of A. We henceforth assume that the spin axis of A is indeed perpendicular to the orbital plane. It is not know whether A rotates in the same sense as the orbit or in the opposite sense, but kinematic considerations [\(Bailes 1988](#page-7-3)) make the former more likely. We discuss this issue further in § [3](#page-5-0) and § [4.](#page-7-2)

In Fig. [1,](#page-1-1) at time  $t_0$  we see A's radio beam pointing at the Earth, causing the radio emission to reach a maximum. At time  $t'_0$  the EM beam is pointing at a direction  $\lambda_b$ , where it emits the signal that will later cause B's response<sup>[1](#page-2-0)</sup>. Between the two events A has rotated by an angle  $\theta = \pm(\lambda_a - \pi/2 - \phi_e)$  where  $\lambda_a = \lambda_b - \pi$  is the longitude of A as seen from the location and time where the EM signal modulated the radio pulse of B (point E at time  $t_1$ , see Fig. [1\)](#page-1-1). The positive sign corresponds to a clockwise rotation of A as shown in Fig. [1,](#page-1-1) i.e., in the same sense of the orbit. The time between the two events is given by

$$
t_0' - t_0 = P_A \frac{\theta}{2\pi},\tag{1}
$$

where  $P_A$  is the spin period of  $A$ .

(ii) After  $t'_0$  the EM pulse of A travels towards B; at time  $t'_1$  it gets to B's exact position. The distance between these two events is  $r_{AB}(\lambda_a)$ , this is calculated in § [2.3.](#page-4-0) In the assumption above (that signal travels at the speed of light) we have

$$
t_1' - t_0' = \frac{r_{AB}(\lambda_a)}{c}.\tag{2}
$$

(iii) What happens near B is less certain. The simplest assumption is that the EM signal is able to travel through B's magnetosphere at the speed of light (this is possible e.g. if the EM signal consists of high-energy photons) and modulates B's Earth-bound radio emission at the point where it is being generated; we designate this as "E".

We must keep in mind that this simplified assumption is not the only possible case: a) the modulation could occur after B's radio signal is produced, i.e., somewhere between point E and the Earth and b) more generally, the chain of events from the emission of the EM signal at  $A(t'_0)$  to the modulation of the radio signal of B  $(t_1)$  might not lie along a single null geodesic. For the time being, we will quantify the simplest case only (see Fig. [1\)](#page-1-1).

Since E is where the Earth-bound radio emission is being generated, we assume it is the point of the radio-emitting region of B's magnetosphere that is in the line of sight from B to Earth. This only happens when B's radio pulse is "on". For most of B's rotational cycle, when its pulse is "off", no part of its radio-emitting region is pointing at Earth, and no response is detected.

In our simplified model, we assume that the distance of E to B is a constant  $\epsilon$  as a function of B's spin phase. Therefore, in the reference frame of the orbital plane (with axes along the line of nodes, perpendicular to the line of nodes and perpendicular to the orbital plane), E is located at fixed coordinates  $(0, \epsilon \sin i, \epsilon \cos i)$  relative to B, where i is the orbital inclination of the system (see Fig. [1\)](#page-1-1).

At  $t_1'$ , the EM wavefront from A reaches B. A small amount of time later, at  $t_1$ , the same wavefront reaches E and produces the response. From that Figure, we can see that

$$
t_1 - t_1' = \frac{\epsilon}{c} \sin \lambda_a \sin i. \tag{3}
$$

Between  $t'_1$  and  $t_1$  the orbital motion of B will make E move by a small amount relative to the center of the binary, this will affect the arrival time at E. We note, however, that for slow pulsars  $\epsilon/c$  is expected to be of the order of 1 ms [\(Blaskiewicz et al. 1991](#page-7-4)). Assuming this is true, a detailed calculation of the  $O(\epsilon c^{-2})$  Doppler correction due to B's (and E's) motion shows that this term is smaller than  $1 \mu s$ . Since the r.m.s. timing precision of A is about  $10 \mu s$ , and the timing precision for B's response is likely to be worse, we will ignore all terms with magnitude  $< 10 \,\mu s$ .

For the total time difference we obtain:

<span id="page-2-2"></span>
$$
t_1 - t_0 \equiv (t_1 - t_1') + (t_1' - t_0') + (t_0' - t_0) = \frac{\epsilon}{c} \sin \lambda_a \sin i + \frac{r_{AB}(\lambda_a)}{c} + P_A \frac{\theta}{2\pi} + O(\epsilon c^{-2}),\tag{4}
$$

which should be valid in any inertial reference frame using the orbital parameters as measured in that frame.

#### 2.2 Response delay

We now calculate the delay between the reception at the SSB of A's radio pulses and B's responses,  $\Delta(\lambda_a)$ . To do this, we will start by adding to  $t_1 - t_0$  the difference in the ranges<sup>[2](#page-2-1)</sup> at which these events occur,  $z_1 - z_0$  divided by c; this is the so-called "Rømer delay".

<span id="page-2-0"></span><sup>&</sup>lt;sup>1</sup> Lower-case subscripts refer to  $\lambda$  computed for the emission-reception-Earth triangle, while uppercase subscripts refer to lambda computed for a line through the centre of mass of the binary system, O. Here we have neglected aberration effects and the small angle between AB and AE, as the corresponding time delays are below the accuracy relevant for this paper.

<span id="page-2-1"></span><sup>&</sup>lt;sup>2</sup> We use the term "range" to indicate the distance of a given event from the center of mass of the binary projected along the direction to the SSB *as seen at the SSB*.

4 Freire et al.

<span id="page-3-0"></span>**Figure 2.** Emission (at  $t'_0$ , on A) and reception at the position of B (at  $t'_1$ ) of the EM signal that causes B's responses. *Upper diagram*: events depicted in the orbital plane. O represents the centre of mass of the system, orbital motion is represented as clockwise. *Lower diagram:* events depicted on a plane that is perpendicular to the orbital plane and the plane of the sky. This contains the line of sight to the Earth and allows a representation of the response delays. The orbital inclination i of the PSR J0737−3039 binary system is much closer to 90° than depicted in this figure [\(Kramer et al. 2006\)](#page-8-2); we represent it as being substantially lower for clarity. The difference in the locations of  $t_0, t'_0$  and  $t'_1, t_1$  is too small to be discerned at this scale. In this figure, the line of periastron just happens to coincide with the line of nodes, with  $\omega_A = 180^\circ$ ,  $\omega_B = 0^\circ$ .

As in the case of  $t_1 - t_0$  (eq. [4\)](#page-2-2),  $z_1 - z_0$  can also be described as the sum of three terms,  $(z_1 - z_1') + (z_1' - z_0') + (z_0' - z_0)$ :

(i) The difference in range between the events at  $t_0$  and  $t'_0$  is given by:

$$
z'_0 - z_0 = (t'_0 - t_0)v_{l,A} = P_A \frac{\theta}{2\pi} v_{l,A},
$$
\n(5)

where  $v_{l,A}$  is the velocity of A relative to the centre of mass, projected along the line of sight to Earth (§[2.3\)](#page-4-0).

(ii) In the lower diagram of Fig. [2,](#page-3-0) we see that the difference in range between the events happening at  $t'_1$  and  $t'_0$  is given by:

$$
z_1' - z_0' = -r_{AB}(\lambda_a) \sin \lambda_a \sin i. \tag{6}
$$

(iii) Ignoring the motion of E between  $t'_1$  and  $t_1$ , we have

 $z_1 - z'_1$  $1 = -e.$  (7)

<span id="page-4-3"></span>Figure 3. Detail on the motion of B in the orbital plane of the system. O represents the centre of mass of the system.

The delay is therefore given by:

<span id="page-4-1"></span>
$$
\Delta_r(\lambda_a) = t_1 - t_0 + \frac{z_1 - z_0}{c} = \frac{r_{AB}(\lambda_a) - \epsilon}{c} \left(1 - \sin \lambda_a \sin i\right) + P'_A \frac{\theta}{2\pi} + O(\epsilon c^{-2}),\tag{8}
$$

where the subscript "r" indicates that we are taking into account the Rømer delay only. In this equation we use  $P'_A$  $P_A(1 + v_{l,A}/c)$  to represent the spin period of A with the classical Doppler correction due to its orbital velocity. This equation is valid at the SSB if we use the orbital parameters as measured there.

In Appendix A we present a detailed calculation of the relativistic contribution to the total response delay  $\Delta$ , known as the "Shapiro delay" ( $\Delta_s$ ). For the range of orbital phases where we observe B's responses  $\Delta_s$  changes 4 µs, i.e., smaller than the r.m.s. timing precision of A. We can therefore assume  $\Delta = \Delta_r + \Delta_s \simeq \Delta_r$  for the remainder of this paper.

#### <span id="page-4-0"></span>2.3 Distance between A at transmission and B at response

Having calculated the response delay as a function of  $\lambda_a$  and the separation between the two pulsars,  $r_{AB}(\lambda_a)$ , we now calculate these two quantities as a function of  $\lambda_A$  at  $t'_0$ . The reason for this is that  $\lambda_A$  can be calculated precisely for any given time using the equations in Damour & Deruelle (1985,1986), furthermore, this quantity determines the instantaneous configuration of the system.

In the equations that follow, we will only use the Newtonian terms to  $O(c^{-2})$ . A detailed calculation shows that the  $O(c^{-3})$  Newtonian terms are much smaller than the r.m.s. timing precision of A. This means that they can be ignored for or present purposes.

At  $t'_{0}$ , the separation of pulsar I (A or B) from the centre of mass is given (see, e.g., Roy 1988) by

<span id="page-4-2"></span>
$$
d_I = a_I \frac{1 - e^2}{1 + e \cos f},\tag{9}
$$

where  $a_I$  is the semi-major axis of its orbit, e is the orbital eccentricity and the angle f is the true anomaly of the system at  $t'_0$   $(f = \lambda_I - \omega_I$ , where  $\omega_I$  is the longitude of periastron of pulsar I at  $t'_0$ ). The components of a pulsar's velocity along the radial (i.e., away from the centre of mass) and transverse directions are given [\(Roy 1988](#page-8-6)) by

$$
\begin{array}{rcl}\n\dot{d}_I & = & v_I e \sin f, \\
d_I \dot{f} & = & v_I (1 + e \cos f),\n\end{array} \tag{10}
$$

where

6 Freire et al.

$$
v_I = \frac{2\pi}{P_b} \frac{a_I}{\sqrt{1 - e^2}},\tag{12}
$$

is the transverse velocity of pulsar I at quadrature  $(f = \pi/2)$  and  $P_b$  is the orbital period of the binary. The velocity of that pulsar relative to Earth is given by (e.g., Green 1985):

$$
v_{l,I} = v_I \sin i \left( \cos \lambda_I + e \cos \omega_I \right). \tag{13}
$$

Calculating this velocity for  $A$  we can immediately quantify the Doppler correction term for  $P_A$  in eq. [8.](#page-4-1)

To calculate the instantaneous distance between the pulsars  $(d_{AB})$ , we replace  $a_I$  by  $a = a_A + a_B$  in eq. [9.](#page-4-2) During the time it takes A's signal to cross this distance  $(d_{AB}/c)$ , B is moving. Because the EM signal is moving in the radial direction, only the radial component of B's motion (dr) will affect the travel time between the two pulsars. During the cross time  $dr \simeq d_B d_{AB}/c$ , i.e., the distance between the events at  $t'_0$  and  $t'_1$  is

<span id="page-5-1"></span>
$$
r_{AB}(\lambda_A) = d_{AB} + dr = d_{AB} \left( 1 + \frac{v_B}{c} e \sin f \right) + O\left(c^{-2}\right); \tag{14}
$$

the perpendicular motion of B between  $t'_0$  and  $t'_1$  is

<span id="page-5-2"></span>
$$
dr_{\perp} \equiv d_B df = d_B f(t'_1 - t'_0) = v_B (1 + e \cos f) \frac{r_{AB}(\lambda_A)}{c}.
$$
\n(15)

Looking at Fig. [3](#page-4-3) we can see that

$$
\lambda_a = \lambda_A + \frac{dr_\perp}{r_{AB}(\lambda_A)} = \lambda_A + \frac{v_B}{c}(1 + e \cos f). \tag{16}
$$

In the derivation above we made the approximation that  $\lambda_a$  is the longitude of A as seen from B at  $t'_1$ . The longitude of A as seen from point E at  $t_1$  is larger by a very small amount,  $\epsilon \sin i \cos \lambda_a / r_{AB}$ .

Noting that  $dx = dr_{\perp} \cos \lambda_A$ ,

$$
r_{AB}(\lambda_A)\sin\lambda_a = r_{AB}(\lambda_A)\sin\lambda_A + dr_\perp\cos\lambda_A.
$$
\n<sup>(17)</sup>

With this result we can re-write eq. [8](#page-4-1) as a function of  $\lambda_A$ :

$$
\Delta(\lambda_A) = \frac{r_{AB}(\lambda_A) - \epsilon}{c} \left(1 - \sin \lambda_A \sin i\right) - \frac{dr_\perp}{c} \cos \lambda_A \sin i + P'_A \frac{\theta}{2\pi} + O(\epsilon c^{-2}).\tag{18}
$$

Using eqs. [9,](#page-4-2) [14](#page-5-1) and [15,](#page-5-2) we can re-write this as a function of a Keplerian term,  $K(\lambda_A)$ , which can be calculated from known orbital parameters and the system's geometry, and the unknown quantities  $\epsilon$  and  $\theta$ :

$$
\Delta(\lambda_A) = K(\lambda_A) - \frac{\epsilon}{c} (1 - \sin \lambda_A \sin i) + P'_A \frac{\theta}{2\pi} + O(\epsilon c^{-2})
$$
\n(19)

$$
K(\lambda_A) = \frac{a}{c}(1-e^2)\left[\frac{1-\sin\lambda_A\sin i}{1+e\cos f}\left(1+\frac{v_B}{c}e\sin f\right)-\frac{v_B}{c}\cos\lambda_A\sin i\right] + O\left(c^{-3}\right). \tag{20}
$$

The  $K(\lambda_A)$  term is the time difference, measured at the SSB, between the events that occurred at  $t'_1$  and  $t'_0$  in the reference frame of the binary; it is by far the largest contribution to the response delay.

# <span id="page-5-0"></span>3 COMPARING MEASUREMENTS OF RESPONSE DELAYS WITH PREDICTIONS

So far, we have just made a theoretical calculation of the response delays,  $\Delta(\lambda_A)$ . We now discuss what we can learn from actually measuring such delays.

#### 3.1 Measuring absolute delays

If we measure  $\Delta(\lambda_A)$  for several  $\lambda_A$  in a single orbit and subtract  $K(\lambda_A)$ , we can measure the delays that are not a priori predictable:

<span id="page-5-3"></span>
$$
\Delta(\lambda_A) - K(\lambda_A) = \frac{\epsilon}{c} \left( \sin \lambda_a \sin i - 1 \right) \pm P'_A \left( \frac{\lambda_a}{2\pi} - \frac{\phi_e}{2\pi} - \frac{1}{4} \right). \tag{21}
$$

In order to measure  $\Delta(\lambda_A)$ , we have to specify a particular radio pulse of A (in principle the closest to the time of emission of the EM signal that caused that particular response) and subtract its (barycentric) time from the response's barycentric time. However, because we have no prior knowledge of the terms in eq. [21,](#page-5-3) there is some ambiguity in the choice of the pulse that is closest to that time of emission.

An experimental method that does away with the issue of the choice of a pulse of A and even the measurement of  $\Delta(\lambda_A)$ entirely would proceed along the following lines:

(i) B's responses are particularly noticeable in an intensity gray-scale plot of time versus spin phase of B as presented by [\(McLaughlin et al. 2004](#page-8-4)). In such a plot, we can determine the precise spin phase corresponding to each response; the precise method to accomplish this and the attainable precision will be discussed elsewhere.

(ii) In the next step, we convert this phase into a barycentric time. This can be achieved using the software package  $TEMP^3$  $TEMP^3$ . The result corresponds to an event that occurred at  $t_1$  in the reference frame of the binary.

(iii) Subtracting  $K(\lambda_A)$ , we obtain a second barycentric time that nearly corresponds to A's emission of the EM pulse  $(t'_0 + \epsilon/c \sin \lambda_A \sin i)$  in the reference frame of the binary). At this time we calculate  $\lambda_A$  from the binary's ephemeris.

(iv) Subtract the nearest time at which the rotational phase of A is zero. This time should be the equivalent of  $\Delta(\lambda_A)$  –  $K(\lambda_A)$ . By fitting this to eq. [21](#page-5-3) we should be able to determine  $\epsilon$ ,  $\phi_e$  and the direction of the spin of A.

With data from different orbits, we can also get a sense for the stability of  $\phi_e$  and  $\epsilon$ . Thus far we have assumed that  $\epsilon$ (the height above B where the response is produced) is a constant as a function of B's rotational phase. It is possible, however, that  $\epsilon$  varies with B's spin phase. This would also introduce a secular variation of the  $\epsilon$  observed for any spin phase of B due to the pulsar's geodetic precession. If that is the case, we could map the height of E above B as a function of the precession phase. Confusion with  $K(\lambda_A)$  can be avoided because, despite the fact that both terms vary with  $1 - \sin \lambda_A \sin i$ , only the latter varies with  $(1 + e \cos f)^{-1}$ .

#### 3.2 Delay variations at a constant  $\lambda_A$

The response delays  $\Delta(\lambda_A)$  will vary in time for any given  $\lambda_A$  because of the apsidal motion  $\dot{\omega}$  changes f, which causes a change in  $K(\lambda_A)$ :

<span id="page-6-2"></span>
$$
\delta_{t_2 - t_1}(\lambda_A) \equiv \Delta_{t = t_2}(\lambda_A) - \Delta_{t = t_1}(\lambda_A) = \frac{a}{c}(1 - e^2)(1 - \sin \lambda_A \sin i)[j(t_2) - j(t_1)],\tag{22}
$$

where  $t_1$  and  $t_2$  are two epochs at which the longitude  $\lambda_A$  occurs and

$$
j(t) = \left(1 + \frac{v_B}{c} e \sin f\right) \left(1 + e \cos f\right)^{-1}.\tag{23}
$$

Other terms of order larger than  $c^{-3}$  cancel out in the subtraction because of the constant  $\lambda_a$ , and the same happens for the terms dependent on  $\theta$  and  $\epsilon^4$  $\epsilon^4$ . The variation of the Doppler correction to  $P_A$  are  $\lt 1 \mu s$  and can therefore be ignored.

The  $\delta_{t_2-t_1}(\lambda_A)$  are important because, being due solely to a variation of  $K(\lambda_A)$ , they are proportional to a. The maximum variation occurs between the time when  $\lambda_A$  coincides with periastron  $(f = 0,$  occurring at  $t = t_p$ ) and apastron  $(f = \pi,$ occurring at  $t = t_a$ , which for PSR J0737-3039 is about 10.65 years later):

<span id="page-6-3"></span>
$$
\delta_{t_a - t_p}(\lambda_A) = \frac{2ae}{c} \left(1 - \sin \lambda_A \sin i\right). \tag{24}
$$

In a single 2003 observation, McLaughlin et al. (2004) observe B's responses from  $\sim 195^{\circ} < \lambda_B < \sim 225^{\circ}$ , i.e., occurring shortly before the magnetosphere of B eclipses A at  $\lambda_B = 270^\circ$ . This corresponds to ~ 15° <  $\lambda_A$  <~ 45°. At these extremes we have  $\delta_{t_a-t_p}(\lambda_A) = 0.3814(3)$ s and 0.1508(1)s. The uncertainty in this prediction is entirely due to the uncertainty of a (which results entirely from the uncertainty in the measurement of  $a_B$ ); it represents  $0.5 - 1.5\%$  of a rotation of A; this means that we should be able to keep track of the response delays with very high confidence.

The variations themselves are certainly measurable, since they are equivalent to many rotations of A. This means that we can always make an independent measurement of a. Depending on the precision and number of measurements of  $\Delta(\lambda_A)$ , the value of a derived in this fashion might be more precise than the present value derived from timing. In that case, we can improve our knowledge of the mass ratio:

<span id="page-6-4"></span>
$$
R = \frac{a\sin i}{cxA} - 1,\tag{25}
$$

where  $x_A$  is the projected semi-major axis of  $A$ 's orbit, in light seconds; this quantity is directly and very precisely measured from the timing of A. This equation (and also eqs. [22](#page-6-2) and [24\)](#page-6-3) show that, to determine R from a and  $x_A$  we need to know sin i. We could in principle determine sin i independently from comparing measurements of  $\delta_{t_2-t_1}(\lambda_A)$  made at different orbital longitudes. However, most theories of gravitation predict the Shapiro "s" term to be the same as sin i [\(Damour & Taylor 1992](#page-8-7); [Will 1993\)](#page-8-8); therefore such an independent determination is not likely to be a useful test of gravitation. For this reason, we can use the extremely precise estimate of  $\sin i$  from s in the estimate of R.

Finally, we remark that there is a small difference between the intrinsic and observed semi-major axes of the pulsar's orbits that is caused by aberration effects. Kramer et al. (2006) estimate that for A these are of the order of  $10^{-6}x_A$ , i.e.,

<span id="page-6-1"></span><span id="page-6-0"></span> $4$  The latter term is likely to cancel even if the main assumption in  $\S2.1$  $\S2.1$  is not correct, i.e., it only requires that any terms dependent on  $\epsilon$  vary with  $\lambda_a$  in a repeatable way.

# 8 Freire et al.

about 1  $\mu$ s; this is similar to the level of precision for the measurement of  $x_A$ . It is highly unlikely that we will measure a to a similar precision, so this should not be a problem for the determination of  $R$  in eq. [25.](#page-6-4) For B, Kramer et al. estimate that the effect of aberration should be of the order of  $10^{-4}x_B$ . It might be possible that we measure  $x_B = a \sin i/c - x_A$  to better than the necessary level of precision. However, to be able to measure the aberration directly, we must be able to measure  $x_B$  from timing with this level of accuracy, so that the difference between the two values becomes evident. The intrinsic uncertainty of the x<sub>B</sub> obtained from timing is about  $10^{-3}x_B$  [\(Kramer et al. 2006](#page-8-2)), one order of magnitude larger than the effect of aberration. Therefore, unless the direct timing of B improves by more than one order of magnitude, the effects of aberration won't be separately measurable.

#### <span id="page-7-2"></span>4 IMPLICATIONS AND PROSPECTS

In this paper we have calculated the delay between the radio pulses of A and the modulated radio pulses of B,  $\Delta(\lambda_A)$ , assuming a simple scenario for that modulation, i.e., that it happens at the point, E, where the radio emission of B is being produced and that the modulating signal is traveling from A to E at the speed of light. Things could be more complicated, particularly considering that this trajectory must intersect the magnetosphere of B.

We will present details of the measurements of  $\Delta(\lambda_A)$  and their timing analysis elsewhere. If the response delays obey the equations presented above in a consistent manner, that will validate our model. In that case, the measurement of these delays relative to the radio pulses of A can provide us with new astrophysical information.

First, a determination of the sense of A's rotation relative to its orbit, something never achieved for any other pulsar, would introduce fundamental constraints on binary evolution scenarios for this pulsar, as well as improved constraints on B's supernova kick. Finding that the orbital angular momentum is anti-aligned with A's angular momentum would require a very large supernova kick [\(Bailes 1988](#page-7-3)). Previous studies (e.g., Willems et al. 2006, Stairs et al. 2006) predict instead that the kick that produced B was rather small, therefore the angular momenta should be aligned. A confirmation of this alignment, combined with the small angle between the momenta, would introduce stringent constraints on the magnitude of the kick. Furthermore, we would know the sign of the expected relativistic spin-orbit contribution to  $\dot{\omega}$  (Damour & Schäfer 1988). It is probable that this contribution will be measured in the near future [\(Kramer & Wex 2009](#page-8-10)); that would allow an estimate of A's moment of inertia. The moment of inertia of A, together with the well-determined mass of the pulsar, will introduce fundamental constraints on the equation of state for dense matter [\(Lattimer & Schutz 2005](#page-8-11)).

Second, by measuring  $\epsilon$ , or by introducing upper limits to it, we might be able to locate the region where the EM signal from A is modulating the radio signal from B and relate it to the region where we expect the radio emission of B is being generated. Thus far, the best location of pulsar radio emission comes from the interpretation of multi-frequency polarimetric pulse profiles in light of a relativistic version of the the familiar rotating vector model [\(Blaskiewicz et al. 1991](#page-7-4)); the results indicate an emission height of a few hundred km. If the signal is being modulated as its being generated, then  $\epsilon$  should be of the order of a few ms and therefore a measurable quantity. If  $\epsilon$  is significantly larger, then the modulation is happening after B's radio signal is generated.

Third, we will make an independent measurement of the orbital separation of the two pulsars, a. If the timing of B's responses is precise enough, this might give us a more precise measurement of the mass ratio of A and B, which would increase the precision of some of the previous tests of general relativity carried out in this binary system. This is a key input parameter for the general tests on conservative gravity theories outlined in Kramer & Wex (2009).

In the ideal case that we can track the response times well, one might think of their reception at the Earth as being equivalent to having a radio telescope at an altitude  $\epsilon$  above B tracking A's rotation and then relaying the results live to Earth. This analogy highlights how fortunate we are to have a phenomenon like B's responses.

# APPENDIX A

Including post-Newtonian corrections, the time taken for a photon to propagate from the point of emission  $x_0$  to x in the gravitational field of a N-body system is given by

<span id="page-8-12"></span>
$$
t - t_0 = \frac{|\mathbf{x} - \mathbf{x}_0|}{c} + \frac{2G}{c^3} \sum_{i=1}^{N} m_i \ln \left[ \frac{r_{0i} + r_i + R}{r_{0i} + r_i - R} \right],
$$
\n(26)

where  $m_i$  is the mass of the *i*-th body located at  $\mathbf{x}_i$ ,  $r_{0i} \equiv |\mathbf{x}_i - \mathbf{x}_0|$ ,  $r_i \equiv |\mathbf{x} - \mathbf{x}_i|$ , and  $R \equiv |\mathbf{x} - \mathbf{x}_0|$  [\(Brumberg 1991\)](#page-7-5). The first term,  $|x - x_0|/c$ , is the Rømer term used in the main text. The second term, the relativistic correction, is the sum of the Shapiro delays caused by the individual bodies in the N-body system.

We now apply equation [\(26\)](#page-8-12) to the signal propagation discussed in this paper (see figures [1](#page-1-1) and [2\)](#page-3-0). Neglecting terms smaller than a few  $\mu$ s one finds for the signal propagating from A to Earth at distance D

$$
\Delta_s^{(A\oplus)} \simeq \frac{2Gm_A}{c^3} \ln \left[ \frac{D}{\delta_R} \right] + \frac{2Gm_B}{c^3} \ln \left[ \frac{2D}{d_{AB}(1 + \cos \lambda_{a,\oplus})} \right] \,. \tag{27}
$$

 $\delta_R$  (≪  $d_{AB}$ ) is the emission height of the radio signal in the magnetosphere of A and  $\lambda_{a,\oplus}$  is the angle between the direction to Earth and the direction to pulsar A as seen from B. For the signal propagating from A to the point E to sufficient accuracy

$$
\Delta_s^{\text{(AE)}} \simeq \frac{2Gm_A}{c^3} \ln \left[ \frac{d_{AB}}{\delta_{\text{EM}}} \right] + \frac{2Gm_B}{c^3} \ln \left[ \frac{2d_{AB}}{\epsilon (1 + \cos \lambda_{a,\oplus})} \right] \,. \tag{28}
$$

 $\delta_{EM}$  ( $\ll d_{AB}$ ) is the emission height of the EM signal that triggers the sub-pulse emission at E. Finally, for the sub-pulse signal emitted at E the Shapiro delay is given by

$$
\Delta_s^{(\text{E}\oplus)} \simeq \frac{2Gm_A}{c^3} \ln \left[ \frac{2D}{d_{AB}(1 - \cos \lambda_{a,\oplus})} \right] + \frac{2Gm_B}{c^3} \ln \left[ \frac{D}{\epsilon} \right] \,. \tag{29}
$$

The contribution of the Shapiro delays to  $\Delta$  is therefore given by

<span id="page-8-13"></span>
$$
\Delta_s = \Delta_s^{(AE)} + \Delta_s^{(E\oplus)} - \Delta_s^{(A\oplus)} \n= \frac{2Gm_A}{c^3} \ln \left[ \frac{2}{1 + \sin i \sin \lambda_A} \right] + \frac{2Gm_A}{c^3} \ln \left[ \frac{\delta_{\rm R}}{\delta_{\rm EM}} \right] + \frac{4Gm_B}{c^3} \ln \left[ \frac{d_{AB}}{\epsilon} \right] ,
$$
\n(30)

where we have used cos  $\lambda_{a,\oplus} = -\sin i \sin \lambda_A$ . The second term of equation [\(30\)](#page-8-13) is constant and, to sufficient accuracy, can be absorbed in  $\phi_e$ . The third term of equation [\(30\)](#page-8-13) changes along the eccentric orbit with an amplitude of just 2  $\mu$ s, and therefore can be absorbed into  $\phi_e$  as well. In principle the first term of equation [\(30\)](#page-8-13) can change quite significantly along the orbit, as  $\sin i \approx 1$  in the double pulsar [\(Kramer et al. 2006](#page-8-2)). However, as mentioned above, the sub-pulses are only observed in the range  $\sim 15^{\circ} < \lambda_A < \sim 45^{\circ}$ . Across this interval the first term of equation [\(30\)](#page-8-13) changes by less than 4  $\mu$ s. Consequently, Shapiro delays can be ignored in the calculations of this paper.
