

Oscillatory thermal instability and the Bhopal disaster

R. Ball

*Mathematical Sciences Institute, The Australian National University
Canberra ACT 0200 Australia*

Abstract

A stability analysis is presented of the hydrolysis of methyl isocyanate (MIC) using a homogeneous flow reactor paradigm. The results simulate the thermal runaway that occurred inside the storage tank of MIC at the Bhopal Union Carbide plant in December 1984. The stability properties of the model indicate that the thermal runaway may have been due to a large amplitude, hard thermal oscillation initiated at a subcritical Hopf bifurcation. This type of thermal misbehavior cannot be predicted using conventional thermal diagrams, and may be typical of liquid thermoreactive systems.

Keywords: Methyl isocyanate, Thermal runaway, Oscillatory instability, Bhopal, Liquid explosives

1. Introduction

2 More than 25 years after the Bhopal disaster its horrific legacy is now well-
3 documented (Mishra et al., 2009), but the causes are still being debated in the
4 international media. Was the tragedy due to neglect, parsimony, or procrastina-
5 tion by Union Carbide on safety and maintenance? Ignorance, corruption, sabo-
6 tage and cover-up? Inadequate regulation of urban and industrial development?
7 Possibly all of the above, but they are putative, secondary or socioeconomic con-
8 tributing factors. (A brief account of the disaster is given in the Appendix.) The
9 primary cause of the thermal runaway that led to the venting of a poisonous mist
10 of methyl isocyanate over the city of Bhopal was physicochemical. In this be-
11 lated work I present a simple stability analysis of the thermokinetics of methyl

URL: www.maths.anu.edu.au/~ball/ (R. Ball)

12 isocyanate (MIC) hydrolysis, revealing rogue thermal misbehavior that appears to
13 be endemic to reactive organic liquids and that cannot be predicted using conven-
14 tional heat generation/loss rate diagrams.

15 The Bhopal incident is by no means the only example of disastrous thermal
16 runaway occurring in a storage tank. The Seveso accident in Italy in July 1976
17 in which large quantities of a toxic dioxin were released into the environment
18 occurred under storage tank conditions (Theophanous, 1983), while more or less
19 minor runaways and explosions due to unforeseen reactions in storage tanks and
20 vessels are relatively common. The special dangers of chemical storage were
21 discussed by Gyax (1988), who pointed out that circumstances favouring heat
22 accumulation are actually *more* likely to occur in storage tanks and equipment
23 parts that are not actively controlled, than in dedicated, well-designed chemical
24 reactors.

25 Despite the acknowledged dangers of large-scale storage of reactive chemi-
26 cals very little has been published on the dynamics of processes that may occur
27 in storage tanks. Velo et al. (1996) summarize the literature on theoretical and
28 experimental validations of runaway criteria and parametric sensitivity in batch
29 reactors and storage tanks. In defining critical conditions they, along with other
30 authors cited therein, begin with the assumption that storage tanks of small vol-
31 ume can be modelled as well-stirred batch reactors with linear thermal coupling
32 to the environment.

33 However batch reactors have no non-trivial steady states, and there is no gen-
34 eral theory for determining whether a thermal excursion will grow or decay. Here it
35 is assumed that the same parameters that govern the stability of a thermoreactive
36 process in nonequilibrium steady state also govern the stability of thermoreactive
37 processes in storage tanks. From the comprehensive stability and bifurcation anal-
38 ysis of the CSTR that was carried out in Ball (1999) these parameters are ambient
39 temperature, residence time, heat loss, and intensive properties of the reacting sys-
40 tem. It is shown in this work that a simple spatially homogeneous, steady state
41 approximation can simulate thermoreactive processes in a storage tank with high
42 fidelity.

43 Another driver for better understanding of thermoreactive processes in liquids
44 has emerged recently; this is the use of organic hydroperoxide explosives by ter-
45 rorists.

Table 1: Known relevant data for the MIC thermal runaway at Bhopal.

| | |
|--|------------------------------------|
| Boiling point of MIC at 1 atm | 39.1° C |
| Density of MIC | 0.9599 g/cm ³ at 20° C |
| Constant pressure heat capacity of MIC | 67.7 J/(K mol) = 1188 J/(K kg) |
| Reaction enthalpy for MIC hydrolysis | -65.1 kJ/mol |
| Reaction frequency for hydration of MIC (Castro et al., 1985) | $3.9 \times 10^{12} \text{s}^{-1}$ |
| Activation energy for hydration of MIC (Castro et al., 1985) | 64 kJ/mol |
| Mass of MIC in Tank 610 | 41 tonnes |
| Initial temperature inside Tank 610 | 13° C |
| Estimated time to criticality | 4 hours |

46 2. MIC chemistry and known relevant data

47 A chemical analysis of the residue in the MIC storage tank (Tank 610) sampled
48 seventeen days after the event found a variety of condensation products, mainly
49 the cyclic trimer (D’Silva et al., 1986). However, experiments to elucidate the
50 organic chemistry of the formation of these products indicated that these con-
51 densations must have been initiated at temperatures and pressures well above the
52 normal boiling point of MIC. Therefore, it is thought that the initial reaction of
53 thermokinetic significance was hydration to the unstable N-methyl carbamate, in-
54 dicated in grey:

56 where $k(T)$ is the temperature-dependent (pseudo-)first order rate constant. The
57 primary thermal effect that led to the onset of critical conditions is thought to be
58 due to the overall reaction

60 Some relevant physicochemical data and quantities for MIC hydrolysis in
61 Tank 610 are given in table 1. The thermodynamic parameters are taken from
62 standard tables.

63 3. Thermokinetics of MIC hydrolysis and thermal instability

The spatially homogeneous flow reactor in which a reactant undergoes a first
order, exothermic conversion is a simple but elucidatory model for thermoreac-

tive systems when it is appropriate to ignore convection, because as a dynamical system it has non-trivial steady states that can be analysed for stability. The mass and enthalpy equations are

$$V \frac{dc}{dt} = -Vck(T) + F(c_f - c) \quad (1)$$

$$V\bar{C} \frac{dT}{dt} = (-\Delta H)Vck(T) - (F\bar{C} + L)(T - T_a). \quad (2)$$

V is the reacting volume, c is the reactant concentration, c_f is the reactant concentration in the inflow, F is the volumetric flow rate, \bar{C} is the averaged volumetric specific heat, T is the reaction temperature, ΔH is the reaction enthalpy, L is the linear heat transfer coefficient, T_a is the ambient temperature. The temperature-dependent (pseudo)-first order reaction rate constant is

$$k(T) = A \exp(-E/RT), \quad (3)$$

where A is the reaction frequency, E is the activation energy, and R is the universal gas constant. For numerical and comparative reasons it is useful to work with the following dimensionless system corresponding to equations (1–2), using (3):

$$\frac{dx}{d\tau} = -xe^{-1/u} + f(1 - x) \quad (4)$$

$$\varepsilon \frac{du}{d\tau} = xe^{-1/u} - (\varepsilon f + \ell)(u - u_a), \quad (5)$$

64 where $x \equiv c/c_f$, $\tau \equiv tA$, $u \equiv RT/E$, $f \equiv F/VA$, $\varepsilon \equiv \bar{C}E/c_f(-\Delta H)R$, $\ell \equiv$
 65 $LE/c_fVA(-\Delta H)R$, $u_a \equiv RT_a/E$. Numerical analysis of equations (4–5) was car-
 66 ried out using rate, thermochemical and temperature data from table 1 and values
 67 of the inverse residence time f , heat loss ℓ , and inflow concentration c_f were
 68 assigned on the basis of available data.

69 The reacting mixture self-heats if the rate of reactive heat generation r_g ex-
 70 ceeds the linear cooling rate r_l . Thermal runaway occurs if r_g exceeds r_l beyond
 71 a system-specific threshold; for the hydrolysis of MIC this is taken as the boiling
 72 point of MIC. The steady-state rates from equations (4–5), are plotted in figure 1,
 73 where the temperature is labeled in dimensional units. The reaction self-heats
 74 until the reactor temperature T reaches the steady state temperature of ~ 305 K at
 75 which the heating and cooling rates are balanced. Since the boiling point of MIC
 76 is 312 K, on the basis of this diagram we would not expect a thermal runaway
 77 to develop, even when the ambient temperature is allowed to drift slowly up to
 78 292 K.

Figure 1: Rates of reactive heat generation r_g (red) and heat loss r_l (blue) versus T from equations (4–5). $u_a = 0.0379$ (corresponding to $T_a = 292\text{ K}$), $f = 1.7$, $\ell = 700$, $\varepsilon = 10$.

79 However thermal balance diagrams such as that in figure 1 can be dangerously
80 misleading because they infer stability rather than assess stability rigorously, al-
81 though such diagrams are often used in chemical reactor engineering. The steady
82 states, periodic solutions, and stability analysis of equations (4–5) were computed
83 numerically (Doedel, 2010) and yielded a dramatically different picture of the the
84 thermal stability of MIC hydrolysis. Figure 2 is a bifurcation diagram in which
85 the steady states and the amplitude envelope of periodic solutions are plotted as
86 a function of T_a . The steady state is stable at $T_a \approx 286\text{ K}$, the temperature at
87 which the tank of MIC had been held for several months. As T_a is quasistatically
88 increased the reaction temperature T increases slowly, but at $T_a = 290.15\text{ K}$ the
89 stability analysis flags an abrupt change in the nature of the solutions. At this point
90 the steady state solutions lose stability to a Hopf bifurcation and the hard onset
91 of a high amplitude thermal oscillation ensues. Clearly, at $T_a = 292\text{ K}$ we have
92 catastrophic thermal runaway, contrary to the inadequate prediction given by fig-
93 ure 1. (In the resulting superheated liquid the exothermic condensation reactions
94 would increase the temperature even further.)

95 This is quite different from classical ignition of a thermoreactive system, which
96 occurs at a steady-state turning point. The dynamics of oscillatory thermal run-
97 away can be understood by studying a close-up of the region around the Hopf
98 bifurcation H_1 in figure 2. This is shown in figure 3. H_1 is subcritical and the
99 emergent limit cycle is **un**stable. The amplitude envelope of the unstable limit cy-
100 cles is marked with a thin dotted line; they grow as T_a is **d**ecreased. At the turning
101 point of the periodic solution branch marked with a large asterisk the limit cycles

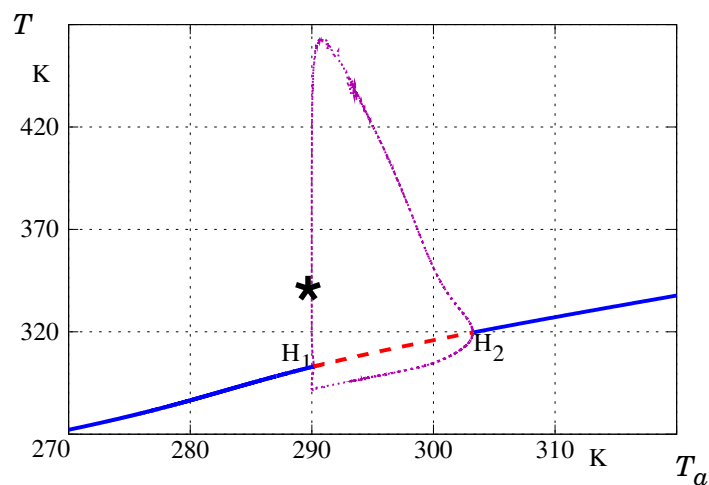

Figure 2: Bifurcation diagram. Stable steady states are plotted with solid blue line, unstable steady states with dashed red line, and the amplitude envelope of periodic solutions is marked with thin dotted magenta line. H_1 and H_2 label the Hopf bifurcation and the large * marks the change in stability of the limit cycles. $f = 1.7$, $\ell = 700$, $\varepsilon = 10$.

102 become stable. Thermal runaway *may* occur if there are significant perturbations
 103 while T_a is within the regime of unstable limit cycles, and it *must* occur when
 104 T_a drifts above H_1 . The arrow indicates the rapid thermal excursion, in principle
 105 to the stable limit cycle but in reality the reactant has vaporised, the pressure has
 106 soared beyond the safety limits of the tank, and the system must vent since the
 107 peak temperature is far above the boiling point of MIC.

108 4. Discussion

109 Although in principle classical thermal ignition is possible for MIC hydrolysis,
 110 in practice the presence of oscillatory instability is all-pervasive and dominant in
 111 this system. This can be appreciated by inspection of figure 4, a plot of the loci of
 112 the steady state turning points and the Hopf bifurcations of equations (4–5) over
 113 the two parameters u_a and the inverse residence time f . In the filled region thermal
 114 runaway will always be oscillatory. The bistable regime occurs at very high flow
 115 rates (short residence times). Here classical ignition at a steady state turning point
 116 to a stable steady state may occur, but the oscillatory instability is still present and
 117 oscillatory thermal runaway occurs (perversely) as the ambient temperature u_a is
 118 reduced.

119 The tendency for oscillatory, non-classical thermal runaway may be typical of

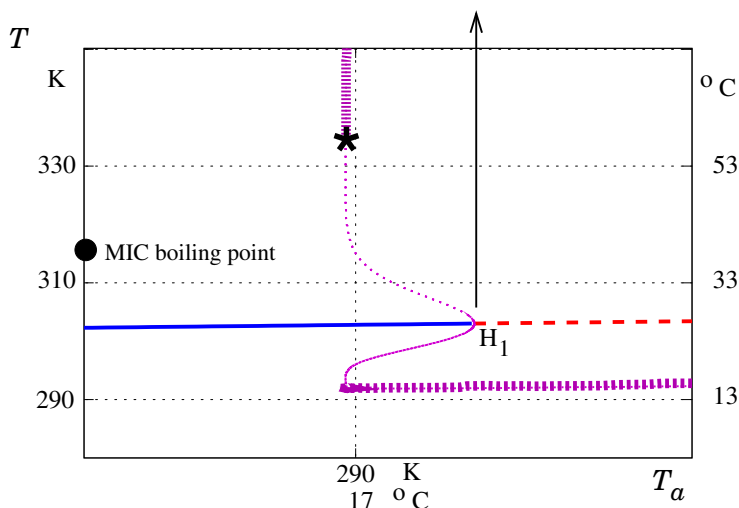

Figure 3: Close-up of the region around the Hopf bifurcation H_1 in figure 2.

120 low-boiling, exothermically reactive organic liquids. In the work of Ball and Gray
 121 (1995) the hydration of 2,3-epoxy-1-propanol in a CSTR was found to exhibit
 122 similar non-classical thermal misbehavior. The design of safe storage systems
 123 for such liquids should focus on damping the oscillatory instability, rather than
 124 shifting a classical ignition point using over-simplistic heat generation/loss rate
 125 diagrams like figure 1.

126 In recent years low-boiling, exothermically reactive liquids such as a variety
 127 of organic peroxides have been used as explosives by terrorists, and their potential
 128 use as murder weapons on aircraft is the reason for current restrictions on the
 129 liquids that passengers may carry on-board. It is possible that peroxide explosions
 130 are due to oscillatory instability rather than classical thermal ignition. Figure 5
 131 shows the two-parameter bifurcation diagram using thermokinetic parameters for
 132 the decomposition of cumene hydroperoxide (Wu and Shu, 2010) in equations
 133 (4–5). In understanding this type of explosion and for deactivating improvised
 134 explosive devices that employ such liquids it is clearly necessary to understand
 135 oscillatory thermal instability.

136 Is it realistic to model a reacting volume inside Tank 610 as a well-stirred flow
 137 reactor? Yes, on a timescale over which the reacting volume remains relatively
 138 constant and gradientless relative to the much faster rate of reaction. Consider a
 139 volume V of liquid in the tank, near the source of the water ingress, within which
 140 the hydration reaction takes place. The reacting volume V grows as water flows

Figure 4: The locus of Hopf bifurcations is marked with a solid line, the locus of steady-state turning points is marked with dashed line. $\ell = 700$, $\varepsilon = 10$.

141 into it and reaction proceeds. This volume can be regarded as the “reactor”, while
 142 the uncontaminated, non-reacting MIC in the rest of the tank can be regarded as
 143 the “coolant” to which heat is transferred linearly. The reacting volume expands
 144 until the rate of inflow matches the rate of outflow of reactant and products from
 145 the reacting volume.

146 In other words, for the purposes of this model in which the focus is on the
 147 dynamics we circumscribe a volume in which the spatial gradients are insignifi-
 148 cant in comparison to the time evolution, and therefore can be neglected. If this
 149 approximation does not hold, then we are free to reduce the circumscribed vol-
 150 ume until it does. There is nothing particularly artificial or manipulative in doing
 151 this; it is just a simplest case scenario for which the powerful tools of stability and
 152 bifurcation theory can be applied.

153 The Union Carbide plant at Bhopal has been derelict since the disaster and
 154 MIC is no longer in use as a bulk chemical, but we cannot afford to close the
 155 book on potential problems in storage tanks. In chemical plants and storage sites
 156 around the world there are tanks containing reactive organic liquids that have sim-
 157 ilar physical properties to MIC and undergo reactions with similar thermokinetics.
 158 Many other chemicals are stored as bulk commodities that can undergo thermally
 159 unstable polymerization, oxidation or decomposition reactions. Analysis of sim-
 160 ple gradientless models of processes that may occur in storage tanks provides
 161 insight into the physical basis of rogue thermal behavior and a starting point for
 162 improved design of safe storage systems. Concomitantly there is a need for more,

Figure 5: The 2-parameter bifurcation diagram from equations (4–5) applied to the decomposition of cumene hydroperoxide also has a large region within which thermal runaway is due to oscillatory instability. The locus of Hopf bifurcations is marked with a solid line, the locus of steady-state turning points is marked with dashed line. $\ell = 700$, $\varepsilon = 20$.

163 and more accurate, thermokinetic data to use in such models. It is notable that the
 164 data for MIC hydration/hydrolysis in table 1 were obtained as part of an unrelated
 165 research project initiated before the Bhopal disaster.

166 5. Conclusions

- 167 1. A belated investigation of the thermal runaway in Tank 610 that led to the
 168 Bhopal disaster has been carried out by modelling the hydrolysis of MIC in
 169 the well-stirred limit and analysing the stability of solutions of the dynamical
 170 system model.
- 171 2. Thermal runaway occurs due to the onset of a hard thermal oscillation at
 172 a subcritical Hopf bifurcation. Classical thermal ignition at a steady state
 173 turning point may occur in principle but over the thermal regime of interest
 174 the system is dominated by oscillatory instability.
- 175 3. This non-classical oscillatory thermal misbehavior may be generic in reac-
 176 tive organic liquids. The results yield valuable intelligence about the causes
 177 of themal runaway that may inform improved designs of storage systems
 178 for large quantities of toxic and reactive substances.
- 179 4. These results may also inform better management of organic peroxide based
 180 explosives.

181 **Appendix**

182 The following brief account of the Bhopal disaster has been compiled from the
183 following sources: Forman (1985), Lepkowski (1994), Shrivastava (1987), Weir
184 (1987) and Abbasi and Abbasi (2005).

185 The Union Carbide plant at Bhopal carried out the production of carbaryl,
186 an agricultural insecticide that has been used widely throughout the world since
187 1945. Methyl isocyanate, a low-boiling, highly reactive and extremely toxic liquid
188 used in the synthesis of carbaryl, was stored in an underground stainless steel tank
189 (Tank 610) which was encased in a concrete shell. The temperature of the 41
190 tonnes of MIC in Tank 610 was 12–14° C rather than the recommended 0–4° C
191 because the refrigeration unit had been non-operational for several months. On
192 the evening of December 2 1984 a worker had been sent to hose out a nearby
193 tank. The hose was left running unattended, and it is believed that a faulty valve
194 allowed entry of water into the connected Tank 610. (Union Carbide disputes this,
195 asserts that nothing was wrong with its equipment and procedures, and argues
196 that sabotage by a disaffected employee must have caused the disaster.) By 11:30
197 pm, when workers detected lachrymose whiffs of leaking MIC, water had been
198 running into Tank 610 for at least four hours. Although a slow rise in temperature
199 and pressure in the tank had been noted, the early signs of trouble were not acted
200 upon. Shortly after 11:30 pm the contents of the tank reached thermal criticality
201 and began escaping as vapor from the flare tower.

202 Downwind of the flare tower lay the crowded suburbs and shantytowns. Most
203 of the fluid in the tank streamed from the tower then drifted low over the city and
204 sank and seeped in deathly mist in lungs in eyes, a period to sleep and swift ar-
205 rest of retreat. More than 3000 lives were claimed immediately and many tens of
206 thousands through the subsequent days and months and years lost their lives or
207 their health to the poison's effects, and the dead are still being counted.
