Using direct numerical simulations we study dynamo action under the Taylor-Green forcing with Prandtl number less than one. We observe bistability with a weak magnetic field branch and a strong magnetic field branch. Both the dynamo branches undergo subcritical dynamo transition. We also observe host of dynamo states including constant, periodic, quasiperiodic, and chaotic magnetic fields. One of the chaotic state originates through a quasiperiodic route with phase locking, while another chaotic attractor appears to follow Newhouse-Ruelle-Takens route to chaos. We also observe intermittent transitions among quasiperiodic and chaotic states for a given Taylor-Green forcing.

I. INTRODUCTION

Dynamo theory has been applied to explain the generation and properties of the magnetic fields present in celestial bodies [\[1](#page-6-0)[–3](#page-6-1)]. In this mechanism, a small magnetic field fluctuation is amplified by the currents induced by the motion of the conducting fluid. One of the important problems of dynamo research is the nature of "dynamo transition" from pure fluid state to dynamo state. The linearized magnetohydrodynamic (MHD) equations yield zero magnetic field in the steady state. Therefore, the dynamo transition is through a nonlinear instability. As a result, the nature of transition is very rich exhibiting host of interesting behaviour including subcritical bifurcations [\[4,](#page-6-2) [5\]](#page-6-3), variety of dynamo states [\[6](#page-6-4), [7](#page-6-5)], multiple coexisiting attractors [\[7\]](#page-6-5) etc. It has been found that the nature of dynamo onset depends critically on various system properties, e.g., the magnetic Prandtl number (ratio of the kinematic viscosity and the magnetic diffusivity), forcing function, system geometry, rotation frequency, etc. Note that the magnetic Prandtl number (Pm) of liquid metals, and of the convective fluids of Earth's outer core and the Sun is very small (of the order of 10[−]⁵), while that of the intergalactic medium is very large (around 10^{14}). In the present paper we explore the nature of dynamo transition for a Prandtl number less than unity, with a hope that it could be a representative of low-Prandtl number dynamo.

One of the strong motivations of the dynamo research is to understand the nature of geodynamo and solar dynamo. To this aim, scientists attempt to address the possible dynamo states, and the extent of the induced magnetic field in these systems. The magnetic Reynolds number Rm (ratio of magnetic advection and magnetic diffusion) of the geodynamo is estimated to be around 125 [\[8](#page-6-6)], which is somewhat near the dynamo transition, so we expect our present work on dynamo transition to be relevant for geodynamo. The ratio of the magnetic energy and the kinetic energy for the geodynamo is large [\[8\]](#page-6-6), hence it is called strong field dynamo. Roberts [\[9](#page-6-7)] argued that rotating sphere with magnetoconvection could show bistability with a weak field branch and a strong field branch. Kuang and Bloxham [\[10](#page-6-8)] numerically simulated convective dynamo in spherical geometry with rotation and observed weak-field dynamo solution in a simplified system and strong-field dynamo solutions in a more realistic system. In the present paper we will show that a similar bistability is exhibited in the box geometry without rotation or convection. We also observe that the transition for both the branches are subcritical.

The magnetic field of the Earth is temporally and spatially chaotic [\[8\]](#page-6-6). The solar magnetic field is spatially random, but the sun-spot cycle appears to indicate that the primary dipolar field is quasiperiodic [\[11](#page-6-9)]. In the von Kármán sodium (VKS) experiment, Monchaux et al. [\[6](#page-6-4)] and Pétrélis at al. $[12]$ reported various dynamo states including constant, periodic, quasiperiodic, and chaotic magnetic fields. In the present paper we simulate dynamo transition for a box geometry, and report various dynamo states (including chaos) similar to those obtained in the VKS experiment.

We focus on the behaviour of Taylor-Green (TG) dynamo for $Pm = 0.5$ fluid in order to probe dynamo behaviour for low magnetic Prandtl number (low- Pm) regime. Numerical simulation of very low- Pm fluid (around 10[−]⁵ corresponding to liquid metals) is very difficult since the corresponding Reynolds number for dynamo transition for such fluid is more than 10^6 [\[6\]](#page-6-4); simulation of such high Reynolds number would require grid resolution far more than presently achievable in the modern supercomputers. We adopt TG forcing since it has somewhat similar flow structure as the VKS experiment.

Earlier, Nore et al. [\[13\]](#page-6-11) simulated TG dynamo for Pm near unity. Ponty et al. [\[14](#page-7-0)] studied dynamo mechanism for low magnetic Prandtl numbers $(Pm \approx 1 \text{ to } 10^{-2})$ using hyperdissipative parameters and large-eddy simulations, and observed a sharp increase in the critical magnetic Reynolds number (threshold of dynamo transition) with the decrease of Pm . Ponty *et al.* [\[4\]](#page-6-2) observed a subcritical dynamo bifurcation for the TG dynamo in the low-Pm regime. Mininni et al. [\[15\]](#page-7-1) and Yadav et al. [\[7](#page-6-5)]

[∗]Email : yadav.r.k.87@gmail.com

studied the energy transfers, and the geometry of the velocity and the magnetic field structures. Yadav *et al.* [\[7](#page-6-5)] also observed a supercritical pitchfork bifurcation for the dynamo transition for $Pm = 1$. They reported a large number of dynamo states including constant, periodic, quasiperiodic, and chaotic magnetic fields. Dubrulle et al. [\[16\]](#page-7-2) investigated various bifurcations in both hydrodynamic (with no magnetic field) and magnetohydrodynamic systems under TG forcing. Scientists have also studied dynamo behaviour for various kinds of forcing, e.g., Roberts, ABC, Ponomarenko, and random, as well as for different geometries, e.g., box, cylinder, sphere etc. [\[17](#page-7-3)]. Dynamo transition and subsequent dynamo states have also been studied using low-dimensional models of dynamo [\[18\]](#page-7-4).

The outline of the paper is as follows: The numerical procedure is described briefly in Section [II.](#page-1-0) Bifurcation analysis is presented in Section [III.](#page-1-1) We analyze several chaotic windows and the routes to chaos in Section [IV.](#page-3-0) We conclude in Section [V.](#page-5-0)

II. SIMULATION METHODOLOGY

The governing equations of dynamo are same as those of MHD, which are

$$
\partial_t \mathbf{u} + (\mathbf{u} \cdot \nabla) \mathbf{u} = -\nabla p + (\mathbf{J} \times \mathbf{B}) + \nu \nabla^2 \mathbf{u} + \mathbf{F}, \tag{1}
$$

$$
\partial_t \mathbf{B} = \nabla \times (\mathbf{u} \times \mathbf{B}) + \eta \nabla^2 \mathbf{B}, \tag{2}
$$

$$
\nabla \cdot \mathbf{u} = 0, \tag{3}
$$

$$
\nabla \cdot \mathbf{B} = 0, \tag{4}
$$

where \bf{u} is the fluid velocity, \bf{J} is the current density, \bf{B} is the magnetic field, p is the hydrodynamic pressure, ν is the kinematic viscosity, η is the magnetic diffusivity, and \bf{F} is the external force field. The density of the fluid is assumed to be unity. The three important parameters related to dynamo instability are the magnetic Prandtl number $Pm = \nu/\eta$, the Reynolds number $Re = UL/\nu$, and the magnetic Reynolds number $Rm = UL/\eta$, where U and L are the large velocity scale and the large length scale, respectively. Note that $Rm = Re \times Pm$, hence only two of the above three parameters are independent. In our study, we fixed the magnetic Prandtl number to 0.5 with $\nu = 0.1$ and $\eta = 0.2$.

We solve the MHD equations (Eqs. $(1-4)$) numerically for a box geometry of size $(2\pi)^3$ with periodic boundary conditions in all the directions. We use a pseudospectral code TARANG [\[19\]](#page-7-5) to carry out our simulations. We apply fourth-order Runge-Kutta scheme for time advancement with dynamically adjusted dt chosen using the CFL condition: $dt = \Delta x / \sqrt{20E^u}$ where Δx is the grid spacing and E^u is the total kinetic energy. On the velocity field we apply Taylor Green forcing

$$
\mathbf{F}(k_0) = F_0 \begin{bmatrix} \sin(k_0 x) \cos(k_0 y) \cos(k_0 z) \\ -\cos(k_0 x) \sin(k_0 y) \cos(k_0 z) \\ 0 \end{bmatrix}, \quad (5)
$$

The box is discretized uniformly in all the directions, with most of the simulations on 64^3 grid. This resolution was sufficient to resolve our simulation near the dynamo transition, as demonstrated by the fact that the product of the Kolmogorov length and the largest wavenumber lies between 1.3 − 9 for all our runs. We also verified the grid-independence by performing few runs of a given dynamo state on $128³$ and $64³$ grids. All our simulation were dealiased using the 2/3 rule. We performed approximately 150 simulations for various forcing parameters $(F_0 = 1 : 46)$, and studied the global kinetic and magnetic energies, as well as the amplitudes of the velocity and magnetic Fourier modes. The magnetic Reynolds number in our simulations ranged from around 3 to 90.

The importance of large scale modes have been amply highlighted in dynamo literature. In our present dynamo simulation, as well as for $Pm = 1$ reported earlier by Yadav et al. [\[7\]](#page-6-5), some of the magnetic and kinetic Fourier modes play a dominant role. For the magnetic Reynolds numbers employed in these simulations, the dominant velocity modes are $(\pm 2, \pm 2, \pm 2)$, $(\pm 4, \pm 4, \pm 4)$, $(\pm 4, \pm 4, 0)$, and the dominant magnetic modes are $(0, 0, \pm 1), (0, 0, \pm 2), (0, 0, \pm 3), (\pm 2, \pm 2, \mp 3),$ $(≠2, ≠2, ±1)$. Here, the three arguments refer to x, y, and z components of a wavenumber in the Fourier space. The $(\pm 2, \pm 2, \pm 2)$ velocity mode contains maximum kinetic energy due to the TG forcing at $k = (2, 2, 2)$. The above set of modes carry more than 95% of the total energy. Note, however, that higher wavenumber velocity and magnetic Fourier modes become important in the turbulent dynamo. We also point out that the above modes play similar roles as the large-scale modes used in the earlier dynamo literature [\[1](#page-6-0), [20](#page-7-6)].

In the present paper we analyze the time series and phase space plots of the Fourier modes. This exercise provides us with information about various dynamo states as well as the nature of bifurcations. Primary and secondary instabilities can be conveniently illustrated using bifurcation diagrams. In the next section we will describe bifurcation diagrams for $Pm = 0.5$ constructed using some of the dominant magnetic Fourier modes.

III. BIFURCATION ANALYSIS & STRONG AND WEAK DYNAMO BRANCHES

We construct a bifurcation diagram by using the time averaged values of the magnitude of the magnetic Fourier mode $\mathbf{B}(0, 0, 1)$ $\mathbf{B}(0, 0, 1)$ for different values of F_0 (see Fig. 1). These values are computed after the system reaches a steady state. Since the Fourier amplitudes are generally complex, it is convenient to use the absolute value of a

FIG. 1: Bifurcation diagram: Time averaged values of $|\mathbf{B}(0, 0, 1)|$ for various forcing amplitude F_0 . The figure illustrates various dynamo states with $ND = no$ -dynamo state, $FP = fixed point (constant in time), P = periodic state, QP$ $=$ quasiperiodic state, and $C =$ chaotic state. The inset for $F_0 = 14:16$ illustrates a sudden jump and a hysteresis loop indicating that the transition is subcritical. Also, oval 'A' exhibits quasiperiodic route to chaos (see Subsection [IV A\)](#page-4-0), and the rectangular box 'B' exhibits Newhouse-Ruelle-Takens route to chaos (see Subsection [IV B\)](#page-4-1).

Fourier mode to depict the dynamo states.

The inset of Fig. [1](#page-2-0) shows a zoomed view of the dynamo transition region near $F_0 = 15.8$. We observe fluid or no-dynamo state for $F_0 < 15.8$. At $F_0 = 15.8$, we obtain a dynamo state with $|\mathbf{B}(0,0,1)|$ as well as the total magnetic energy (E^b) showing a finite jump. However, when we use the dynamo state at $F_0 = 15.8$ as our initial condition and gradually decrease the forcing amplitude, as shown in the inset of Fig. [1,](#page-2-0) the dynamo state continues till $F_0 \approx 15.2$, at which point there is a sudden jump to the fluid state. This feature of hysteresis for $F_0 = 15.2$: 15.8 demonstrates the subcritical nature of the transition, with a "subcritical pitchfork bifurcation" at X and a "saddle-node bifurcation" at Y (see the inset of the figure). These points are joined together using a dashed curve to depict the unstable branch. In a recent study, Krstulovic et al. [\[21\]](#page-7-7) also observed subcritical dynamo transition in their simulation and low-dimensional model. In a planetary dynamo context, Kuang et al. [\[22](#page-7-8)] argued that the sudden termination of Martian dynamo could be due to subcriticality.

Another noteworthy feature during the transition at $F_0 = 15.8$ is that the Reynolds number is sufficiently high (≈ 60) for the fluid to be temporally chaotic. However, in the corresponding dynamo states at the same F_0 , both the velocity and magnetic fields become constant in time, as shown in Fig. [2.](#page-2-1) This is due to the presence of the newly-born finite magnetic field. Morin et al. [\[23\]](#page-7-9) reported similar effects of magnetic field for spherical shell dynamo. After $F_0 \approx 16.2$, the dynamo solution bifurcates to periodic states, and subsequently

FIG. 2: The total kinetic energy (top panel) and the total magnetic energy (bottom panel) for a forcing amplitude of 15.8 indicating a constant value for the steady state.

to quasiperiodic and chaotic states as shown in Fig. [1.](#page-2-0)

For some of our dynamo runs, $\langle |\mathbf{B}(0, 0, 1)| \rangle$ is negligible, as shown by the dots on the x axis of Fig. [1.](#page-2-0) For these simulations, the magnetic mode $\mathbf{B}(0,0,2)$ becomes dominant; we denote the set of these states as the " $\mathbf{B}(0,0,2)$ branch". The other collection of states with $\mathbf{B}(0, 0, 1)$ as the most dominant mode is referred to as the " $\mathbf{B}(0,0,1)$ branch". We observe that the properties of these two branches are quite different. We illustrate this feature using another bifurcation diagram whose vertical axis is $E^{\vec{b}}/E^u$, the ratio of the magnetic energy and the kinetic energy (shown in Fig. [3\)](#page-3-1). This bifurcation diagram reveals two distinct branches: the upper curve is the $\mathbf{B}(0,0,2)$ -branch, for which the magnetic field remains constant in time, and the lower one is the $\mathbf{B}(0,0,1)$ branch. The $\mathbf{B}(0,0,2)$ branch was constructed using the fixed point solution at $F_0 = 39.7$, which is marked with small arrows in Figs. [3](#page-3-1) and [1,](#page-2-0) as initial condition. Also, the ratio E^b/E^u for the **B**(0,0,2)-branch is larger than the corresponding ratio for the $\mathbf{B}(0, 0, 1)$ -branch. Thus we address the former as a "strong-field branch", and the latter as a "weak-field branch". The above feature regarding the strength of the magnetic field is corrobo-rated in Fig. [4](#page-3-2) where we plot the magnetic energy (E^b) vs. the magnetic Reynolds number (Rm) . The two distinct branches described above demonstrate that the TG dynamo at $Pm = 0.5$ exhibits "bistability", similar to those reported by Simitev and Busse [\[24\]](#page-7-10).

The dynamo transition for the $\mathbf{B}(0,0,2)$ -branch differs significantly from that of the $\mathbf{B}(0,0,1)$ -branch described earlier. For the $\mathbf{B}(0,0,1)$ -branch, the jumps in the kinetic and magnetic energy shown in Fig. [5\(](#page-3-3)a) is consistent with the subcritical nature of the transition described earlier. However, the $\mathbf{B}(0,0,2)$ -branch exhibits chaos at the dynamo transition itself. The origin of the chaotic state

FIG. 3: Bifurcation diagram: Ratio of the total magnetic energy and the total kinetic energy (E^b/E^u) vs. the forcing amplitude (F_0) . Description of different symbols is provided in Fig. [1.](#page-2-0) The $\mathbf{B}(0, 0, 2)$ -branch was constructed using the dynamo state marked with an arrow as initial condition.

FIG. 4: Bifurcation diagram: Total magnetic energy (E^b) vs. the magnetic Reynolds number (Rm) . Description of different symbols is provided in Fig. [1.](#page-2-0)

becomes apparent when we decrease F_0 from the fixed point solution. As shown in Fig. [5\(](#page-3-3)b), the fixed point bifurcates to quasiperiodic (purple triangles of the figure) and subsequently to chaotic state (red squares) as the F_0 is decreased. The route to chaos for the $\mathbf{B}(0,0,2)$ branch may be similar to those observed by Pal et al. [\[25](#page-7-11)] for zero-Prandtl number convection. The quasiperiodic and the chaotic states are clustered in Fig. [3](#page-3-1) near the transition.

Earlier, the weak field branch and strong field branch of dynamo have been reported in the context of convectiondriven hydromagnetic dynamos [\[9](#page-6-7), [10,](#page-6-8) [26,](#page-7-12) [27](#page-7-13)]. Pierre [\[28](#page-7-14)] and Stellmach and Hansen [\[29](#page-7-15)] numerically demonstrated this phenomenon in Childress-Soward dynamo where they reported that the Strong-field branch goes even

FIG. 5: A plot of the total kinetic energy (E^u) and the total magnetic energy (E^b) vs. the F_0 near the dynamo transition. Description of different symbols is provided in Fig. [1.](#page-2-0) (a): The $\mathbf{B}(0,0,1)$ -branch portrays the subcritical nature of the transition. (b): The $\mathbf{B}(0,0,2)$ -branch illustrates transition from a fixed point state to quasiperiodic (purple triangles) and subsequently to chaotic state (red square) as F_0 is decreased.

further back than the weak-field branch in the parameter space, analogous to the $\mathbf{B}(0,0,2)$ -branch reported in this paper. Similar behaviour has also been reported by Sreenivasan and Jones [\[30\]](#page-7-16) in a rapidly rotating spherical shell dynamo. It is interesting that our system in the box geometry, without any convection or rotation, exhibits weak and strong dynamo branches.

In the next section we will focus on several chaotic dynamo states and study routes to chaos for these states.

IV. ROUTES TO CHAOS

The phase space portraits drawn using the Fourier modes reveal multiple windows of chaos near the dynamo transition itself. In the present paper we describe routes to chaos for two chaotic windows: the oval-shaped enclosure 'A' and the rectangular-shaped box 'B' shown in Fig. [1.](#page-2-0) In the following discussion we show that the origin of chaos for the dynamo states of box 'A' follow a quasiperiodic route to chaos through phase locking, while the corresponding route to chaos for the box 'B' is through the Newhouse-Ruelle-Takens scenario.

We study the routes to chaos using some of the dom-

FIG. 6: Phase space projections on the $|\mathbf{B}(0,0,1)|$ - $|\mathbf{B}(0,0,3)|$ plane demonstrating a quasiperiodic route to chaos through phase-locking. The forcing amplitudes (F_0) for different attractors are marked with arrows. $F_0 = 41, 42, 43$ (pink), $F_0 = 43.85$ (green), and $F_0 = 44.75$, 46 (red) correspond to quasiperiodic, phase-locked, and chaotic states, respectively.

inant modes of magnetic field, viz. $\mathbf{B}(0, 0, 1)$, $\mathbf{B}(0, 0, 2)$, and $\mathbf{B}(0, 0, 3)$. We use time series, phase-space projec-tions, and Poincaré sections for this study [\[31\]](#page-7-17).

A. Quasiperiodic route to chaos through phase-locking

In Fig. [6](#page-4-2) we illustrate the phase space projections of dynamo states on $|\mathbf{B}(0,0,1)|$ - $|\mathbf{B}(0,0,3)|$ plane for the forcing range of $F_0 = 41:46$ (corresponding to the oval-shaped enclosure 'A' of Fig. [1\)](#page-2-0). For $F_0 = 41, 42,$ and 43, the system is quasiperiodic since the phase space projection is densely filled up. The approximate values of the two incommensurate frequencies for the $F_0 = 43$ dynamo state are 0.0165 and 0.0208 (for $|\mathbf{B}(0, 0, 1)|$ time series). For $F_0 = 43.85$, the system becomes periodic or phaselocked. The time period of the periodic orbit is relatively large. The emergence of periodic orbit after quasiperiodic solutions is called "phase locking" [\[31\]](#page-7-17). A subsequent increase of F_0 leads to a chaotic state, as evident from the phase space projections for $F_0 = 44.75$ and 46. The nature of attractors is corroborated by the Poincaré sections for $F_0 = 43, 43.85, 44.75,$ and 46 presented in Fig. [7](#page-4-3) (a, b, c, d) , respectively. These Poincaré sections were obtained by using the $|\mathbf{B}(0,0,3)| = 1.15$ as the Poincaré intersection plane for the phase space trajectories in the subspace of $|\mathbf{B}(0, 0, 1)|$ - $|\mathbf{B}(0, 0, 2)|$ - $|\mathbf{B}(0, 0, 3)|$. Thus the route to chaos for the chaotic trajectories in the oval-box 'A' of Fig. [1](#page-2-0) is through the quasiperiodic route via phase locking, first reported for circle map [\[31\]](#page-7-17).

FIG. 7: Poincaré sections for some of the attractors of Fig. [6](#page-4-2) with $|\mathbf{B}(0, 0, 3)| = 1.15$ as the Poincaré plane. (a): quasiperiodic attractor for $F_0 = 43$, (b): phase-locked attractor for $F_0 = 43.85, (c,d)$: chaotic attractors for $F_0 = 44.75$ and 46.

B. Newhouse-Ruelle-Takens scenario

We observe an interesting set of dynamo states in the rectangular-box 'B' of Fig. [1.](#page-2-0) Fig. [8\(](#page-5-1)a) illustrates the phase space projections on the $|\mathbf{B}(0,0,1)|$ - $|\mathbf{B}(0,0,3)|$ plane for $F_0 = 39.3$ and 39.464, corresponding to the two purple triangles in the rectangular-box 'B' of Fig. [1.](#page-2-0) Also, the power spectral density plot (PSD) of the $|{\bf B}(0, 0, 1)|$ time series of these two dynamo states is shown in Fig. $9(a,b)$. The PSD reveals that the state at $F_0 = 39.3$ contains two incommensurate frequencies f_1 and f_2 (Fig. [9\(](#page-5-2)a)), while the state at $F_0 = 39.464$ has three incommensurate frequencies f_1 , f_2 , and f_3 (Fig. [9\(](#page-5-2)b)). Thus the corresponding dynamo states reside on "2-torus" (T^2) and "3-torus" (T^3) respectively in the subspace. We expect that a further increase of F_0 should push the system to chaos following a Newhouse-Ruelle-Takens scenario. However, we have not yet found the corresponding chaotic attractor. Recently, Stefani et al. [\[32](#page-7-18)] have observed similar quasiperiodic routes to chaos in a dynamo model.

Instead of transition from T^3 to a chaotic dynamo state, a very small increase of F_0 pushes the system to a new chaotic attractor, whose span is much larger than those of the T^2 or T^3 . In Fig. [8\(](#page-5-1)b), we illustrate the larger chaotic attractor obtained for $F_0 = 39.51$, corresponding to the red square in the rectangular-box 'B' of Fig. [1.](#page-2-0) In Fig. [8\(](#page-5-1)b), T^2 or T^3 states reside in the circled region. The large attractor for $F_0 = 39.51$ has a different origin as the PSD shown in Fig. $9(c)$ is quite different from those in Fig. [9](#page-5-2) (a, b). The origin of the larger attractor

FIG. 8: Phase space projections on the $(|\mathbf{B}(0,0,1)| |\mathbf{B}(0, 0, 3)|$ plane. Panel (a) contains a stable 2-torus and a 3-torus quasiperiodic state and panel (b) shows a close lying (in parameter space) large chaotic attractor. The corresponding forcing amplitude is marked with arrow. The circle drawn in (b) portrays a rough phase space span of the attractors shown in (a).

is not well understood, however, it is possibly through a "crisis". Note that a large number of attractors exists for this range of F_0 , as evident from the Fig. [1.](#page-2-0) Chaos can emerge due to the intersections of multiple attractors or their basins of attraction [\[31\]](#page-7-17). A detailed investigation of these issues is beyond the scope of this paper.

We performed dynamo simulations near $F_0 = 39.51$ and observe interesting features involving intermittent transitions between three attractors; this dynamics will be described in the next subsection.

C. Intermittent transitions between various attractors

For the forcing amplitude $F_0 = 39.4658$ we observe intermittency. A long time series for $F_0 = 39.4658$ simulation is illustrated in Fig. [10\(](#page-6-12)a), which illustrates that the system makes intermittent transitions among three attractors, '2F', '3F', 'C', shown below the time series. Note that the 2F, 3F, and C attractors are qualitatively similar to the state shown in Fig. [8](#page-5-1) obtained for $F_0 = 39.3, 39.464,$ and 39.51, respectively. Thus, at $F_0 = 39.4658$ the system appears to hop over various attractors. The intermittent transition among various attractors described above is similar to "intermittency" in which a system switches between an "ordered" state and a chaotic state for a single parameter. In Fig. [10](#page-6-12) the quasiperiodic states are the ordered state. The system has been evolved for 50000 eddy turnover times, and only a part of this time series has been shown in Fig. [10\(](#page-6-12)a). Hence the observed phenomena is not a transient. The large fluctuations for time near 21250 in Fig. [10\(](#page-6-12)a) are transient fluctuations that settle down quickly.

FIG. 9: Power Spectral Density (PSD) plot of the dynamo states shown in Fig. [8.](#page-5-1) The dominant frequencies are depicted in the figures with arrows. (a): For $F_0 = 39.3$, the state has two incommensurate dominant frequencies; (b): For $F_0 =$ 39.464, the state has three incommensurate frequencies; (c): A dense power spectrum corresponding to the large chaotic attractor portrayed in Fig. [8\(](#page-5-1)b).

V. CONCLUSIONS AND SPECULATIONS

Our Taylor-Green dynamo simulations for $Pm = 0.5$ near the dynamo transition reveal interesting properties. We observe bistability, with a weak magnetic field branch and a strong magnetic field branch. The dominant Fourier modes for the two branches are $\mathbf{B}(0,0,1)$ and $\mathbf{B}(0,0,2)$ respectively. Both of these branches have subcritical origin. Qualitatively, these branches resemble the weak- and strong-field dynamo actions in rotating magnetoconvection reported earlier [\[9,](#page-6-7) [10\]](#page-6-8). Note that the subcritical dynamo transition for $Pm = 0.5$ is in sharp contrast with the TG dynamo for $Pm = 1$ which shows a supercritical pitchfork bifurcation at the transition [\[7](#page-6-5)]. This observation is consistent with the recent work by Krstulovic et al. [\[21\]](#page-7-7).

Our simulations also reveal various kinds of dynamo states including constant, periodic, quasiperiodic, and chaotic magnetic fields. We analyzed two chaotic windows among several ones observed in our simulations. Chaos for these windows arise through quasiperiodic route. One of them undergoes a phase-locking, while the other one appears to be through the Newhouse-Ruelle-Takens route. We also observe an intermittent transitions between quasiperiodic (T^2, T^3) and chaotic attractors. Various dynamo states reported in our simulations

FIG. 10: Time evolution of a dynamo state at $F_0 = 39.4658$ showing intermittent transitions among three attractors: quasiperiodic state $T^2(b)$, quasiperiodic state $T^3(c)$, and chaotic state(d). The subfigures (b,c,d) are the phase space projections at three different time intervals during the evolution.

are quite similar to those observed in the VKS experiment [\[6\]](#page-6-4).

We performed our simulations on a periodic box, which is an idealized geometry. Yet, we observe similarities with the VKS experiment and geodynamo simulations. This could be due to similarities in the inherent nonlinearities in the system (independent of the geometry etc.). Also, the behaviour of dynamo transition and dynamo states for $Pm = 0.5$ discussed in the present paper differs significantly from that for $Pm = 1$ studied by Yadav et al. [\[7\]](#page-6-5). Extensions of the present work to more realistic geometry and lower magnetic Prandtl numbers would

yield interesting insights into this challenging field.

VI. ACKNOWLEDGMENTS

We thank Binod Sreenivasan, Stephan Fauve, and Mani Chandra for fruitful discussions and comments. This work was supported by a research grant of DST India as Swarnajayanti fellowship to MKV. Part of the simulation was done on VEGA cluster of IIT Madras and HPC cluster of IIT Kanpur.
