ABSTRACT

^aHarvard Smithsonian Center for Astrophysics, Cambridge, MA 01238, USA

We present variability analysis of data from the Northern Sky Variability Survey (NSVS). Using the clustering method which defines variable candidates as outliers from large clusters, we cluster 16,189,040 light curves, having data points at more than 15 epochs, as variable and non-variable candidates in 638 NSVS fields. Variable candidates are selected depending on how strongly they are separated from the largest cluster and how rarely they are grouped together in eight dimensional space spanned by variability indices. All NSVS light curves are also cross-correlated to the Infrared Astronomical Satellite, AKARI, Two Micron All Sky Survey, Sloan Digital Sky Survey (SDSS), and Galaxy Evolution Explorer objects as well as known objects in the SIMBAD database. The variability analysis and cross-correlation results are provided in a public online database which can be used to select interesting objects for further investigation. Adopting conservative selection criteria for variable candidates, we find about 1.8 million light curves as possible variable candidates in the NSVS data, corresponding to about 10% of our entire NSVS samples. Multi-wavelength colors help us find specific types of variability among the variable candidates. Moreover, we also use morphological classification from other surveys such as SDSS to suppress spurious cases caused by blending objects or extended sources due to the low angular resolution of the NSVS.

Subject headings: astronomical databases: miscellaneous – methods: data analysis – methods: statistical – stars: variables: general

1. Introduction

Emerging projects in time-domain astronomy produce a large amount of time-series data, and allow discoveries of new variable sources and better understanding of known vari-ability types (see Paczyński 2000; [Djorgovski et al. 2001](#page-22-0); [Bono, Trevese, & Turatto 2003,](#page-21-0) for a review). This new era needs a computationally intensive processing of massive time-series data with computational algorithms to recover interesting objects with a broad range of variability types [\(Eyer 2006\)](#page-22-1).

Investigating time variability of astronomical objects begins with detecting any significant changes in brightness. Detection methods can be optimized to specific variability types. For example, image subtraction method is commonly used to detect supernovae, microlens-ing, and other variable sources (e.g., [Alard & Lupton 1998;](#page-21-1) [Wozniak 2000](#page-26-0); Gössl & Riffeser [2002;](#page-22-2) [Becker et al. 2004;](#page-21-2) [Corwin et al. 2006;](#page-21-3) [Yuan & Akerlof 2008\)](#page-26-1). Instead of detecting variability in images, recognizing variability in light curves can also be tailored to a particular type of variability signal such as transit (e.g., [Protopapas, Jimenez, & Alcock 2005;](#page-24-1) [Renner et al. 2008\)](#page-24-2).

We presented a new framework of detecting general variability types in massive timeseries data by using a non-parametric infinite Gaussian mixture model (GMM) in our previous paper [\(Shin, Sekora, & Byun 2009,](#page-25-0) hereafter, Paper I). In our approach, variable objects are considered as outliers from non-variable objects which should constitute a dominant fraction of given data, in multi-dimensional space spanned by several variability indices. In the results from the infinite GMM where each group is described by a multivariate Gaussian distribution [\(Robert 1996\)](#page-24-3), we recognize large groups as groups of non-variable objects, tagging outliers from these large groups as possible candidates of variable objects (see [Liao 2005,](#page-23-0) for other methods of clustering). The strength of our approach is based on the assumption that non-variable objects, which do not have enough signals of variable phenomena in their light curves, represent the dominant fraction of data and share the same systematic effects hidden in the given data such as sampling patterns and noise properties. Therefore, by extracting common properties of dominant non-variable objects from the given data, our approach can be less biased than choosing specific types of variability with assumptions of systematic patterns.

In this paper, the second of a series of papers, we apply our methodology to all data from the Northern Sky Variability Survey (NSVS; Woźniak et al. 2004a). The NSVS catalog includes about 14 14 million¹ objects with the optical magnitude ranging from 8 to 15.5 and declinations higher than −38 deg. These objects are so bright that deeper imaging surveys such as Pan-STARRS [\(Kaiser et al. 2010\)](#page-23-1) and Large Synoptic Survey Telescope [\(Tyson 2002\)](#page-25-1) cannot produce useful photometric data due to saturation in their normal observation modes. Therefore, variability analysis of the current NSVS data will be still useful for investigation of bright stars even after deeper images are acquired in the future surveys. Moreover, the NSVS data have not been fully exploited because several previous trials have been focused on particular types of variable objects with specific criteria for variability signals (e.g., Woźniak et al. 2004b; [Nicholson, Sutherland, & Sutherland 2005;](#page-24-4) [Kinemuchi et al. 2006](#page-23-2); [Wils, Lloyd, & Bernhard 2006](#page-26-4); [Kelley & Shaw 2007](#page-23-3); [Kiss et al. 2007;](#page-23-4) [Hoffman et al. 2008;](#page-22-3) [Usatov 2008;](#page-25-2) [Dimitrov 2009;](#page-22-4) [Schmidt et al. 2009;](#page-24-5) [Hoffman, Harrison, & McNamara](#page-22-5) [2009\)](#page-22-5).

Most NSVS objects are already included in other previous surveys. In particular, the NSVS catalog can cover most of the optical magnitude range of objects detected in IRAS

¹ Because some NSVS objects are included in multiple separate light curves from different observation fields, the total number of light curves is larger than that of objects.

[\(Clegg 1980\)](#page-21-4), Two Micron All Sky Survey (2MASS; [Kleinmann 1992](#page-23-5)), and Galaxy Evolution Explorer (GALEX; [Bianchi & The GALEX Team 1999\)](#page-21-5) observations. Since colors can be used to identify the particular types of spectral energy distributions, associating variability analysis to colors can be an effective way to discover new variable sources at a specific phase of stellar evolution such as Mira-type variables (e.g., [Pojmanski & Maciejewski 2005\)](#page-24-6) or extragalactic variable objects such as quasars (e.g., [Bianchi et](#page-21-6) al. [2007\)](#page-21-6). Associating the NSVS objects with other optical surveys is also critically important. Since the NSVS data do not have a high angular resolution with small telescopes, a large fraction of objects might be affected by blending, poor positioning, and incorrect identification of extended objects as stars in the NSVS data. Our new variability analysis of the whole NSVS data will help others find specific variable sources by combining their data and these other multi-wavelength surveys.

This paper is organized as follows. In Section [2,](#page-3-0) we explain the application of the infinite GMM to the NSVS data. In Section [3,](#page-6-0) we describe how to extract variable candidates by using the results from the GMM. In Section [4,](#page-8-0) we explain the Web database of our variability analysis. Properties of variable candidates are explained in Section [5,](#page-9-0) considering their associations to archival data. Finally, summary and discussions are given in the last section.

2. Method

2.1. Data and variability indices

We extract 16,189,040 light curves from the NSVS data (Wozniak et al. [2004a](#page-26-2)) by limiting samples that have more than 15 good photometric data points. The good photometric points are defined as not having bad photometry flags: SATURATED, NOCORR, LONPTS, HISCAT, HICORR, HISIGCORR, and RADECFLIP (see Woźniak et al. [2004a,](#page-26-2) for meanings of the flags). Since one object can be included as several light curves in different observation fields in the NSVS catalog, the number of objects is slightly smaller than that of the light curves in our sample. Here, we consider each light curve as a separate entity. Among 644 observation fields of the NSVS data, six fields (123c, 145c, 146c, 147c, 156c, 156d) do not have any light curves having more than 15 good photometric data points.

In addition to six variability indices used in Paper I, we also derive skewness and kurtosis from each light curve. The definitions of these indices are summarized in Table [1.](#page-47-0) σ/μ , γ_1 , and γ_2 are not sensitive to structure of light curves. However, estimating them is computationally cheap, describing simple low-order patterns of light curves easily. We note that our definitions of skewness and kurtosis is not the same as the traditional measures (see [Joanes & Gill 1998](#page-23-6), for a discussion). Other five indices describe more complex patterns in light curves. Con represents how many sets of three consecutive data points are at least 2σ fainter or brighter than the median magnitude, tracing continuous variations in light curves [\(Wozniak 2000](#page-26-0)). η measures the ratio of the mean square successive difference to the sample variance [\(von Neumann 1941\)](#page-26-5). J and K have been commonly used for multi-band light curves although these can be estimated for single-band light curves [\(Stetson 1996\)](#page-25-3). Here, we use only single-band light curves with a slightly modified definition which uses sequential pairs of data points. Finally, we also use the analysis of variance (ANOVA) statistic which is useful for identifying periodic signals [\(Schwarzenberg-Czerny 1996;](#page-24-7) [Shin & Byun 2004](#page-24-8)). The maximum value of the ANOVA (AoVM) is used to measure the strength of periodicity. Even with an incorrect period of the light curve, AoVM can be a valuable quantity that infers periodicity [\(Shin & Byun 2007](#page-25-4)).

2.2. GMM and results

We follow the same procedure of the infinite GMM as in our Paper I. The GMM is derived for each NSVS observation field with the eight variability indices. Even though the GMM converges much earlier than 100 iterations, we conduct 100 iterations as shown in Paper I. Since finding large groups is our main concern to find out non-variable objects from the samples, the number of iterations is not an important factor which affects how many small groups can be recovered. Each GMM component^{[2](#page-4-0)} is described by a multivariate Gaussian distribution with its mean, i.e. center, and covariance matrix:

$$
p_m(\mathbf{x}) = \frac{1}{(2\pi)^{D/2} |\Sigma_m|^{1/2}} \exp(-\frac{1}{2} (\mathbf{x} - \mu_m)^T \Sigma_m^{-1} (\mathbf{x} - \mu_m)),
$$
(1)

where m is an index of a mixture component, $\mathbf{x} = (\sigma/\mu, \gamma_1, \gamma_2, \text{Con}, \eta, J, K, \text{AoVM})$ is a vector of parameters, and D is the number of parameters (in our case $D = 8$). Furthermore, $\mu_{\bf m}$ is a vector of mean values (i.e., mixture centers), and Σ_m is the covariance matrix of the Gaussian distribution.

Figure [1](#page-27-0) shows how many groups are recovered with the infinite GMM and how many light curves are included in large groups. Since a small number of observation epochs provide poor sampling of light curves and have a low probability of detecting variability, fields having few observation epochs (i.e., few observed frames) are expected to have a small number of groups, while large groups dominate the whole population of light curves. In fields with a

 2 We use *component* as the same term as *cluster* and *group* in this paper. *Component* is a specific term for the GMM.

large number of light curves, the infinite GMM recovers many groups because these fields are likely to include various kinds of variable light curves. But the fraction of data included in the large groups does not change simply as a function of the number of light curves because the total number of light curves in the field does not affect the probability that a single light curve represents a non-variable object.

We measure the Davies – Bouldin (DB) index in each field to check systematic differences of the GMM results. The DB index is commonly used to measure the compactness of clusters and separations among them [\(Davies & Bouldin 1979;](#page-22-6) [Vendramin, Campello, & Hruschka](#page-25-5) [2010\)](#page-25-5). The index is defined as

DB =
$$
\frac{1}{n_c} \sum_{i=1}^{n_c} \max_{j=1,\dots,n_c, i \neq j} \left(\frac{s_i + s_j}{d_{ij}} \right),
$$
 (2)

where n_c is the number of clusters, s_i is the average distance of data points included in the cluster i with respect to its center, and d_{ij} is the distance between centers of two clusters i and j. Distance is defined as the L^2 norm which is one of the simple measurements (see [Yu et al. 2006](#page-26-6), for a discussion). As each cluster is compact and well separated from others, this DB index decreases.

Strong systematic differences of the DB index do not appear among the 638 NSVS fields as shown in Figure [2.](#page-28-0) In most fields, the groups in the GMM results have a DB index smaller than 10. We do not find any strong systematic dependence of the DB index on the number of frames and the number of light curves in each field. The highest DB index \sim 29 is found in the field 100c which has a small number of frames and light curves. Moreover, in that field the number fraction of the top three groups is highest among the sample fields.

2.3. Largest cluster

Center coordinates of the largest cluster show a significant variation for different fields. Since each NSVS field has different characteristics, it is not surprising to see this variation shown in Figure [3.](#page-29-0) Importantly, γ_1 and γ_2 are not close to zero in contrast to the expectation from assuming a normal distribution for light curves. These non-zero γ_1 and γ_2 imply that a dominant fraction of light curves are not well described by a normal distribution due to sampling or systematic observational effects. The same implication is also found by η which has an expected average ∼ 2 for a normal distribution [\(Williams 1941\)](#page-26-7). Figure [3](#page-29-0) proves the importance of including several variability indices which catch different features of light curves with different sensitivities as we showed in Paper I.

We also examine covariance matrices of the largest cluster in each field. Comparing

the absolute values of the covariance matrix elements, the variances of J or AoVM have maximum values in the largest cluster of all 638 fields. In 604 fields, the variances of J range from about 20 to 800. But the variances of AoVM in the rest of the fields range from about 20 to 400. The largest clusters in the rest 34 fields also have a higher central value of AoVM than other fields generally. In the covariance matrix of the largest cluster, the covariance between η and J has the smallest negative value from about −6 to 0. Only minor fraction of fields show the smallest negative covariance between η and AoVM. As shown in Paper I, a substantial number of light curves exhibit negative correlations between η and J , or between η and AoVM in the NSVS data, implying systematic properties of the NSVS data.

3. Separation of variable candidates

One disadvantage of clustering algorithms is that there is no useful validation process for clustering results as in other unsupervised learning methods. Our approach using the infinite GMM also shares this problem with other clustering methods. Therefore, there is no one absolutely right way to define a boundary between variable and non-variable objects in multi-dimensional space with the clustering results. In many situations, the selection rule of variable objects can be limited by practical issues such as the number of objects which can be investigated further in follow-up studies. Here, we suggest three possible ways to separate variable objects from non-variable objects by using clustering results.

As suggested in Paper I, first, we can select as variable candidate objects which are not included in large groups [3](#page-6-1) . Figure [1](#page-27-0) shows that the largest group in each field includes a different number of objects. Therefore, defining objects in the largest group as non-variable objects produce different numbers of variable candidates in each field. Moreover, if there were any systematic patterns in light curves, or if the majority of non-variable light curves is not well described by a multivariate Gaussian distribution, data in each field would make the second or third large groups include non-variable objects or objects affected by the systematic patterns in their light curves. Basically, the existence of small clusters, i.e., the exact number of clusters, is not an important factor to select variable candidates.

Figure [4](#page-30-0) presents the change of cumulative fractions of data included in groups as the number of large groups increases. Since we find only six clusters in the field 147d, the fraction of data included in the top four groups is about 99%. However, the median fraction of data included in the top four large groups is about 89%. To select variable candidates from minor

³We warn that this approach does not work if the most dominant fraction of light curves corresponds to variable sources.

groups in each field, one could adopt a 90% cut of the cumulative fraction and avoid light curves included in large groups.

Another possible approach is using distances of objects from the center of the largest group in the eight-dimensional space spanned by the variability indices. In Paper I, we introduced the Mahalanobis distance from the largest cluster:

$$
D_M = \sqrt{(\mathbf{x} - \mu_0)^{\mathrm{T}} \Sigma_0^{-1} (\mathbf{x} - \mu_0)},
$$
\n(3)

where the center μ_0 and covariance matrix Σ_0 of the largest cluster are used with the position of an individual object x in the eight-dimensional space. Unlike a commonly used Euclidean distance, D_M depends on Σ_0 which describes how broadly the objects in the largest cluster disperse [\(Sharma & Johnston 2009\)](#page-24-9). Objects with large distances can be considered as variable objects because they have strong dissimilarity from the dominant fraction of light curves (e.g., [Jolion, Meer, & Bataouche 1991\)](#page-23-7). In Figure [5,](#page-31-0) the distribution of D_M for all objects with respect to the largest cluster in each field shows a peak of the distribution around $D_M \sim 2$ corresponding to the mode value of the beta distribution which is expected for the distribution of D_M [\(Ververidis & Kotropoulos 2008\)](#page-25-6). It also shows another concentration of objects between $D_M \sim 10^4$ and 10^6 , implying the possible signature of a large number of variable candidates or any systematic patterns hidden in the NSVS light curves. This feature varies strongly in each field as shown for the fields 088d and 147d in Figure [5.](#page-31-0)

We can derive the cut of D_M that includes a specific fraction of members in the largest cluster by integrating the multivariate Gaussian distribution with the largest cluster's center μ_0 and covariance matrix Σ_0 . For example, the b% cut of D_M can be found with

$$
\int_{\mathbf{x}: \mathbf{D}_{\mathbf{M}}(\mathbf{x}) < \mathbf{D}_{\mathbf{M}}^{\text{cut}}} p(\mathbf{x} | \mu_0, \Sigma_0) \mathbf{dx} = \mathbf{b},\tag{4}
$$

where $p(x)$ is a multivariate Gaussian distribution. Practically, the integration can be estimated by using the Monte Carlo method [\(Chen, Morris, & Martin 2006\)](#page-21-7). Each field has a different value of D_M^{cut} for the same probability cut. For example, the 99% cut in the field 088d is $D_M^{\text{cut}} = 5.634$, while $D_M^{\text{cut}} = 5.105$ corresponds to the 99% cut in the field 147d. Since the largest cluster has the sharper concentration of D_M in the field 147d than in the field 088d (see Figure [5\)](#page-31-0), D_M^{cut} in the field 147d is smaller than that in the field 088d.

These two approaches have their own different problems. Avoiding large groups does not guarantee that minor groups are well separated from the largest group. In a multidimensional space, a few minor groups can be close to the large groups with a small D_M . When selecting objects with $D_M > D_M^{\text{cut}}$ as variable candidates, those objects with a large D_M can form large groups representing systematic observational features in each field. Although Figure [5](#page-31-0) implies that members of most large groups have a small D_M , using only one method can cause more contamination of non-variable objects or objects dominated by systematic patterns in each observation field.

We can define variable candidates conservatively by combining both methods. For example, we find objects having the larger D_M than the D_M^{cut} of the 99% cut and not being included in the top four large groups. Figure [6](#page-32-0) represents the number fraction of objects selected by this conservative method compared to results of selecting objects with the D_M^{cut} of the 99% cut. We use this conservative selection of variable candidates in Section [5.](#page-9-0) Because the top four large groups are closely located in the eight-dimensional space generally, excluding the members of the top four large groups from the variable candidates usually determines the size of variable candidates.

4. Database

We provide the results of our variability analysis and clustering for all sample light curves online. The database stores the eight variability indices, the cluster identification number in each field, D_M from the largest cluster for every light curve as well as the basic information of the light curves such as the NSVS object id and coordinates. The database is supplemented with the number of light curves analyzed, the number of groups found by clustering, the number fractions of group members, and the D_M cuts of 99%, 95%, and 90% cuts from the largest group in each field. Therefore, users of the database can select variable candidates by using these clustering results with their own selection rules of variable candidates.

The database is also supplemented by association to other astronomical catalogs. All objects analyzed are cross-matched to the SIMBAD database, 2MASS All-Sky Catalogs of Point Sources [\(Skrutskie et al. 2006\)](#page-25-7), the photometric catalog of the Sloan Digital Sky Survey (SDSS) Data Release 7 [\(Abazajian et al. 2009](#page-21-8)), and the photometric catalog of the GALEX GR4/GR5 Data Release [\(Morrissey et al. 2007](#page-23-8)) with the NSVS coordinates and a search radius of 6′′. When multiple objects are matched within the search radius, the nearest match is associated with the NSVS object. In addition to these catalogs, we also present matching results of the NSVS coordinates to IRAS [\(Helou & Walker 1988;](#page-22-7) [Moshir et al.](#page-24-10) [1990\)](#page-24-10) and AKARI [\(Murakami et al. 2007\)](#page-24-11) catalogs as separate files online. This association to other catalogs can be used to identify the morphology of the NSVS objects as galaxies or stars, to find astronomical types of known objects, to check blending effects with neighbor objects, and to estimate colors of objects as we show in the following section. In particular, because the spatial resolution of the NSVS data is much worse than the SDSS and 2MASS catalogs, the morphological information from these catalogs can help database users to avoid blended objects and less precise photometry in the NSVS catalog.

The database can be accessed through the Web interface^{[4](#page-9-1)}. Searching the light curves and their variability analysis is possible with equatorial coordinates and a search radius given by users. In particular, the simple cone search interface^{[5](#page-9-2)} is also provided for compatibility with the Virtual Observatory environment [\(Williams et al. 2008](#page-26-8)). We plan to provide the basic components of the database in Vizier^{[6](#page-9-3)} too.

5. Properties of variable candidates

In this section, we examine properties of variable candidates which are not included in the top four groups and have D_M larger than the 99% cut. With these conservative selection criteria, we find 1,840,310 light curves as possible variable candidates. We emphasize that this selection of variable candidates is highly conservative. When we select variable candidates simply with D_M larger than the 95% or 99% cut, the total number of variable candidates is 6,640,387 or 5,826,587, which is about 3.6 or 3.1 times more than the number of variable candidates selected with the conservative definition, respectively. Meanwhile, when we select objects not included in the top four groups as variable candidates, the number of candidates is 1,918,580, which is similar to the result of the conservative selection. But we remind that this selection of variable candidates is still affected by the intrinsic limits of the NSVS data such as blending effects and completely different uncertainty properties of photometry for extended objects compared to stellar objects.

5.1. Known objects and new candidates

We search all NSVS samples with the SIMBAD database to recognize any known objects and their basic properties such as well-known names. As explained in Section 4, the nearest SIMBAD object around the coordinates of the NSVS objects is retrieved with a search radius of 6′′. Since the NSVS data do not have information about morphological classification such as galaxy and star, the auxiliary information of the SIMBAD database is useful to sort out spurious variability of extended objects. About 6% of the NSVS objects are matched with

⁴<http://stardb.yonsei.ac.kr>

 5 http://stardb.yonsei.ac.kr/conesearch/nsvs_conesearch.php

 6 <http://vizier.u-strasbg.fr/viz-bin/VizieR>

at least one SIMBAD object. But this fraction is affected by the precision of the NSVS coordinates.

Based on the object classification given in the SIMBAD database^{[7](#page-10-0)}, we find that 16,061 NSVS light curves correspond to known or suspected variable stars. Considering only variable candidates with our conservative selection criteria, the number of known or suspected variable stars is 11,080 among our variable candidates. Finally, excluding known or suspected variable stars as well as known galaxies in the SIMBAD database, the number of new variable candidates is 1,824,123, with our conservative selection. Hereafter, our investigation of variable candidates is limited to these 1,824,123 NSVS objects. We note that uncertain coordinates in either NSVS or the SIMBAD databases can cause us to miss some known galaxies and known or suspected variables. The classifications in the SIMBAD databases might not be as complete as other catalogs of variable stars such as the AAVSO International Variable Star Index (VSX)^{[8](#page-10-1)} [\(Watson 2006](#page-26-9)) as we discuss in Appendix.

Figure [7](#page-33-0) shows light curves of six example NSVS objects which are not included in our conservative selection of variable candidates, but which are known or suspected variables in the SIMBAD database. These examples are among 11 objects, which are not included in our candidates, in the NSVS field 112a corresponding to a part of the constellation Aquila. If we selected variable candidates as objects with D_M larger than the 95% cut, four objects, including GSC 00490-04680 [\(Bernhard & Lloyd 2000](#page-21-9)) and NSV 12564 [\(Kinnunen & Skiff](#page-23-9) [2000\)](#page-23-9) in Figure [7,](#page-33-0) would be included in variable candidates among the 11 objects. The field 064d misses the largest number of known or suspected variable stars (236 objects) with our conservative selection of candidates. However, its fraction is only 0.6% with respect to the total number of objects that are analyzed by our clustering method. We note that most these missing objects are identified as variable objects in the *Kepler* field by HATNET which uses image subtraction method [\(Hartman et al. 2004\)](#page-22-8).

Figure [8](#page-34-0) presents example light curves of known or suspected variable stars matched with the SIMBAD database and included in our conservative selection of variable candidates for the NSVS field 112a. We find 88 known or suspected variable stars among our 6,389 variable candidates in the field 112a, corresponding to about 1%.

In Figure [9,](#page-35-0) we show 12 examples of new variable candidates which are matched to any kind of known objects except variable stars in the SIMBAD database. CCDM J19302+0219AB is not typed as variable stars in the SIMBAD database. But this ob-

⁷<http://simbad.u-strasbg.fr/simbad/sim-display?data=otypes>

⁸<http://www.aavso.org/vsx/>

ject is a known system of double stars [\(Dommanget & Nys 1994](#page-22-9)) which might have been affected by blending in the NSVS data. 2MASS J19391065+0543500 is also not included as a variable star in the SIMBAD database. But [Usatov & Nosulchik \(2008\)](#page-25-8) suggest that this object is a red asymptotic giant branch (AGB) variable star, supporting that the light curve shown in Figure [9](#page-35-0) exhibits true light variation. These examples show that our conservative selection of variable candidates can catch real variable objects.

We also compare our variable candidates to those found by others using the NSVS data. For example, 785 RR Lyrae candidates were reported already (Wils, [Lloyd, & Bernhard](#page-26-4) [2006\)](#page-26-4). These 781 objects are included in our conservatively selected candidates. But all 785 objects are found when we select variable candidates as objects having larger than the 99% D_M cut. When we select variable candidates with the 95% D_M cut, all new β Lyrae and Algol-type variable candidates from [Hoffman et al. \(2008\)](#page-22-3) are recovered with our method if they are included in our original NSVS samples. But we recover 95% of them with the conservative selection of variable candidates. About 4700 variable candidates of other kinds such as δ Scuti stars and Cepheid objects were also studied with the NSVS data [\(Hoffman, Harrison, & McNamara 2009](#page-22-5)). Again, our selection with the 95% D_M cut recovers most variable candidates except for objects which have different light curves due to different definitions of good photometric data and different systematic patterns in light curves [\(Hoffman, Harrison, & McNamara 2009\)](#page-22-5). These other studies use simple rules such as 0.1 mag dispersion of light curves, which are conservative selection methods for specific types of variable candidates. Therefore, the number of variable candidates is much larger in our approach than in others.

5.2. IRAS sources

For the conservative selection of variable candidates, we find *IRAS* sources which are spatially matched to the NSVS coordinates with a search radius of 6^{$\prime\prime$} in the IRAS point source catalog [\(Helou & Walker 1988\)](#page-22-7) and the IRAS faint source catalog [\(Moshir et al.](#page-24-10) [1990\)](#page-24-10). Among all NSVS samples, 31,852 light curves have the matching IRAS sources. Considering the IRAS sources only for our conservative variable candidates, the number is 12,987, which is about 41%.

We derive two colors of the IRAS sources by using the IRAS photometric flux at 12, 25, and 60 μ m ($F_{12\mu$ m, $F_{25\mu}$ m, and $F_{60\mu$ m). The conventional definition of the IRAS colors (e.g., [van der Veen & Habing 1988;](#page-25-9) [Olivier, Whitelock, & Marang 2001;](#page-24-12) [Sevenster 2002](#page-24-13)) is

$$
C_{12/25} = 2.5 \log(\frac{F_{25\mu\text{m}}}{F_{12\mu\text{m}}}); C_{25/60} = 2.5 \log(\frac{F_{60\mu\text{m}}}{F_{25\mu\text{m}}})
$$
(5)

where we do not apply any color corrections to the fluxes.

The IRAS colors have been commonly used for classification of infrared sources. In particular, the two-color diagram like Figure [10](#page-36-0) helps us understand what kind of variable candidates show variability which is relevant to the late stage of stellar evolution such as AGB stars with evolved circumstellar dust [\(Zuckerman 1987;](#page-26-10) [van der Veen & Habing 1988;](#page-25-9) [Kwok, Volk, & Bidelman 1997;](#page-23-10) [Ramos-Larios et al. 2009\)](#page-24-14). In Figure [10,](#page-36-0) we plot the colors of IRAS sources with the quality number $Q = 3$ at all three wavelengths 12, 25, and 60 μ m [\(Helou & Walker 1988](#page-22-7)). AGB stars dominate colors of $C_{25/60} < -0.3$, while planetary nebulae and young stellar objects dominate $-0.3 < C_{25/60} < 0.4$ and $0.4 < C_{25/60}$, respectively $(Jackson, Ivezić, & Knapp 2002)$.

In Figure [11,](#page-37-0) we show example light curves of variable candidates that have the corresponding IRAS identifications. Although these IRAS sources are not known variable stars in the SIMBAD database, some of them have been investigated in various ways without variability information. IRAS 03534+6945 (NSVS 513536) and IRAS 23400+6320 (NSVS 1487299) were found as H- α emitting stars in [Stephenson \(1986\)](#page-25-10) and [Coyne & MacConnell](#page-21-10) [\(1983\)](#page-21-10), respectively. These sources are also found as a possible variable sources in the VSX catalog (see Appendix). IRAS 17203-1534 (NSVS 16483061) and IRAS 01005+7910 (NSVS 262162) are post-AGB stars which are sub-classified as hot post-AGB stars and high galactic latitude supergiants [\(Szczerba et al. 2007](#page-25-11)), respectively. IRAS 01005+7910 has also been observed with the *Hubble Space Telescope* which found nebulae around it (Siódmiak et al. [2008\)](#page-25-12).

5.3. AKARI sources

Bright objects included in this paper are expected to be included in AKARI observations which have been conducted with two instruments Far-Infrared Surveyor (FIS) and Infrared Camera (IRC; [Murakami et al. 2007\)](#page-24-11). Both instruments produced all-sky source catalogs which are much deeper and spatially better resolved than *IRAS* [\(Oyabu et al. 2010\)](#page-24-15).

We match our NSVS samples to AKARI/IRC All-Sky Point Source Catalog (Version 1.0; [Ishihara et al. 2010a](#page-22-11)[,b\)](#page-22-12) and AKARI/FIS All-Sky Survey Bright Source Catalog (Version 1.0; [Yamamura et al. 2010](#page-26-11)), with a search radius of 6′′. The numbers of our NSVS samples matching to the AKARI objects are 267,732 and 8,742 for the IRC and FIS catalogs, respectively. This matching rate with the IRC catalog is much higher than that with the IRAS.

Figure [12](#page-38-0) shows a color – color diagram of AKARI fluxes like Figure [10.](#page-36-0) In the plot,

we show objects as identified as point sources with only good photometric observations of AKARI IRC at 9 and 18 μ m, and FIS at 65 μ m, which are found with IRC photometric flags of conditions $qS09 = 3$, $f09 = 0$, $X09 = 0$, $qS18 = 3$, $f18 = 0$, $X18 = 0$, and with FIS photometric flags of conditions $q_S65 > 1$. The number of the NSVS objects with the good photometric data is 374, while only 54 AKARI point-source objects with good photometric data correspond to the variable candidates selected conservatively. The distribution of AKARI colors is similar to that of IRAS colors because of the similar wavelength ranges of the observation bands.

As we find with the *IRAS* colors, the variable candidates with the corresponding AKARI objects might be long-period late-type stars [\(Ita et al. 2010\)](#page-22-13). Figure [13](#page-39-0) shows example light curves of the variable and non-variable candidates in the SIMBAD database. AKARI IRC 200011367 (NSVS 1713088) corresponds TYC 3668-112-1, which is also an IRAS object. Even though this light curve does not have many observed data points, the light curve is selected as a possible variable candidate in the NSVS field 013b. AKARI IRC 200843875 (NSVS 3393876) is close to IRAS 22164+6427, which might be the same object. The light curve of AKARI IRC 200752804 does not have many observed data points. But its variation seems reasonable because of the fact that it is a post-AGB star or a protoplanetary nebula, corresponding to HD 331319 and IRAS 19475+3119. The light curves of the other three objects presented in Figure [13](#page-39-0) do not correspond to any known objects in the SIMBAD database, and are not selected as variable objects.

5.4. 2MASS and SDSS photometry

Near-infrared (NIR) colors are also commonly used to identify basic properties of stars and to separate non-stellar objects such as quasars. We match all variable candidates to the 2MASS All-Sky Catalog of Point Sources [\(Skrutskie et al. 2006](#page-25-7)) with a search radius 6". A total of 1,439,381 variable candidates have corresponding 2MASS sources. Hereafter, 2MASS photometry data are given in Vega system.

Figure [14](#page-40-0) shows colors of the matched 2MASS objects with unblended, unsaturated, and accurate photometry which is described by read flag Rflg $= 2$, blend flag Bflg $= 1$, and contamination and confusion flag $Cfg = 0$ in all three bands of 2MASS data [\(Covey et al.](#page-21-11) [2007\)](#page-21-11), and with the separation between the NSVS and 2MASS positions less than 1′′. Most variable candidates have colors similar to those of normal stars in our Galaxy which are mainly $0 < J - H < 1$ (e.g., [Finlator et al. 2000;](#page-22-14) [Zoccali et al. 2003](#page-26-12)). Although quasars have distinctive colors in $J-H$ versus $H-K_s$ where most variable candidates are not found (see [Chiu et al. 2007;](#page-21-12) [Kouzuma & Yamaoka 2010](#page-23-11), for discussions), some fraction of variable candidates might be quasars with colors around $J - H \sim 0.9$ and $H - K_s \sim 0.3$.

Late-type variable candidates such as red giant branch (RGB) and AGB stars can be identified more reliably with the 2MASS colors. As shown in Figure [14,](#page-40-0) the dominant NIR color of pulsating variable stars found in the Magellanic clouds [\(Ita et al. 2004\)](#page-22-15) is different from the major colors of our variable candidates and known quasars. In particular, $J - K_s \sim 1.4$ is the boundary between oxygen-rich and carbon stars (Nikolaev [& Weinberg](#page-24-16) [2000;](#page-24-16) [Cole & Weinberg 2002;](#page-21-13) [Kiss & Bedding 2003](#page-23-12)). Therefore, our variable candidates with colors similar to those of known variables might be pulsating RGB and AGB stars [\(Ita et al.](#page-22-15) [2004;](#page-22-15) [Kouzuma & Yamaoka 2009](#page-23-13)).

By using the NIR color – color diagram given in Figure [14,](#page-40-0) we can also investigate whether our variable candidates include possible obscured young stars with or without disks such as T Tauri stars [\(Meyer, Calvet, & Hillenbrand 1997;](#page-23-14) [Tsujimoto et al. 2002;](#page-25-13) Ozawa, Grosso, & Montm [2005\)](#page-24-17). If reddening is significant in some of our variable candidates, their colors might be consistent with those of young stars.

Figure [15](#page-41-0) shows six example light curves of the NSVS objects which have corresponding 2MASS measurements. 2MASS 18552297+0404353 (NSVS 13924374) is a Herbig Ae/Be candidate star [\(Vieira et al. 2003\)](#page-26-13) with a different name PDS 551. The source 2MASS $09322353+1146033$ (NSVS 10229563 and IRAS 09296+1159) is a post-AGB star (Blommaert, van der Veen [1993\)](#page-21-14). We find that its variation recorded in the NSVS light curve is regular with a period of about 46.88 days^{[9](#page-14-0)}. 2MASS 22230120+2216565 (NSVS 11767619) is confirmed as a carbon star in spectroscopic observations by [Mauron, Gigoyan, & Kendall](#page-23-15) [\(2007](#page-23-15)). But other objects presented in Figure [15](#page-41-0) have not been assigned a type.

We also match the NSVS coordinates of the variable candidates to the SDSS Data Release 7 with 6′′ search radius. The five bands of the SDSS photometric systems have been commonly used to identify stellar and non-stellar sources by using their distinctive colors (e.g., [Fan 1999;](#page-22-16) [Fukugita et al. 2011\)](#page-22-17). Combining the 2MASS photometry with the SDSS photometry also helps us determine stellar source types precisely (e.g., [Finlator et al.](#page-22-14) [2000\)](#page-22-14). Among 438,087 variable candidates having corresponding SDSS photometric objects, 406,564 candidates have also corresponding 2MASS sources.

Figure [16](#page-42-0) presents the distribution of colors for the variable candidates. We plot only good SDSS photometric data and clean 2MASS photometric data as we explained earlier. In particular, the matched objects with less than 1′′ distance are shown in the plot. The good

 9 This period is found by using the tool provided in http://www.astro.lsa.umich.edu/~msshin/science/code/MultiSt [\(Shin & Byun 2004](#page-24-8)).

SDSS photometric data are defined as stellar (i.e., unresolved) objects without the SDSS photometric flags EDGE, BLENDED, PEAKCENTER, NOPROFILE, COSMIC RAY, SATU-RATED, NOTCHECKED, DEBLENDED AS MOVING, SATUR CENTER, INTERP CENTER, DEBLEND NOPEAK, and PSF FLUX INTERP [\(Stoughton et al. 2002\)](#page-25-14). We check these flags in each SDSS band. Therefore, the number of objects shown in each panel of Figure [16](#page-42-0) varies for different color combinations. In all SDSS photometric data, we use PSF magnitudes. We also find SDSS objects with limiting magnitudes $m_u = 22.3$, $m_g = 23.3$, $m_r = 23.1, m_i = 22.3, \text{ and } m_z = 20.8.$

The SDSS color – color diagram can be used to pick out probable RR Lyrae variables which are pulsating horizontal branch stars (Gautschy $\&$ Saio [1996\)](#page-22-18). As suggested in the theoretical prediction of colors for RR Lyrae stars in the SDSS photometric system [\(Marconi et al. 2006](#page-23-16)), the following color ranges can be used to find RR Lyrae candidates [\(Sesar et al. 2010\)](#page-24-18):

$$
0.75 < u - g < 1.45,\tag{6}
$$

$$
-0.25 < g - r < 0.4,\tag{7}
$$

$$
-0.2 < r - i < 0.2,\tag{8}
$$

$$
-0.3 < i - z < 0.3,\tag{9}
$$

which are shown as boxes in Figure [16.](#page-42-0) A large number of variable candidates are identified as F-, G-, and K-type stars in the figure.

Among the variable candidates selected by the RR Lyrae color cuts, we present example light curves of two objects, SDSS J105513.79+564747.5 (NSVS 2594623) and SDSS J145313.21+421031.8 (NSVS 5152328), which have been also observed in the SDSS spectroscopy, in Figure [17.](#page-43-0) Both objects are not classified as variable sources in the SIM-BAD database. However, SDSS J105513.79+564747.5 is found variable in GALEX observations [\(Welsh et al. 2005\)](#page-26-14) as included in the VSX catalog (see Appendix). We can estimate approximate periods of these two variables with the NSVS light curves as 0.541757 and 0.489448 days, respectively. These examples clearly show that a low cadence in the NSVS data is not high enough to derive complete light curves of these RR Lyrae variables, which have short periods [\(Sterken & Jaschek 2005](#page-25-15)), except few NSVS objects with enough data [\(Kinemuchi et al. 2006\)](#page-23-2). Therefore, further follow-up observations of interesting NSVS objects will be required to confirm their variability classes. SDSS J105513.79+564747.5 was identified as a probable RR Lyrae by [Wheatley, Welsh, & Browne \(2008](#page-26-15)), although they could not retrieve a complete light curve from their GALEX observations. SDSS J145313.21+421031.8 was also recognized as a blue horizontal branch star in the SDSS observation [\(Sirko et al. 2004](#page-25-16)). These examples prove that using colors of objects is complementary to variability analysis to identify object types.

Six other examples of variable candidates are presented in Figure [18](#page-44-0) where NSVS objects have corresponding reliable SDSS and 2MASS photometric data. Except for SDSS J021532.23-104029.3, these objects have $(g - i)$ colors without the SDSS bad photometric flags. Spectral types of stars can be described approximately by $(g - i)$ colors where B0, A0, F0, G0, K0, and M0 correspond to $(g - i) \sim -0.94, -0.44, 0.09, 0.52, 0.83,$ and 1.95, respectively [\(Covey et al. 2007](#page-21-11)). Most variable candidates are close to G5 as shown in Figure [16.](#page-42-0) Although $(g - i)$ is generally a good proxy of spectral types, SDSS J155325.80+530924.2 (NSVS 5206326) was already confirmed spectroscopically as M8 III star for its $(q - i)$ = 5.81. We also note that this object is also included in the VSX catalog as a variable star (see Appendix). These examples reassert that the low cadence in the NSVS data does not guarantee a certain classification of variable objects, requiring further follow-up observations with different cadences.

5.5. SDSS and *GALEX* photometry

Hot stellar objects such as white dwarfs and massive main-sequence stars are generally not detected in NIR, but they can be more easily recognized over UV wavelength ranges which cover most stellar flux. In the $GALEX \, \text{GR}4/5^{10}$ $GALEX \, \text{GR}4/5^{10}$ $GALEX \, \text{GR}4/5^{10}$, we find objects matching our NSVS variable candidates' coordinates within 6''. When multiple GALEX objects are matched to a single NSVS object, we choose the nearest GALEX object as the best match. A total of 739,625 variable candidates, i.e., about 40% of the candidates, correspond to GALEX photometric objects. A total of 286,185 candidates have corresponding SDSS objects too.

In Figure [19,](#page-45-0) we present colors of variable candidates with reliable GALEX and SDSS photometric measurements. In addition to following the same conditions for the reliable SDSS photometric measurements as in Section [5.4,](#page-13-0) we require that the GALEX objects should have the distance from the center of the $GALEX$ field of view \lt 0. \degree 6, and both FUV and NUV magnitudes $\langle 25 \rangle$ (Agüeros et al. 2005; [Maxted et al. 2009](#page-23-17)). The FWHM angular resolution is about $6''$ in the NUV channel [\(Morrissey et al. 2005\)](#page-23-18). Considering the combined effects of poor spatial resolution in the NSVS and GALEX data, the spatial association among the NSVS, SDSS, and GALEX objects needs a careful check when people select interesting NSVS objects with the corresponding SDSS and GALEX objects together in our database.

Colors of most variable candidates presented in Figure [19](#page-45-0) are consistent with the expected colors of normal stars [\(Seibert et al. 2005](#page-24-19); [Bianchi et al. 2007](#page-21-6), [2009\)](#page-21-16), considering the

 10 <http://galex.stsci.edu>

Galactic extinction that makes overall colors red. The color distribution of known quasars [\(Trammell et al. 2007](#page-25-17)) is well separated from that of stars in the diagram of $(FUV - q)$ and $(g - i)$. Because our variable candidates are bright objects, all of them might not be quasars but stars even though some objects seem to have quasar-like colors. Hot white dwarf candidates can be selected with the color cut of $(FUV - NUV) < 0$ and $(g-r) < -0.2$ (Agüeros et al. 2005). But we warn that the multiple matches of the NSVS coordinates to both SDSS and GALEX catalogs have worse precision than a single match to either SDSS or GALEX catalogs. Therefore, the color combining both SDSS and GALEX photometric data might not be reliable when the objects are faint or close to neighboring objects in the SDSS and GALEX catalogs. Since the precision of the SDSS objects' coordinates is much better than those of the GALEX catalogs, the SDSS colors are more reliable than the GALEX colors in the color – color diagram combining both catalogs.

Among the NSVS objects with the corresponding SDSS and GALEX objects, several SIMBAD objects are found with further information about their properties. For example, NSVS 7609761 corresponds to SDSS J115800.38+295731.4 and GALEX J115800.4+295731 with $(FUV - NUV) = 1.63$ and $(g - i) = -0.55$. This object is included in [Brown et al.](#page-21-17) (2008) as CHSS 835 which is a star with a spectral type of B8. In the diagram of $(FUV - NUV)$ and (NUV – r), NSVS 4819428 is known as a spectral type B subdwarf FBS 0839+399 [\(Wegner & McMahan 1985;](#page-26-17) [Mickaelian 2008\)](#page-23-19) with $(FUV - NUV) = -0.35$ and $(NUV - r)$ $= -1.28$. The light curves of these two objects given in Figure [20](#page-46-0) do not show distinctive features due to the poor sampling rate in the NSVS data. Flare-like variation can be presumed from the light curve of NSVS 2744942 which is recognized as an active M dwarf, corresponding to an X-ray object RX J1447.2+5701 [\(Mochnacki et al. 2002\)](#page-23-20). The NSVS light curve of this object shows about 1.5 mag variation even with the poor sampling rate.

Figure [20](#page-46-0) also shows the light curves of the three variable candidates which have reliable data of the SDSS g – and i-band photometry as well as the $GALEX$ NUV measurement. None of them have any different identification in SIMBAD database. The light variation seems real, but the low cadence in the NSVS data does not produce complete light curves with distinctive types.

6. Summary and discussion

A new systematic investigation of variable candidates in the NSVS data was presented with a clustering method for time-series data. Assuming that the dominant fraction of light curves represents non-variable objects, our method finds clusters of light curves with their eight dimensional features, and then finds how many light curves are included in each cluster.

When choosing as variable candidate objects which are not included in the top four large clusters and which have $D_M > 99\%$ cut from the largest cluster, the total number of new variable candidate light curves is 1,824,123 in our entire sample of the NSVS data.

The cross-correlation with IRAS, AKARI, 2MASS, SDSS, and GALEX catalogs helps us to identify interesting objects with specific spectral types or variability classes [\(Eyer & Mowlavi](#page-22-19) [2008\)](#page-22-19). In particular, variable stars over the instability strip can be selected easily from their specific colors (e.g., see Figure [17\)](#page-43-0). We also show examples of long-period variables which can be selected from their IRAS, AKARI, or 2MASS colors (e.g., see Figures [11,](#page-37-0) [13,](#page-39-0) and [15\)](#page-41-0).

Our analysis is presented online with the information on cross-correlations with other catalogs. Because the sampling pattern in the NSVS data is not good enough to identify detailed structures of different variability types, follow-up observations of variable candidates will be necessary to understand these variable sources by taking more photometric data points and improving the sampling rates. Moreover, some variable candidates such as IRAS sources might be new maser sources which are interesting objects in the radio region.

Our approach of detecting variable candidates in the NSVS data is supplementary to previous methods of finding variable candidates. We do not claim that this method is the best way in all cases. Definitely, if observation systems, including instruments, environments, and data reduction procedures, are well known prior or are well controlled, supervised methods can be superior than unsupervised methods like our approach because supervised methods can simulate observing systems with known variable and non-variables sources to find the best separation between variable and non-variable sources. This separation can be applied to detect new variable candidates in the test data. Therefore, when the data properties, including all kinds of systematic patterns and real variability patterns, are understood and modeled well, detecting variable sources becomes a *classification* problem instead of a *clus*tering problem.

Our analysis results can be used with many different methods of selecting variable candidates. In this paper, our conservative selection method is avoiding the top four large clusters and objects with $D_M < 99\%$. However, when people are interested in infrared variable sources, they can choose as variable candidate objects corresponding to IRAS objects with $D_M > 90\%$. If known variable objects can produce clusters with reasonable sizes, finding clusters with many known variable objects can be an efficient way to find variable candidates. Unfortunately, this approach is not feasible now because the number of known variable objects is too small in each NSVS observation field.

Several variability surveys cover the same apparent magnitude ranges as the NSVS

does. A large fraction of sky has been already observed in the All Sky Automated Survey (ASAS; [Pojmanski 1997\)](#page-24-20) and SuperWASP [\(Street et al. 2003](#page-25-18)). Our approach of variability detection can be applied to those data sets too. In addition, objects included in both the NSVS and others can be combined to extend the span of time-series data or to complement different sampling patterns. We plan to update the online database with these additional data sets in the future. Furthermore, because almost all objects included in our analysis will be monitored by the *GAIA* mission for five years [\(Cacciari 2009](#page-21-18)), our analysis will be combined with the future time-series data and astrometric/kinematic information.

Our method can also be improved to catch much broader types of variable objects and objects with weak variability signals. For this purpose, it is important to include various features of light curves as we emphasized in Section [2.](#page-3-0) In particular, the usage of AoVM as one feature of light curves is strongly limited because a complete form of a periodogram has more information of light curves. Therefore, it must be useful to develop new features describing periodograms more completely if the new features can be estimated in computationally cheap ways. Moreover, Stetson's I index [Stetson \(1996](#page-25-3)) can be included in our method if data include multi-band light curves. For instance, J and K can be derived in each band, while I is estimated with multi-band light curves. Our usage of J can also be changed to use all pairs of data points instead of using sequential pairs.

We thank Bernie Shao and Przemek Wozniak for helping us access the *GALEX* data and the NSVS light curves, respectively. We also thank Michael Sekora, Charles Cowley, Mark Reynolds, and Stefan Kraus for useful discussions and careful reading. We are grateful to the anonymous referee for comments which improved this manuscript. Y.I.B. acknowledges the support of National Research Foundation of Korea through Grant 2011-0030875.

This publication makes use of the data from the Northern Sky Variability Survey created jointly by the Los Alamos National Laboratory and University of Michigan. The NSVS was funded by the Department of Energy, the National Aeronautics and Space Administration, and the National Science Foundation. This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France. This research is based on observations with AKARI, a JAXA project with the participation of ESA. This publication also makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation. Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society, and the Higher Education Funding Council for England. The SDSS Web Site is [http://www.sdss.org/.](http://www.sdss.org/) The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions. The Participating Institutions are the American Museum of Natural History, Astrophysical Institute Potsdam, University of Basel, University of Cambridge, Case Western Reserve University, University of Chicago, Drexel University, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, the Joint Institute for Nuclear Astrophysics, the Kavli Institute for Particle Astrophysics and Cosmology, the Korean Scientist Group, the Chinese Academy of Sciences (LAMOST), Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Ohio State University, University of Pittsburgh, University of Portsmouth, Princeton University, the United States Naval Observatory, and the University of Washington. GALEX (Galaxy Evolution Explorer) is a NASA Small Explorer, launched in April 2003. We gratefully acknowledge NASA's support for construction, operation, and science analysis for the GALEX mission, developed in cooperation with the Centre National d'Etudes Spatiales (CNES) of France and the Korean Ministry of Science and Technology.

A. Known or suspected variables found in the VSX

The SIMBAD database is commonly used to identify known objects. We also use the database to find all known variable objects and extragalactic objects as shown in Section [5.1.](#page-9-4) However, the SIMBAD database is not as complete as other catalogs of variable stars. In particular, the AAVSO International Variable Star Index (VSX)[\(Watson 2006\)](#page-26-9) catalog is frequently updated with new reports of variable stars.

We check how many variable candidates selected by our conservative selection are not classified as variable sources in the SIMBAD database, but are included in the VSX catalog. Here, we use the catalog released online on Nov. 15, 2009, including 178,599 stars. Among 1,824,123 variable candidates chosen by our conservative selection and not included in the SIMBAD database, we find that 41,019 objects are included as variable stars in the VSX catalog. These known variable stars in the catalog are largely included with references to the ASAS observations (9,999 objects) [\(Pojmanski 1997](#page-24-20)), and to the NSVS observations (15,958 objects) that we also use here. A total of 1,147 objects are matched to suspected variable stars in the catalog. Interestingly, a total of 1,106 suspected variables are included with references to the NSVS light curves. Therefore, at least 1,783,104 variable candidates are newly selected in our method. In the online database, we provide links to the most recent VSX catalog for the NSVS light curves which we examine.

This preprint was prepared with the AAS IATEX macros v5.2.

Fig. 1.— GMM results with respect to the number of observation epochs (left) and the number of light curves (right). From top to bottom, each panel shows the number of groups, the number fraction of the largest group, and the number fraction of the top three large groups, respectively.

Fig. 2.— Distributions of the DB index. When the DB index is low, groups are compact and well separated from others. The NSVS field 100c shows the highest DB index \sim 29.

Fig. 3.— Center coordinates of the largest cluster. Since Con is 1 in all fields, we do not show its distribution here. The distribution shows that there are field-by-field variations of systematic effects which produce variations of the largest cluster's central position in the eight-dimensional space.

Fig. 4.— Cumulative fraction of objects included in groups. The median fraction as a function of the number of groups is presented with the solid line, while dashed lines describe the minimum and maximum fractions. For example, top four large groups explain about 89% of light curves as the median fraction. The median fraction of about 99% is found with top ten large groups.

Fig. 5.— Distributions of D_M . The peak of the distributions around $D_M \sim 2$ corresponds to a mode value of D_M for a multivariate normal distribution [\(Ververidis & Kotropoulos](#page-25-6) [2008\)](#page-25-6). Compared with the distribution for all objects (solid line), the field 147d (dotted line), which has the smallest number of light curves, and the field 088d (dashed line), which has the largest number of light curves, in our samples are more dominated by objects around the largest cluster in the eight-dimensional space.

Fig. 6.— Fraction of objects selected as variable candidates. As found in the different ranges of the horizontal axis and the vertical axis, the size of variable candidates can be decreased significantly by combining the constraints of D_M^{cut} and group sizes together.

Fig. 7.— Example light curves of known or suspected variable objects which are not selected by our conservative variability detection. The SIMBAD names of the objects are given in the top of each panel.

Fig. 8.— Example light curves for known or suspected variable objects included in our conservative variable candidates. The SIMBAD names of the objects are given in the top of each panel.

Fig. 9.— Example light curves of variable candidates matched to SIMBAD objects of nonvariable stars. Each light curve corresponds to the SIMBAD object with the name given in the top of each panel. Although IRC +00434 and 2MASS J19391065+0543500 are not found as known variable sources in the SIMBAD database, these objects are found in the VSX catalog [\(Pojmanski 2002](#page-24-21); [Usatov & Nosulchik 2008\)](#page-25-8) as we explain in Appendix.

Fig. 10.— IRAS two-color diagram of variable candidates. The solid line represents the color of oxygen-rich Mira variables and variable OH/IR stars from [van der Veen & Habing](#page-25-9) [\(1988\)](#page-25-9). Cross symbols correspond to objects shown in Figure [11.](#page-37-0)

Fig. 11.— Example light curves of variable candidates that are IRAS sources. The IRAS designations and $(C_{12/25}, C_{25/60})$ are presented in the top of each panel. Objects on the left column have colors near the curve presented in Figure [10.](#page-36-0)

Fig. 12.— AKARI two-color diagram of variable candidates and other objects. Following the definition of the *IRAS* colors given in Equation [\(5\)](#page-11-0), AKRAI colors are defined by using fluxes at its IRC 9, 18 μ m and FIS 65 μ m. Filled circles represent new variable candidates selected with our conservative selection, while empty squares correspond to non-variable objects or objects that are known variable stars or galaxies in the SIMBAD database.

Fig. 13.— Example light curves of variable candidates (left) and non-variable objects (right) that are AKARI sources. The AKARI designations in the IRC catalog and $(C_{9/18}, C_{18/65})$ are presented in the top of each panel.

Fig. 14.— 2MASS color-color diagram of variable candidates. The color distribution of variable candidates (solid-line contours) is similar to the overall color distribution of or-dinary stars [\(Covey et al. 2007](#page-21-11)), while observed colors of 6658 QSOs with redshifts > 0.3 from Véron-Cetty $&$ Véron (2006, dotted-line contours) are not similar to those of variable candidates. The color distribution of known pulsating variable stars in LMC and SMC (dashed-line contours; [Ita et al. 2004](#page-22-15)) implies that variable candidates redder than $(J - K_s)$ $= 1.4$ (dots) might be variable carbon-rich stars. The loci of classical T Tauri stars with de-reddened colors is presented as a thick solid line [\(Meyer, Calvet,](#page-23-14) & Hillenbrand [1997](#page-23-14)). Cross symbols correspond to objects shown in Figure [15.](#page-41-0) The Galactic extinction is not considered here.

Fig. 15.— Example light curves of the NSVS objects with the reliable 2MASS photometry. The 2MASS designations and $(J - H, H - K_s)$ are given in the top of each panel. 2MASS 18552297+0404353 is also PDS 551 which is a Herbig Ae/Be candidate star [\(Vieira et al.](#page-26-13) [2003\)](#page-26-13). 2MASS 09322353+1146033 corresponds to IRAS 09296+1159.

Fig. 16.— SDSS color–color diagrams of the variable candidates. Boxes represent the ranges of single-epoch colors for RR Lyrae variable candidates from [Sesar](#page-24-18) et al. [\(2010\)](#page-24-18). Solid lines in the panel of $(g - r)$ and $(r - i)$ colors represent $(g - i)$ colors corresponding to spectral types O5, A0, F0, G0, K0, M0, and M5 from left to right, which are derived from synthesized stellar spectra [\(Covey et al. 2007\)](#page-21-11). The Galactic extinction is not included here.

Fig. 17.— Example light curves of the NSVS objects selected as RR Lyrae variable candidates with the SDSS spectroscopic data. The left column shows the raw NSVS light curves, while the right column presents the light curves folded with approximate periods of 0.541757 (top) and 0.489448 (bottom) days, respectively.

Fig. 18.— Example light curves of variable candidates with the reliable SDSS and 2MASS photometric measurements. Top two objects are included in all color–color diagrams shown in Figure [16.](#page-42-0) SDSS J155325.80+530924.2 is not classified as a known variable star in the SIMBAD database. However, it is a spectroscopically confirmed giant star with another designation 2MASS J15532581+5309244 [\(Cruz et al. 2003](#page-21-19)), and is found as a variable star in Woźniak et al. (2004b). SDSS J021532.23-104029.3 is identified as a field horizontal branch star BPS CS 22175-0003 by [Wilhelm et al. \(1999\)](#page-26-18).

Fig. 19.— Color-color diagrams of variable candidates with the SDSS and GALEX photometric data. The plots show variable candidates matching the SDSS objects within 1". Contours correspond to the color distributions of quasars which are detected in both SDSS and GALEX [\(Trammell et al. 2007](#page-25-17)).

Fig. 20.— Example light curves of variable candidates with the reliable GALEX and SDSS photometry. Three objects (left) have further identification in SIMBAD, while other three objects (right) are selected in the order of increasing $(NUV - g)$ color from top to bottom.

Table 1. Variability indices.

Index	Definition	
$\frac{\sigma}{\mu}$	$\frac{\sqrt{\sum_{n=1}^{N}(x_n - \mu)^2/(N - 1)}}{\sum_{n=1}^{N} x_n/N}$	
γ_1	$\frac{\sqrt{N(N-1)}}{N-2} \frac{\sum_{n=1}^{N} (x_n - \mu)^3/N}{\sqrt[3]{\sum_{n=1}^{N} (x_n - \mu)^2/N}}$	
γ_2	$\frac{N-1}{(N-2)(N-3)}\left\{(N+1)\left(\frac{\sum_{n=1}^{N}(x_n-\mu)^4/N}{(\sum_{n=1}^{N}(x_n-\mu)^2/N)^2}-3\right)+6\right\}$	
Con	$1 \; + \; \tfrac{1}{N-2} \sum_{n=1}^{N-2} \left\{ \begin{array}{ll} 1 & \text{if } (x_n-\mu_0) > 2\sigma \text{ and } (x_{n+1}-\mu_0) > 2\sigma \text{ and } (x_{n+2}-\mu_0) > 2\sigma \\ 1 & \text{if } (x_n-\mu_0) < -2\sigma \text{ and } (x_{n+1}-\mu_0) < -2\sigma \text{ and } (x_{n+2}-\mu_0) < -2\sigma \\ 0 & \text{otherwise} \end{array} \right.$	-48
η	$\frac{\sum_{n=1}^{N-1}(x_{n+1}-x_n)^2/(N-1)}{-2}$	
J	$\sum_{n=1}^{N-1} sign(\delta_n \delta_{n+1}) \sqrt{ \delta_n \delta_{n+1} }$	
K	$\frac{1/N\sum_{n=1}^{N} \delta_n }{\sqrt{1/N\sum_{n}N-\delta_n^2}}$	

AoVM The maximum value of the analysis of variance (ANOVA) statistic [\(](#page-24-22)Schwarzenber[g](#page-24-22)-Czern[y](#page-24-22) 1996)

Note. $-\sigma$, μ , γ_1 , γ_2 , and μ_0 are standard deviation, average, skewness, kurtosis, and
point of N magnitudes x, in each light curve respectively. δ is $\sqrt{N/(N-1)}(x-\mu)/a$ median of N magnitudes x_n in each light curve, respectively. δ_n is $\sqrt{N/(N-1)}(x_n - \mu)/e_n$
where e_n is a photometric error for each data point. sign($\delta_n \delta_{n+1}$) is the sign of $\delta_n \delta_{n+1}$.
