Keywords: Spin-glasses, inverse freezing/crystallization, finite-temperature RKKY interaction

In reference[1], van Hemmen (vH) introduced a classical spin model with frustration, which is analytically solvable and reproduces many experimental features of a spin glass (SG) quite well[1]. It consists of N Ising-spins interacting via a long-range random coupling of the form $J_{ij} = J_0/N - (J/N)(\xi_i\eta_j + \xi_j\eta_i)$; ξ_i and η_j are identically distributed random variables with zero mean and finite variance. J_0 is a net direct exchange, and J represents the strength of the strongly-oscillating and long-ranged Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction. vH phase diagram (Fig.1) is universal[2, 3]; i.e., robust against variations of the distribution of ξ_i and η_j . The ferromagnetic state (FE), whenever it exists ($J_0/J > x_c = 2/\pi$), is the low temperature phase; vH considered this is a limitation of his model. Apparently, it cannot account for phenomena such as inverse freezing, where an ordered phase appears at higher temperatures than a less-ordered one. This comment is intended to show that the vH model, in its original classical version, can also account for transitions from a SG phase to a higher-temperature FE state.

The so far ignored fact is the temperature dependence of J . For $T > 0$, the RKKY interaction becomes exponentially damped. The envelope function has the asymptotic form $I(T) = I(0)e^{-\pi T k_F r / T_F}$, for $T < T_F$, irrespective of the dimensionality[4]. T_F and k_F are the Fermi-temperature and wave-vector, and r is the generic dis-

is representative of the long-range RKKY coupling, this can be roughly estimated taking the value of the envelope function at $k_F r = \pi$. Hence, $J(T) \sim J(0)e^{-\gamma T}$, with $\gamma = \pi^2/T_F$ and $J(0) = J(T=0)$. For a given system, the corresponding $x = J_0/J$ will increase as one goes up in temperature. In other words, a system is represented by fixed $J_0/J(0)$ and γ ; heating/cooling a sample does not correspond to a vertical line in Fig.(1). A FE phase may appear upon heating a glass state if $\gamma J(0) \geq x_c^{-1} \ln(1/x_c)$; or in terms of T_F ,

$$J(0)/T_F \geq \pi^{-2} x_c^{-1} \ln(1/x_c). \quad (1)$$

To check whether this is a reasonable constraint, let use the effective mass approximation. The damping coefficient is rewritten as $\gamma = 4\pi^2 m^* k_B (3n_e/\pi)^{-2/3} / \hbar^2$, in terms of the effective mass m^* and concentration n_e of conduction electrons. k_B and \hbar are the Boltzmann- and Planck-constant. Substituting the respective values, we obtain

$$m_{\text{rel}}^* n_e^{-2/3} J(0) \geq 10^{-17} \text{ K m}^2 \quad (2)$$

where m_{rel}^* is the effective mass relative to the free electron mass. For a good metal ($n_e \sim 10^{28} \text{ m}^{-3}$), Eq.(2) gives $m_{\text{rel}}^* J(0) \geq 50 \text{ K}$; and for a bad metal or a doped semiconductor ($n_e \sim 10^{22} \text{ m}^{-3}$), $m_{\text{rel}}^* J(0) \geq 0.005 \text{ K}$. This is quite reasonable; therefore, vH model may reproduce the inverse crystallization of actual systems. Lastly, it is worth noting that the exponential decay of J can be also used above the tricritical point ($T/J = 1$; $J_0/J = 1$), as long as the latter remains below the Fermi temperature. This will hold if $J(0)/T_F < e^{\pi^2}$, which is satisfied in most reasonable cases. Similarly, taking into account the temperature dependence of the RKKY interaction may change our interpretation of other models.
