Abstract. We studied one of the most X-ray luminous cluster of galaxies in the REFLEX survey, RXC J1504.1-0248 (hereafter R1504; $z = 0.2153$), using *XMM-Newton* X-ray imaging spectroscopy, VLT/VIMOS optical spectroscopy and WFI optical imaging. The mass distributions were determined using the hydrostatic method with X-ray imaging spectroscopy and dynamical method with optical spectroscopy, respectively, which yield $M_{500}^{\text{H.E.}} = (5.81 \pm 0.49) \times 10^{14} M_{\odot}$ and $M_{500}^{\text{caustic}} = (4.17 \pm 0.42) \times 10^{14} M_{\odot}$. According to recent calibrations the richness derived mass estimates agree well with the hydrostatic and dynamical mass estimates. The line-of-sight velocities of spectroscopic members reveal a high-velocity ($>1000 \text{ km s}^{-1}$) group at a projected distance near $r_{500}^{\text{H.E.}} = (1.18 \pm 0.03) \text{ Mpc}$ south-east of the cluster centroid, which is also indicated in the X-ray two-dimensional (2-D) temperature, density, entropy and pressure maps. The dynamical mass estimate is 80% of the hydrostatic mass estimate at $r_{500}^{\text{H.E.}}$. It can be partially explained by the $\sim 20\%$ scatter in the 2-D pressure map that could be propagated in the hydrostatic mass estimate. The uncertainty of the dynamical mass estimate due to the substructure of the high-velocity group is $\sim 14\%$. The dynamical mass estimate using blue members is 1.23 times of that using red members. The observed scaling relations of R1504 agree with those for nearby clusters although its stellar mass fraction is rather low.

1. Introduction

Simulations show that the formation of galaxy clusters is not a purely gravitational process; the galaxy velocity dispersion in clusters exhibits evidence of heating compared to the cold dark matter velocity dispersion normalized to the *WMAP* and large-scale structure distributions (e.g. Evrard et al. 2008). Cluster mergers not only disturb the X-ray appearance of the hot intracluster medium (ICM; e.g. Ricker & Sarazin 2001; Poole et al. 2006; Zhang et al. 2009; Böhringer et al. 2010), but also affect the properties of the cluster galaxies (e.g. Sun et al. 2007). The ICM and galaxies react on different time scales during merging (e.g. Roettiger et al. 1999). Clusters with similar X-ray global properties can contain rather different galaxy populations (e.g. Popesso et al. 2007). There is a higher fraction of blue galaxies in rich galaxy clusters at $z \gtrsim 0.2$ compared to local clusters (Butcher & Oemler 1978, the so-called Butcher-Oemler effect). This effect may be due to episodes of star formation in a subset of cluster members driven by merging (e.g. Saintonge et al. 2008). The kinematic analysis thus complements the X-ray analysis to probe the dynamical structure of a cluster and its consequence on the mass measurement.

Recent comparisons between X-ray and weak lensing mass estimates suggest 10–20% deviations from hydrostatic equilibrium at r_{500} for relaxed clusters of galaxies and yield controversial findings for disturbed clusters based on different observations (e.g. Zhang et al. 2008, 2010; Mahdavi et al. 2008). The comparison between the X-ray hydrostatic and optical dynamical mass measurements complements the X-ray versus weak lensing mass comparison, and can thus cross check deviations from hydrostatic equilibrium. Lensing is prone to projection effects because it is sensitive to all mass along the line-of-sight. Line-of-sight velocities of cluster galaxies via the redshifts of cluster galaxies can probe substructures along the line-of-sight. Even for undisturbed clusters, the dynamically relaxed central regions are surrounded by infalling regions in which galaxies are bound to the clusters but are not in equilibrium (e.g. Biviano et al. 2006; Rines & Diaferio 2006). Optical spectroscopy can constrain the dynamical properties up to large radii (e.g. Braglia et al. 2007, Ziparo et al. 2012), where it is difficult to probe with current X-ray satellites. On the other hand, X-ray data can supply two-dimensional (2-D) cluster morphology projected on the sky. We will use the two probes together with the optical colour information to constrain substructures, and model causes of deviations from hydrostatic equilibrium.

RXC J1504.1-0248 (hereafter R1504; $z = 0.2153$), a prominent cool-core cluster, is one of the most relaxed clusters in the REFLEX galaxy cluster survey (Böhringer et al. 2001). Böhringer et al. (2005) investigated the central region of R1504 with *Chandra*, and found the core region of R1504 appears quite relaxed. With optical data from Integral Field Spectroscopy and X-ray data from *XMM-Newton*, Ogrea et al. (2010) found AGN feedback can slow down the cooling flow to the observed mass deposition rate in R1504 if the black hole accretion rate is of the order of $0.5M_{\odot} \text{ yr}^{-1}$ with 10% energy output efficiency. The *XMM-Newton* data in the R1504 field cover about 2 times radial range of the *Chandra* data, and the large effective area of *XMM-Newton* ensures high photon statistic for a 2-D spectral analysis. R1504 is also followed up by the ESO Visible Multi-Object Spectrograph at the 8.2 m UT3 of the Very Large Telescope (VLT/VIMOS) up to about $3r_{500}$. Optical imaging data exist from the ESO Wide-Field Imager (WFI) in three bands and Subaru in two bands.

We studied the radial and 2-D gas and galaxies properties of R1504 based on *XMM-Newton*, VLT/VIMOS and WFI data with the outline as follows. We describe the X-ray analysis and results in Sect. 2, and optical spectroscopic and imaging analyses and results in Sect. 3 and Sect. 4. We discuss systematic uncertainties and interpretations of the results in Sect. 5. In Sect. 6, we summarize our conclusions. Throughout the paper, we assume $\Omega_m = 0.3$, $\Omega_{\Lambda} = 0.7$ and $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$. Thus, $1'$ at the distance of R1504 corresponds to 209.8 kpc. Confidence intervals correspond to the 68% confidence level.

2. X-ray data analysis and results

2.1. *XMM-Newton* observations and data preparation

The *XMM-Newton* observations (ID: 0401040101) were taken in 2007 with thin filter in full frame (FF) for MOS and extended full frame (EFF) for pn, respectively. The fraction of out-of-time (OOT) effect amounts 2.32%, which we used to normalize the pn OOT product before subtracting it from the pn normal product.

We apply an iterative 3σ clipping procedure (e.g. Sect. 2.1 of Zhang et al. 2006) to filter flares using the light curves in both the soft band (0.3–10 keV) binned in 10 s intervals and the hard band (10–12 keV for MOS and 12–14 keV for pn) binned in 100 s intervals. There are 34.9 ks clean data for MOS1, 34.5 ks for MOS2 and 31.6 ks for pn left. We generated a list of the bright point sources with the *XMMSAS* task `edetect_chain` applied to five energy bands: 0.3–0.5 keV, 0.5–2 keV, 2–4.5 keV, 4.5–7.5 keV and 7.5–12 keV. All confirmed sources were subtracted from the event lists using a radius of $40''$, which is comparable to the *XMM-Newton* Point Spread Function (PSF) with a cutoff radius of $45''$ and encloses $\sim 90\%$ of the flux of the point sources. A weight column is created with the *SAS* `evweight` command and accounts for the vignetting correction for off-axis observations.

2.2. Temperature and surface brightness distributions

Following Sect. 2.3 of Zhang et al. (2010), we measured the X-ray flux-weighted centroid to be $RA=15^{\text{h}}04^{\text{m}}07^{\text{s}}.801$, $\delta=-02^{\circ}48'10''.29$ (J2000). We applied the double-background subtraction method developed for clusters at similar redshifts by Zhang et al. (2006, the so-called DBS II method therein). We chose the *XMM-Newton* blank sky accumulations in the *Chandra* Deep Field South (CDFS), which used the medium filter and are also in FF/EFF mode for MOS/pn as R1504, as background observations. The count rate in the hard band is used to normalize the CDFS observations before subtracting them from the target observations. The cluster X-ray emission is confined within $R < 6'$, so that we use the annulus region outside $R = 8'$ to probe the residual background and subtract it, taking into account the area correction for gaps and point sources. We chose the bin size of each annulus for the spectral extraction to be ≥ 0.5 and have about 4000 net counts in the 2–7 keV band. The former ensures a redistribution fraction of less than 20% of the flux due to the PSF, and the latter ensures no more than 20% errors in the temperature measurements. Fig. 1 shows the X-ray spectra extracted from the central $\leq 0.5'$ circle. The spectra were fitted with the *XSPEC* software by the combined `mekal*wabs` model, in which the former describes the ICM emission, and the latter describes the Galactic absorption with a Galactic hydrogen column density of n_{H} . We freeze the cluster redshift to 0.2153 and n_{H} to $6.08 \times 10^{20} \text{ cm}^{-2}$ given by the LAB survey (Hartmann & Burton 1997; Arnal et al. 2000; Bajaja et al. 2005; Kalberla et al. 2005) at the X-ray flux-weighted centroid.

The left panel of Fig. 2 shows that the radial temperature distribution follows the universal profile of relaxed clusters (e.g. Markevitch et al. 1998; Vikhlinin et al. 2006; Zhang et al. 2006; Pratt et al. 2007). The observed strong cool core is also shown in *Chandra* data by Böhringer et al. (2005). The amplitude of the temperature distribution is, however, 20% lower than that of the *Chandra* measurements. Snowden et al. (2008) found that temperature measurements with *Chandra* are over-estimated for those which are hotter than 5 keV due to a calibration problem, which was corrected only recently with *Chandra* CALDB v3.5.2. The temperature over-estimation with previous *Chandra* CALDB thus accounts for the amplitude difference between the temperature distributions measured with *Chandra* by Böhringer et al. (2005) and with *XMM-Newton* in this work. The right panel of Fig. 2 shows the surface brightness distribution. We carried out the PSF de-convolution and de-projection as detailed in Sect. 2.3 of Zhang et al. (2007), in which the *XMM-Newton* PSF matrices were created according to Ghizzardi (2001).

2.3. Mass distribution using the hydrostatic method

We assume that the ICM is in hydrostatic equilibrium within the gravitational potential dominated by dark matter, and that the matter distribution is spherically symmetric. The mass can

thus be calculated from the X-ray measured radial density and temperature distributions of the ICM by

$$\frac{1}{\mu m_p n_e(r)} \frac{d[n_e(r)kT(r)]}{dr} = -\frac{GM(\leq r)}{r^2}, \quad (1)$$

in which $\mu = 0.62$ is the mean molecular weight per hydrogen atom, and k is the Boltzmann constant. The mass estimate is computed from a set of input parameters, β , n_{e0i} and r_{ci} ($i = 1, 2$) representing the double- β electron number density profile, $n_e(r) = n_{e01}(1 + r^2 r_{c1}^{-2})^{-1.5\beta} + n_{e02}(1 + r^2 r_{c2}^{-2})^{-1.5\beta}$, and P_i ($i = 1, \dots, 7$) representing the de-projected temperature profile, $T(r) = P_3 \exp[-(r - P_1)^2 P_2^{-1}] + P_6(1 + r^2 P_4^{-2})^{-P_5} + P_7$. We propagated the uncertainties of the electron number density and temperature measurements using Monte Carlo simulations to compute the mass uncertainty. The cluster radius r_Δ (e.g. r_{500}) is defined as the radius within which the mass density is Δ (e.g. 500) times of the critical density at the cluster redshift, $\rho_c(z) = 3H_0^2(8\pi G)^{-1}E^2(z)$, in which $E^2(z) = \Omega_m(1+z)^3 + \Omega_\Lambda + (1 - \Omega_m - \Omega_\Lambda)(1+z)^2$.

The cumulative mass distribution using the hydrostatic method is shown in Fig. 3 as small boxes. The cluster radius is $r_{500}^{\text{H.E.}} = (1.18 \pm 0.03)\text{Mpc}$, and the total mass estimate is $M_{500}^{\text{H.E.}} = (5.81 \pm 0.49) \times 10^{14} M_\odot$ as listed in Table 1. The mass profile can be well fitted by an NFW model (Navarro et al. 1997) with a concentration parameter of $c_{500} = 2.93 \pm 0.14$.

2.4. 2-D spectrally measured maps

We adopted the adaptive binning-methods developed by Sanders (2006) and Cappellari & Copin (2003; also Diehl & Statler 2006), respectively, to define the masks for the 2-D analysis. We followed the steps in Sect. 5 of Zhang et al. (2009) except for two changes. (i) We adopt a threshold of signal-to-noise (S/N) ratio of 30 instead of 45 to ensure an adequate number of bins in the mask. (ii) We use the double-background subtraction strategy (i.e. DBS II) since there is sufficient outer area within the *XMM-Newton* field of view (FoV) to model the residual background.

The X-ray spectrally measured 2-D maps using the Sanders (2006) mask are shown in Fig. 4. Those using the Cappellari & Copin (2003) mask appear in Fig. A.1. At a projected distance of $\sim r_{500}^{\text{H.E.}}$ south-east of the centroid, the surface brightness shows a clump with its value 2.25 times the azimuthal average, $(2.4 \pm 0.4) \times 10^{-3}$ counts s^{-1} arcmin^{-2} , at the same projected distance. This enables us to carry out the 2-D spectral analysis toward larger radii in the south-east direction than the other directions. In the temperature map, we also observe a hot stripe at $\sim 0.3r_{500}^{\text{H.E.}}$ west of the centroid.

We followed Zhang et al. (2009) to calculate the scatter of the fluctuations in the 2-D maps to diagnose the ICM substructure. In Fig. 5, the temperature, electron number density, entropy and pressure distributions in the 2-D maps are shown as a function of projected distance from the X-ray flux-weighted centroid. Their non-parametric locally weighted regression (e.g. Becker et al. 1988) was used as the mean profile. The differential scatter and error were calculated from the area weighted absolute fluctuations with all bins at that projected distance. The temperature, electron number density, entropy

and pressure maps show less than $\sim 15\%$, 30% , 20% and 25% scatter, respectively. The scatter of the temperature measurements increases with radius, and is $\sim 12\%$ at the radii beyond $0.3r_{500}^{\text{H.E.}}$. On the contrary, the electron number density appears more relaxed at large radii. This may indicate different relaxation time scales of the ICM temperature and electron number density.

The 2-D maps using the Cappellari & Copin (2003) mask demonstrate a mild elongation along the east-west major axis on the scale of $\sim r_{500}^{\text{H.E.}}$.

3. Optical spectroscopic data analysis and results

3.1. VLT/VIMOS observations and data preparation

Multi-object spectroscopy in the R1504 field was performed with the VLT/VIMOS spectrograph using the low-resolution blue grism (LR-Blue) with the OS-blue filter, which samples the $[3700\text{--}6700]\text{\AA}$ wavelength range with $\lambda/\Delta\lambda = 180$ (PID: 077.A-0058). The observations were carried out in service mode which include bias, dark and flat calibration sequence with the latter using the same set-up as the observations.

R1504 was observed with air masses between 1.124 and 1.172. The seeing is less than $1''.5$ for two pointed observations and $> 2''$ for one pointed observation. Individual targets for the spectroscopic follow-up were selected based on *I*-band magnitudes of the pre-imaging data. In total 784 slits were placed in the 12 masks spread over three pointed observations.

Data were reduced with the VIPGI pipeline (Scoddeggio et al. 2005). Redshifts were computed by comparing the observed spectra to galaxy and stellar templates with the EZ software (Garilli et al. 2010) and improved with customized tools from Verdugo et al. (2008) by fitting a Gaussian profile to each observed strong spectral feature. Not all lines, namely [O II] $\lambda\lambda 3726, 3729\text{\AA}$, [Ca II K] $\lambda 3934\text{\AA}$, [Ca II H] $\lambda 3968\text{\AA}$, H δ $\lambda 4102\text{\AA}$, H β $\lambda 4861\text{\AA}$, G-band ($\sim 4304\text{\AA}$), [O III] $\lambda\lambda 4959, 5007\text{\AA}$, Mg 1b ($\sim 5050 - 5430\text{\AA}$) and [Fe VI] $\lambda 5335\text{\AA}$, are present in each spectrum. The redshift determined from each spectrum is the mean of the individual shifts for all visible line features. The error is the standard deviation of these shifts, which takes into account systematic errors in the wavelength calibration and differences in the S/N. The average error in the individual redshift estimates is $\Delta z = 0.00076$.

The R1504 field overlaps with the stellar stream of the Globular cluster Palomar-5 (e.g. Odenkirchen et al. 2001). There are thus a large number of white- and red-dwarf stars contaminating the spectroscopic sample. Interlopers were cleaned up with the member selection procedure in Sect. 3.2.

3.2. Spectroscopic member selection

In hierarchical structure formation scenarios, the spherical infalling model predicts a trumpet-shaped region in the diagram of line-of-sight velocity versus projected distance, the so-called caustic (e.g. Kaiser 1987). The boundary defines galaxies inside the caustic as cluster members and those outside of the caustic as fore- and background galaxies.

Several methods can select cluster members according to their line-of-sight velocities. A constant gap or gaps weighted by projected distances can separate member galaxies from foreground and background galaxies (e.g. Beers et al. 1990; Girardi et al. 1993; den Hartog & Katgert 1996; Katgert et al. 1996, 2004; Popesso et al. 2005a; Biviano et al. 2006). Alternatively, an adaptive kernel method, sensitive to the presence of peaks, has been widely used to select members (e.g. Pisani 1993, 1996; Fadda et al. 1996; Diaferio & Geller 1997; Diaferio 1999; Geller et al. 1999; Rines & Diaferio 2006).

We modified the adaptive kernel method of Diaferio (1999) for medium distance clusters (e.g. Harrison & Noonan 1979; Danese et al. 1980), and used it to identify the interlopers as follows. Galaxies with redshifts $|cz - cz_{cl}| \leq 4000 \text{ km s}^{-1}$ were preliminarily selected and located in the (r, v) diagram, where r is the galaxy transverse separation from the cluster centroid, and v is the line-of-sight velocity of the galaxy relative to the cluster. At the redshift of R1504, we modify the calculation of (r, v) to $r = D_a \sin \theta$ and $v = (cz - cz_{cl} \cos \theta)/(1 + z_{cl})$. Here D_a , θ , z and z_{cl} are the angular diameter distance of the cluster, angular separation of the galaxy from the cluster centroid, galaxy redshift and cluster redshift. The angular diameter distance is defined as $D_a = cH_0^{-1}(1 + z_{cl})^{-1} \int_0^{z_{cl}} E^{-1}(z) dz$. We scaled r and v to ensure approximately equal weights in v and r , and computed the 2-D adaptive density distribution $f(r, v)$. The boundary of the caustic is defined by $f(r, v) = \kappa$, in which κ is determined by minimizing $|\langle v_{esc}^2 \rangle_{\kappa, R} - 4\langle v^2 \rangle_R|^2$. Here $\langle v_{esc}^2 \rangle_{\kappa, R} = \int_0^R \mathcal{A}^2(r) \varphi(r) dr / \int_0^R \varphi(r) dr$ is the escape velocity, R and $\langle v^2 \rangle_R$ are the mean projected distance and velocity dispersion of the members, and $\varphi(r) = \int f(r, v) dv$. $\mathcal{A}(r) = \min\{|v_u|, |v_d|\}$ takes the minimum of the upper and lower solutions of $f(r, v) = \kappa$.

Fig. 7 shows the histogram of the line-of-sight velocity and the diagram of line-of-sight velocity versus projected distance of galaxies. The 53 galaxies inside the caustic boundary are considered as members. Our further dynamics analysis is based on those 53 spectroscopic member galaxies.

3.3. Mass distribution using the caustic method

We applied the bi-weight estimator developed by Beers et al. (1990) to measure the redshift and velocity dispersion, in which the errors are estimated through 1000 bootstrap simulations. The cluster redshift is given by the biweight estimator of location of the recessional velocities, cz_i . The velocities in the cluster reference frame are derived from the recessional velocities by $v_{rest, i} = (cz_i - cz_{cl})(1 + z_{cl})^{-1}$. The velocity dispersion is given by the biweight estimator of scale of those $v_{rest, i}$. With all 53 spectroscopic members, the measured redshift is (0.2165 ± 0.0005) , and the velocity dispersion is $(1132 \pm 94) \text{ km s}^{-1}$.

The escape velocities of galaxies extracted from the amplitude of the caustic scale with the gravitational potential of the dark matter halo (e.g. Diaferio & Geller 1997; Diaferio 1999; Rines & Diaferio 2006)

$$GM(\leq r) = \frac{1}{2} \int_0^r \mathcal{A}^2(x) dx. \quad (2)$$

The error of the cumulative mass estimate within r_i is defined as $\delta M_i = \sum_{j=1}^i |2m_j \delta \mathcal{A}(r_j) / \mathcal{A}(r_j)|$, in which m_j is the mass estimate in the j^{th} shell, $\delta \mathcal{A}(r) / \mathcal{A}(r) = \kappa / \max\{f(r, v)\}$, and $\max\{f(r, v)\}$ takes the maximum of $f(r, v)$ at fixed r . Since the caustic of a spherical system is symmetric, the minimum of the upper and lower caustics is taken as the caustic amplitude at each radius, which better excludes interlopers than taking the average of the upper and lower caustics as the caustic amplitude. The caustic method does not assume dynamical equilibrium, and is thus robust to measure cluster masses at large radii. The mass distribution using the caustic method is shown in Fig. 3, and it gives $r_{500}^{\text{caustic}} = (1.06 \pm 0.04) \text{ Mpc}$ (Table 1).

3.4. 2-D kinematic structure

As clusters of galaxies formed at moderate look-back times, they often contain substructures caused by accretion of and merging with smaller systems. Quantification of substructures is thus important to assess the reliability of different mass measurements and infer the dynamical history of the cluster. It is, however, difficult to quantify substructures at large radii with *XMM-Newton* data because of the high background level compared to the faint X-ray emission near $r_{500}^{\text{H.E.}}$. Optical spectroscopic data provide a promising alternative to quantify substructures at all radii.

Dressler & Shectman (1988, DS hereafter) developed a statistical method for detecting substructures in galaxy clusters with deviations in the spatial and/or velocity structure, which we summarize as follows. The deviation of the local velocity mean and dispersion from the global mean and dispersion of the cluster is defined as

$$\rho_{\text{DS}} = \sqrt{\frac{N_{\text{local}} + 1}{\sigma^2} [(\bar{v}_{\text{local}} - \bar{v})^2 + (\sigma_{\text{local}} - \sigma)^2]}. \quad (3)$$

The local line-of-sight velocity and dispersion, \bar{v}_{local} and σ_{local} , are measured with its $N_{\text{local}} = 10$ nearest neighbours in projection. The global line-of-sight velocity and dispersion, $\bar{v} = 64950 \text{ km s}^{-1}$ and $\sigma = 1132 \text{ km s}^{-1}$, are given in Sect. 3.3 as measured with all (i.e. $N_{\text{all}} = 53$ for R1504) spectroscopic cluster members. A cumulative deviation $\Delta_{\text{DS}} = \sum_{i=1}^{N_{\text{all}}} \rho_{\text{DS}, i}$ is of the order of N_{all} when the line-of-sight velocity obeys a Gaussian distribution and local variations are only random fluctuations, and differs from N_{all} when the line-of-sight velocity distribution deviates from Gaussian. Therefore, the Δ_{DS} statistic is sensitive to presence of substructures. A higher Δ_{DS} value indicates a higher possibility of having substructures.

In Fig. 4, we display the 53 spectroscopic galaxies by circles with their radii proportional to $\exp[\rho_{\text{DS}}^2]$. The blue, red and green colours denote three galaxy populations with their cluster centric velocities (i) toward the observer greater than 1000 km s^{-1} , (ii) away from the observer greater than 1000 km s^{-1} and (iii) smaller than 1000 km s^{-1} . The DS test yields $\Delta_{\text{DS}, \text{obs}} = 86.8$, and reveals a clustering of galaxies with large ρ_{DS} values at a projected distance of $\sim r_{500}^{\text{H.E.}}$ south-east of the cluster centroid. This may indicate the presence of a relatively high-velocity ($> 1000 \text{ km s}^{-1}$) group associated to the main cluster.

To estimate the robustness of the Δ_{DS} statistic, we carried out $n_{\text{MC}} = 10,000$ Monte Carlo simulations by randomly shuffling the line-of-sight velocities to member galaxies. This procedure erases any true correlations between line-of-sight velocities and positions. The probability of having substructures can be estimated by $P_{\text{DS}} = \sum_{j=1}^{n_{\text{MC}}} \delta_j / n_{\text{MC}}$, in which $\delta_j = \Delta_{\text{DS},j}$ when $\Delta_{\text{DS},j} > \Delta_{\text{DS,obs}}$ and $\delta_j = 0$ otherwise (e.g. Hou et al. 2012). The Monte Carlo realization of the Δ_{DS} statistic gives a probability of 6% for *not* having substructures. This indicates a non-negligible possibility of having this high-velocity group. The histogram of the line-of-sight velocities of possible member galaxies of the high-velocity group is shown as (red) dashed lines in the left panel of Fig. 7.

4. Optical imaging data analysis and results

4.1. WFI observations and data preparation

R1504 was observed with the ESO/MPG 2.2 m telescope with the WFI (Baade et al. 1999) in the $B/123$ -, $V/89$ - and $R_c/162$ -bands (hereafter B -, V - and R -bands) during three runs in June 2009, 2010 and 2011 mostly under non-photometric conditions. The WFI has a 4×2 mosaic detector of $2k \times 4k$ CCDs, which has a pixel size of $0''.238$ and a FoV of $34' \times 33'$. We reduced the data and co-added the single exposures using the THELI pipeline (Erben et al. 2005). The co-added B -, V - and R -band images have total exposure times of 9238 s, 8317 s and 11035 s with $1''.27$, $1''.21$ and $0''.96$ seeing. Fig. 8 shows the WFI B -band image.

As the observing conditions of the imaging vary, photometric calibration of the WFI R -band was tied to the shallower SDSS r -band data in the same field. The B - and V -band images were calibrated against the R -band by fitting the observed main sequence of stars with that of a photometrically calibrated field. Cross-checks were applied by comparing predicted versus observed colours for galaxies with spectroscopic redshifts using procedures typical of photometric redshift codes. The absolute calibration of the photometric zero point is better than 0.1 magnitude. The internal colour calibration is better than 0.04 magnitude.

Photometry was carried out with SExtractor (Bertin & Arnouts 1996) in dual mode with the R -band image set as the detection frame. Galaxy colours were measured in an aperture of $2''.5$ diameter.

4.2. Photometric member selection

The broad B - and R -bands can probe the spectral range across the 4000 \AA break for galaxy clusters at $z \sim 0.2 - 0.3$, which characterizes the bulk of stellar populations. Early-type galaxies display red colours and reside in a narrow band, the so-called red sequence (e.g. Baum 1959), in the colour–magnitude diagram. The $B - R$ colour versus R -band magnitude is shown in the left panel of Fig. 9 for all galaxies within $r_{500}^{\text{H.E.}}$, in which we highlight the 29 blue and 24 red spectroscopic members regardless of their cluster centric distances.

We fit the red sequence with a robust bi-weight linear-fitting algorithm, which resists skewness (e.g. Beers et al. 1990,

Gladders et al. 1998). The best fit is $B - R = -0.097R + 3.88$ with a scatter of $\sigma = 0.083$ magnitude (Table 1).

We define red members as those galaxies within 3σ of the best-fit red sequence. Galaxies, which are more than 3σ bluer than the red sequence, are considered as blue galaxies. Galaxies that are more than 3σ redder than the red sequence are discarded because they are most likely background galaxies. We also discard galaxies bluer than 1.5 magnitude of the red sequence to reduce foreground contamination. These limits are marked in Fig. 9.

The comparison between the galaxy number counts in the R1504 field and in the Garching-Bonn Deep Survey (GaBoDS, Erben et al. 2005; Hildebrandt et al. 2006) fields shows that our photometric sample is 100% complete down to $R = 22$ magnitude. This limit corresponds to $M_R \approx -18$ magnitude for galaxies of different colours at $z_{\text{cl}} = 0.2153$ shown as an oblique curve in Fig. 9. The CLASS_STAR parameter provided by SExtractor is completely reliable down to $R = 21.5$ magnitude and 90% reliable down to $R = 22$ magnitude. We thus limit the analysis to the galaxies brighter than $R = 22$ magnitude. The limiting magnitude is $R = 24.44$ magnitude at 5σ , calculated in an aperture of $1''$ diameter. The stellar contamination should be quite low in the photometric sample because of the high quality of the WFI imaging.

4.3. Galaxy luminosity function and stellar mass

To obtain photometric properties of the cluster population, we corrected for contaminations of the fore- and background galaxies along the line-of-sight by a statistical subtraction using a subset (2.25 deg^2) of the GaBoDS, which were completed in all bands. We applied the same magnitude and colour cuts to the GaBoDS fields as to the R1504 field, and constructed the galaxy number counts as a function of magnitude for red and blue galaxies, respectively. The galaxy number counts in the GaBoDS fields were normalized to the R1504 sky area and subtracted from the corresponding galaxy number counts in the R1504 field. The size of the magnitude bin used to construct the galaxy number counts is chosen to be large enough to ensure positive counts in all magnitude bins after subtracting the background. Errors are a combination of Poisson statistical error and cosmic variance. The latter is the standard dispersion of the galaxy number counts across the GaBoDS fields. The Poisson statistical error dominates the error budget at inner radii because there are relatively fewer objects, whereas cosmic variance dominates at large radii.

The right panel of Fig. 9 shows the R -band galaxy luminosity functions for red (red), blue (blue) and all (black) members within $r_{500}^{\text{H.E.}}$. We derived the best-fit Schechter (1976) functions for red and all members, respectively, with a χ^2 minimization algorithm. The red members show a shallower slope at the faint end than that of all members. As listed in Table 1, both the characteristic R -band magnitude, R^* , and the slope at the faint end, α , are in agreement with that of nearby clusters (e.g. Christlein & Zabludoff 2003; Popesso et al. 2005b; Durret et al. 2011). No fit was possible for blue galaxies.

The bright central galaxy (BCG) is very blue ($B - R = 0.98$) and bright ($R = 16$ magnitude). Since the BCG is normally not described by the Schechter function, we explicitly removed the BCG from the photometric sample in the above calculation of the galaxy luminosity function. The total R -band luminosity of the cluster is computed by explicitly adding the BCG luminosity to the integration of the galaxy luminosity function. We tested how the BCG colour affects the measured optical luminosity by adding the BCG luminosity to the red and blue populations, respectively. The resulting uncertainty in the R -band luminosity is within 3%. The measured R -band optical luminosity within $r_{500}^{\text{H.E.}}$ is listed in Table 1.

We adopted the stellar mass-to-optical light ratio from Table 7 of Bell et al. (2003), $\log(M_*/L_R) = a + b(B - R)$, in which $a = -0.523$, $b = 0.683$, $B - R$ is the rest-frame colour, and a “diet” Salpeter (1955) stellar Initial Mass Function (Bell & de Jong 2001) is adopted. We show the cumulative stellar mass profiles for red and blue galaxies, respectively, in Fig. 3. The stellar mass estimates for blue, red and all photometric members within $r_{500}^{\text{H.E.}}$ are given in Table 1. R1504 has a rather low stellar mass fraction among nearby clusters (e.g. Biviano & Salucci 2006) although there is an agreement given the large scatter for nearby clusters (e.g. Andreon 2010; Zhang et al. 2011b). The contribution to the total stellar mass budget associated with intra-cluster light (e.g. Zibetti et al. 2005) could reach 10–20% level at the mass scale of galaxy groups (e.g. Gonzalez et al. 2007). The difference in the R -band luminosity caused by adding the BCG luminosity to the blue and red populations, respectively, is within 3% for R1504. Therefore, both the intra-cluster light and BCG play non-dominant roles to explain the low stellar mass fraction.

4.4. Blue galaxy fraction

Understanding rapid galaxy-morphology transformation is essential to model the mass assembly history of galaxy clusters. Red galaxies with low levels of ongoing star formation are considered as the descendants of blue star-forming galaxies that have been accreted from the surrounding filamentary structure and quenched by specific processes (e.g. Braglia et al. 2007; Verdugo et al. 2011). How spirals were transformed into ellipticals remains open (e.g. Poggianti & Wu 2000). The efficiency of different transformation processes varies with environment. Ram pressure stripping, for instance, is more effective in the cluster core where there is dense ICM (e.g. Fujita & Nagashima 1999). Galaxy-galaxy merging, on the other hand, is more effective in infalling groups at the cluster outskirts (e.g. Kauffmann et al. 1999).

In the left panel of Fig. 10, we present the number density profiles of the red and all member galaxies, respectively, as a function of projected distance from the X-ray flux-weighted centroid. Similar to the findings for other clusters (e.g. Lin et al. 2004), the red population in R1504 is well fitted by a projected NFW profile (Navarro, Frenk & White 1997; Bartelmann 1996), in which the reduced χ^2 is 1.03. The fit by a projected NFW profile to all members is relatively poor with $\chi^2 = 2.24$. The right panel of Fig. 10 displays the blue galaxy fraction.

Within a projected distance of 700 kpc, where the ICM is dense, the galaxy population is dominated by red galaxies with a fraction larger than 70%. Beyond 700 kpc, the blue galaxy fraction first increases rapidly, reaching 60% at $\sim r_{500}^{\text{H.E.}}$, and then stays almost constant in the outskirts.

The large error bars of the blue galaxy fraction at large radii take into account the uncertainty in the background. The colours of the field galaxies have their own variation. One cannot exclude that the high blue galaxy fraction is coincidentally due to an increasing field-galaxy contamination. A reliable measure of the blue galaxy fraction free of background contamination requires extensive spectroscopy. Nevertheless, the high blue galaxy fraction beyond $r_{500}^{\text{H.E.}}$ may indicate a critical distance where specific processes in clusters like ram-pressure stripping (e.g. Quilis et al. 2000) or starvation (e.g. Balogh et al. 2000) start to affect the properties of infalling galaxies. This distance may, however, depend on the environment (e.g. Urquhart et al. 2010). Urquhart et al. (2010, Figure 10 therein) pointed out an excess of extremely blue galaxies in massive groups, in which active star-burst galaxies are driven by galaxy-galaxy interactions in the group environment. The radial blue galaxy fraction and presence of the high-velocity group in R1504 support this interpretation.

4.5. Richness derived mass estimates

There are a number of approaches to calculate the cluster total mass based on photometric measurements (e.g. Hansen et al. 2005, 2009; Johnston et al. 2007; Reyes et al. 2008).

Iteratively we can estimate the mass from the richness distribution according to existing scaling calibrations between richness and mass estimates at a fixed overdensity. The cluster total mass is measured within the radius where the mass density is 200 times the critical density in Johnston et al. (2007) and Hansen et al. (2009), but 200 times the mean density of the Universe in Hansen et al. (2005) and Reyes et al. (2008). To be consistent with the mass definition, we use the calibrations between richness and weak lensing mass measurements in Johnston et al. (2007), eq. (26), and Hansen et al. (2009), eq. (10), respectively, to calculate the richness derived mass estimates. In their calibrations, the richness is measured down to $0.4L^*$ in the SDSS i -band, equivalent to $(i^* + 1)$ magnitude. Since there are no i -band data for R1504, we use the R -band derived richness down to $(R^* + 1)$ to approximate their i -band derived richness down to $(i^* + 1)$. Nevertheless, the characteristic magnitude can be taken as a characteristic scale for galaxy formation at a similar cosmic epoch that those galaxies brighter than $(i^* + 1)$ overlap significantly with those brighter than $(R^* + 1)$. The richness derived mass estimates (see Table 1) agree well with the hydrostatic and dynamical mass measurements.

5. Discussion

5.1. Uncertainties in the dynamical mass estimates

To quantify the uncertainties in the dynamical mass estimate due to substructures and infalling blue galaxies, we need a

method to derive the dynamical mass estimate based on a small number of member galaxies. A different method from the caustic one, which was detailed in Sect. 3 of Biviano et al. (2006) based on a sample of simulated clusters, serves this purpose, and is summarized as follows.

We measured the velocity dispersion ($\sigma_{a,p}$ in Biviano et al. 2006) with a number of member galaxies defined according to Sect. 5.1.1 and Sect. 5.1.2, respectively. An initial estimate of the mass was derived through eq. (2) in Biviano et al. (2006), $M_v \equiv A[\sigma_v/(10^3 \text{ km s}^{-1})]^3 \times 10^{14} h^{-1} E^{-1}(z) M_\odot$ with $A = 1.50 \pm 0.02$ under the assumption of $\sigma_v = \sqrt{3}\sigma_{a,p}$. An estimate of the corresponding cluster radius, \tilde{r}_v , is derived through steps 7 and 9 in Biviano et al. (2006). Replacing the true quantities r_v and σ_a with their estimates \tilde{r}_v and $\sqrt{3}\sigma_{a,p}$ in Fig. 4 in Biviano et al. (2006), we obtained an improved estimate of σ_v . The final cluster mass estimate (M^{B06} hereafter) was calculated with eq. (2) in Biviano et al. (2006) with the improved estimate of σ_v . The mass error is derived by combining in quadrature the error in the velocity dispersion converted to mass, additional velocity dispersion error introduced by the uncertainty in Fig. 4 in Biviano et al. (2006), and the 10% mass systematic according to the Biviano et al. (2006) sample. We computed M_{500}^{B06} from M_{200}^{B06} with the NFW model, in which the concentration parameter is given in step 7 in Biviano et al. (2006), $c^{\text{B06}} = 4[\sigma_{a,p}/(700 \text{ km s}^{-1})]^{-0.306}$.

5.1.1. Uncertainty due to substructures

The high-velocity group, which is revealed by the DS test, overlaps with the substructure in the 2-D X-ray maps. In the high-resolution weak lensing shear map by Klein et al. (in prep.) based on Subaru observations, there is a main lensing peak at the BCG position additional to a secondary peak near the high-velocity group. The elongation of the surface mass density follows the elongation shown in the X-ray 2-D maps.

The dynamical mass measurement over-estimates the total mass of a cluster with substructures (e.g. Biviano et al. 2006). We quantified the uncertainty in the dynamical mass estimate due to the high-velocity group as follows. The velocity dispersion is $(1132 \pm 94) \text{ km s}^{-1}$ based on all 53 spectroscopic members. Excluding the five galaxies belonging to the high-velocity group, which are shown as big red circles at $\sim r_{500}^{\text{H.E.}}$ south-east of the cluster centroid in Fig. 4, the velocity dispersion is reduced to $(1079 \pm 97) \text{ km s}^{-1}$. As shown in Table 1 and Fig. 3, the total mass estimate is $M_{500,53m}^{\text{B06}} = (6.355 \pm 1.711) \times 10^{14} M_\odot$ based on the 53 members and $M_{500,48m}^{\text{B06}} = (5.452 \pm 1.573) \times 10^{14} M_\odot$ based on the 48 members excluding the high-velocity group, following the Biviano et al. (2006) method. The mass uncertainty caused by the substructure of the high-velocity group is $\sim 14\%$. Excluding the high-velocity group improves the agreement between the X-ray hydrostatic and dynamical mass estimates. This highlights the importance of a proper analysis of the structures of evolving systems like cluster of galaxies in order to obtain robust mass measurements.

5.1.2. Mass discrepancy using red and blue galaxies

For a cluster in dynamical equilibrium, both blue and red galaxy populations behave similarly in the diagram of line-of-sight velocity versus projected distance, which reflects the same underlying mass distribution. For a cluster with a rich infalling population, the blue population tends to over-estimate the total mass since the infalling members bias the velocity dispersion toward high values (e.g. Carlberg et al. 1997). 55% of the spectroscopic member galaxies are blue galaxies. To quantify the uncertainty of the dynamical mass estimate due to infalling blue galaxies, we derived the velocity dispersion and dynamical mass estimates for blue members and red members separately. The blue population has a velocity dispersion of $(1170 \pm 125) \text{ km s}^{-1}$, which yields a cluster mass estimate of $M_{500,\text{blue}}^{\text{B06}} = (7.057 \pm 2.373) \times 10^{14} M_\odot$ according to Biviano et al. (2006). The red population has a velocity dispersion of $(1096 \pm 156) \text{ km s}^{-1}$, which yields a cluster mass estimate of $M_{500,\text{red}}^{\text{B06}} = (5.722 \pm 2.517) \times 10^{14} M_\odot$. The dynamical mass estimate derived from red members, $M_{500,\text{red}}^{\text{B06}}$, is in better agreement with the hydrostatic mass estimate than that using all members. The cluster mass estimate based on the blue population, $M_{500,\text{blue}}^{\text{B06}}$, is 1.23 times the mass estimate based on the red population (Table 1 and Fig. 3). It indicates that R1504 may not have a rich infalling population, which is also supported by the caustic comparison between R1504 and the simulated clusters (e.g. Figure 6 of Gill et al. 2005).

5.2. Hydrostatic versus dynamical versus photometric mass estimates

We derived the mass distribution using the hydrostatic method based on X-ray imaging spectroscopy and the dynamical method based on optical spectroscopy, independently (Fig. 3). At $r_{500}^{\text{H.E.}}$, the mass estimate from the caustic method is $(4.66 \pm 0.47) \times 10^{14} M_\odot$, which is 80% of the X-ray hydrostatic mass estimate (Table 1). The discrepancy between the hydrostatic and dynamical mass estimates is comparable to the mass discrepancy using red and blue galaxies. In addition, the 2-D pressure map shows $\sim 20\%$ scatter which can be propagated in the hydrostatic mass estimate. Despite the mass uncertainties, the X-ray hydrostatic mass estimate is slightly higher than the dynamical one at $r_{500}^{\text{H.E.}}$ because the mass profile of the latter appears more concentrated than the former.

As shown in Table 1 the richness derived mass estimates according to recent calibrations (e.g. Johnston et al. 2007; Hansen et al. 2009) agree well with the hydrostatic and dynamical mass estimates.

It is also important to compare the mass measurements at fixed overdensities (e.g. 500 and 200) as these masses are used in cosmological applications. At the overdensity of 500, the mass estimate from the caustic method is 72% of the hydrostatic mass estimate. This is due to the less concentrated mass distribution using the hydrostatic method than that determined from the dynamical method, which can be caused by the disturbed ICM in the cluster core because of AGN feedback as discussed in Sect. 5.4. At the overdensity of 200, the richness derived mass estimates according to Hansen et al. (2009) and

Johnston et al. (2007) are about 0.8–1.2 times the hydrostatic mass estimate and 1.0–1.4 times the dynamical mass estimate.

5.3. Agreement with the scaling relations

The X-ray properties of R1504 are tabulated in Table 1. The global temperature and metallicity are measured with the *XMM-Newton* spectra extracted from the $(0.2 - 0.5)r_{500}^{\text{H.E.}}$ annulus. The X-ray luminosity was derived by integrating the surface brightness up to $r_{500}^{\text{H.E.}}$. We show the X-ray luminosity of the 0.1–2.4 keV band and 0.01–100 keV (bol hereafter) band in rest frame, respectively, including the cool core (incc hereafter) and correcting the cool core (cocc hereafter), respectively. The X-ray luminosity corrected for the cool core is computed by assuming a constant value of the surface brightness distribution in the cluster core, $S_X^{\text{cocc}}(R < 0.2r_{500}^{\text{H.E.}}) = S_X(0.2r_{500}^{\text{H.E.}})$ for the reason detailed in e.g. Zhang et al. (2007, 2008).

The global properties of R1504 obey the scaling relations of nearby clusters. R1504, for instance, matches well the $M - Y_X$, $M - M_{\text{gas}}$, $M - T$ and $M - L^{\text{cocc}}$ relations provided by e.g. Arnaud et al. (2005, 2007), Vikhlinin et al. (2006) and Zhang et al. (2008). This supports that the ICM in R1504 is quite relaxed within $r_{500}^{\text{H.E.}}$. Whether the high-velocity substructure is excluded or not, R1504 is well within the 26% scatter of the $L^{\text{cocc}} - \sigma$ relation for the clusters at similar redshifts by Zhang et al. (2011a). According to the dynamical mass estimate M_{200}^{caustic} and the richness within r_{200}^{caustic} , R1504 agrees with the mass versus richness scaling relations of Johnston et al. (2007) and Hansen et al. (2009) who used weak lensing masses instead.

5.4. Cluster core

Strong cool-core systems usually show peaked iron abundance in the cluster cores. However, R1504 displays a relatively flat radial distribution of iron abundance ranging within [0.2, 0.3] times solar abundance (Fig. 6). Guo & Mathews (2010) pointed out in simulations that AGN outbursts efficiently mix metals in the cluster core and may even remove the central abundance peak if it was not broad enough.

R1504 is one of the nine known clusters hosting radio mini-halos. The presence of mini-halos supports the above interpretation of mixing metals in the cluster core. The BCG is blue with a $B - R$ colour of 0.98, and has strong emission lines. The BCG sky position, RA=15^h04^m07^s.573, δ =−02°48′14″.26 (J2000), is 4″ (14 kpc) off from the X-ray flux-weighted centroid, which is within the *XMM-Newton* spacial resolution with a 6″ full width half maximum. The BCG harbours a radio source with a brightness of 62 mJy at 1.4 GHz (Bauer et al. 2000). Giacintucci et al. (2011) reveal gas sloshing in the cluster core, where turbulence may generate particle acceleration to form mini-halos. The gas sloshing in the cluster core may partially account for the slightly less concentrated mass distribution using the X-ray hydrostatic method than that determined from the caustic method (Fig. 3).

6. Conclusions

To summarize, we studied one of the most X-ray luminous clusters of galaxies in the REFLEX survey, R1504, using *XMM-Newton* imaging spectroscopy, VLT/VIMOS spectroscopy and WFI photometry.

The mass distribution determined using the hydrostatic method based on X-ray imaging spectroscopy agrees with that using the caustic method based on optical spectroscopy within 1σ uncertainties at most radii although the former appears less concentrated than the latter. The mass estimate using the caustic method is 80% of the hydrostatic mass estimate at the X-ray mass determined radius $r_{500}^{\text{H.E.}}$.

At the overdensity of 500, the dynamical mass estimate is 72% of the hydrostatic mass estimate. At the overdensity of 200, the richness derived mass estimates according to more recent calibrations of the mass–richness relation (e.g. Johnston et al. 2007; Hansen et al. 2009) are about 0.8–1.2 times the hydrostatic mass measurement and 1.0–1.4 times the dynamical mass measurement.

With the line-of-sight velocities of spectroscopic members, the DS test reveals a relatively high-velocity ($>1000 \text{ km s}^{-1}$) group at a projected distance of $\sim r_{500}^{\text{H.E.}}$ south-east of the cluster centroid. The high-velocity group is also indicated in the 2-D X-ray maps and weak lensing shear map. The dynamical mass estimate is reduced by 14% when the substructure of the high-velocity group is excluded. This highlights the importance of a proper analysis of the structures of evolving systems like cluster of galaxies in order to obtain precise mass measurements.

R1504 has a rather low stellar mass fraction among nearby clusters (e.g. Biviano & Salucci 2006) although there is an agreement given the large scatter for nearby clusters (e.g. Andreon 2010; Zhang et al. 2011b). Both the intra-cluster light and BCG play non-dominant roles to explain the low stellar mass fraction.

Within a projected distance of 700 kpc, the galaxy population is dominated by red galaxies ($>70\%$) based on photometric data. Beyond 700 kpc, there is a rapid increase in the fraction of blue galaxies. The blue galaxy fraction reaches about 60% at $r_{500}^{\text{H.E.}}$ and stays almost constant beyond. The dynamical mass measurement calculated using blue spectroscopic members is 1.23 times the value derived using red spectroscopic galaxies.

Despite the high-velocity group in the cluster outskirts and the gas sloshing in the cluster core, R1504 appears relatively relaxed up to $r_{500}^{\text{H.E.}}$. R1504 obeys the observed scaling relations found for similar nearby clusters.

Table 1. Basic properties of R1504.

| | |
|--|---|
| X-ray properties | |
| $r_{500}^{\text{H.E.}}$ | (1.18 ± 0.03) Mpc |
| $M_{500}^{\text{H.E.}}$ | $(5.81 \pm 0.49) \times 10^{14} M_{\odot}$ |
| $r_{200}^{\text{H.E.}}$ | (1.76 ± 0.05) Mpc |
| $M_{200}^{\text{H.E.}}$ | $(7.65 \pm 0.65) \times 10^{14} M_{\odot}$ |
| c_{500} | 2.93 ± 0.14 |
| $M_{\text{gas},500}(\leq r_{500}^{\text{H.E.}})$ | $(0.907 \pm 0.051) \times 10^{14} M_{\odot}$ |
| $f_{\text{gas},500}(\leq r_{500}^{\text{H.E.}})$ | 0.156 ± 0.015 |
| $T_{(0.2-0.5)r_{500}^{\text{H.E.}}}$ | (7.25 ± 0.13) keV |
| $Z_{(0.2-0.5)r_{500}^{\text{H.E.}}}$ | $(0.28 \pm 0.03) Z_{\odot}$ |
| $L_{0.1-2.4\text{keV},500}^{\text{incc}}(\leq r_{500}^{\text{H.E.}})$ | $(2.13 \pm 0.04) \times 10^{45} \text{ erg s}^{-1}$ |
| $L_{0.1-2.4\text{keV},500}^{\text{cocc}}(\leq r_{500}^{\text{H.E.}})$ | $(0.61 \pm 0.04) \times 10^{45} \text{ erg s}^{-1}$ |
| $L_{\text{bol},500}^{\text{incc}}(\leq r_{500}^{\text{H.E.}})$ | $(5.48 \pm 0.11) \times 10^{45} \text{ erg s}^{-1}$ |
| $L_{\text{bol},500}^{\text{cocc}}(\leq r_{500}^{\text{H.E.}})$ | $(1.56 \pm 0.11) \times 10^{45} \text{ erg s}^{-1}$ |
| Optical spectroscopic properties with all 53 members | |
| r_{500}^{caustic} | (1.06 ± 0.04) Mpc |
| M_{500}^{caustic} | $(4.17 \pm 0.42) \times 10^{14} M_{\odot}$ |
| r_{200}^{caustic} | (1.66 ± 0.06) Mpc |
| M_{200}^{caustic} | $(6.43 \pm 0.65) \times 10^{14} M_{\odot}$ |
| $M_{500}^{\text{caustic}}(\leq r_{500}^{\text{H.E.}})$ | $(4.66 \pm 0.47) \times 10^{14} M_{\odot}$ |
| $\sigma_{53\text{m}}$ | $(1132 \pm 94) \text{ km s}^{-1}$ |
| $r_{500,53\text{m}}^{\text{B06}}$ | (1.217 ± 0.109) Mpc |
| $M_{500,53\text{m}}^{\text{B06}}$ | $(6.355 \pm 1.711) \times 10^{14} M_{\odot}$ |
| Optical spectroscopic properties with 48 members excluding the high-velocity group | |
| $\sigma_{48\text{m}}$ | $(1079 \pm 97) \text{ km s}^{-1}$ |
| $r_{500,48\text{m}}^{\text{B06}}$ | (1.157 ± 0.111) Mpc |
| $M_{500,48\text{m}}^{\text{B06}}$ | $(5.452 \pm 1.573) \times 10^{14} M_{\odot}$ |
| Optical spectroscopic properties with all 29 blue members | |
| σ_{blue} | $(1170 \pm 125) \text{ km s}^{-1}$ |
| $r_{500,\text{blue}}^{\text{B06}}$ | (1.260 ± 0.141) Mpc |
| $M_{500,\text{blue}}^{\text{B06}}$ | $(7.057 \pm 2.373) \times 10^{14} M_{\odot}$ |
| Optical spectroscopic properties with all 24 red members | |
| σ_{red} | $(1096 \pm 156) \text{ km s}^{-1}$ |
| $r_{500,\text{red}}^{\text{B06}}$ | (1.175 ± 0.172) Mpc |
| $M_{500,\text{red}}^{\text{B06}}$ | $(5.722 \pm 2.517) \times 10^{14} M_{\odot}$ |
| Photometric properties within X-ray determined $r_{500}^{\text{H.E.}}$ down to $R = 22$ magnitude | |
| Galaxy luminosity function | all members: $R^* = 18.11 \pm 0.61$, $\alpha = -1.24 \pm 0.16$, $\Phi^* = 20.95 \pm 12.24$ red members: $R_{\text{red}}^* = 18.98 \pm 0.34$, $\alpha_{\text{red}} = -0.86 \pm 0.19$, $\Phi_{\text{red}}^* = 34.87 \pm 11.75$ |
| $f_{\text{blue}}(\leq r_{500}^{\text{H.E.}})$ | 0.37 ± 0.06 |
| $N_{\text{red}}(\leq r_{500}^{\text{H.E.}})$ | 180.2 ± 15.5 |
| $N_{\text{all}}(\leq r_{500}^{\text{H.E.}})$ | 283.9 ± 22.4 |
| $L_{\text{R},\text{blue}}(\leq r_{500}^{\text{H.E.}})$ | $(0.81 \pm 0.14) \times 10^{12} L_{\odot}$ |
| $L_{\text{R},\text{red}}(\leq r_{500}^{\text{H.E.}})$ | $(1.77 \pm 0.19) \times 10^{12} L_{\odot}$ |
| $L_{\text{R},\text{all}}(\leq r_{500}^{\text{H.E.}})$ | $(2.58 \pm 0.24) \times 10^{12} L_{\odot}$ |
| $M_{*,\text{blue}}(\leq r_{500}^{\text{H.E.}})$ | $(0.31 \pm 0.07) \times 10^{12} M_{\odot}$ |
| $M_{*,\text{red}}(\leq r_{500}^{\text{H.E.}})$ | $(3.42 \pm 0.66) \times 10^{12} M_{\odot}$ |
| $M_{*,\text{all}}(\leq r_{500}^{\text{H.E.}})$ | $(3.73 \pm 0.66) \times 10^{12} M_{\odot}$ |
| $f_{*,500}(\leq r_{500}^{\text{H.E.}})$ | 0.0064 ± 0.0013 |
| Richness derived mass measurements down to $(R^* + 1)$ magnitude | |
| r_{200}^{J07} | (1.851 ± 0.082) Mpc |
| M_{200}^{J07} | $(8.948 \pm 1.190) \times 10^{14} M_{\odot}$ |
| N_{200}^{J07} | 92.67 ± 9.63 |
| r_{200}^{H09} | (1.651 ± 0.077) Mpc |
| M_{200}^{H09} | $(6.347 \pm 0.887) \times 10^{14} M_{\odot}$ |
| N_{200}^{H09} | 83.89 ± 9.16 |

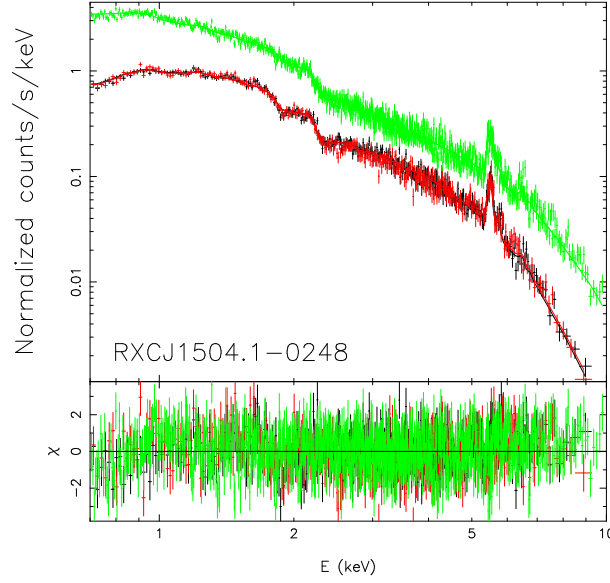

Fig. 1. MOS1 (black), MOS2 (red) and pn (green) spectra extracted from the central ≤ 0.5 circle. The lower panel shows deviations of the models from the data points normalized by the 1σ errors.

Fig. 2. *Left:* Deprojected temperature measurement versus radius with the parametrized temperature distribution in solid curve and 1σ interval in dashed curves. The vertical line denotes $0.1r_{500}^{\text{H.E.}}$. *Right:* Surface brightness versus projected distance from the X-ray flux-weighted centroid with the parametrized surface brightness distribution in solid curve. The upper panel shows deviations of the model from the data points normalized by the 1σ errors.

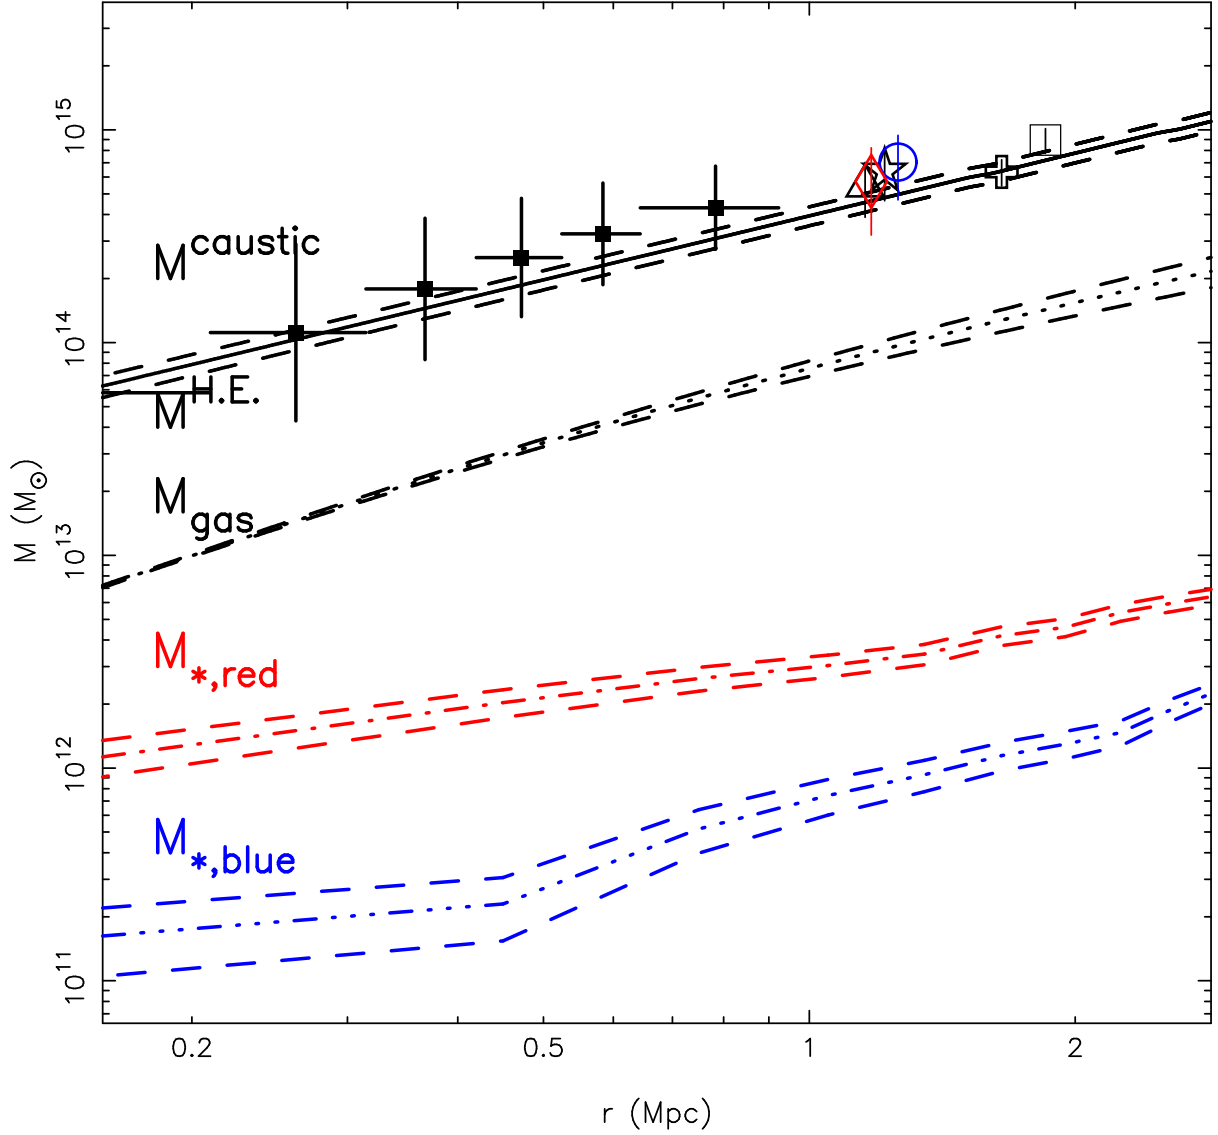

Fig. 3. Cumulative mass distributions (1) using the X-ray hydrostatic method (filled squares), (2) using the caustic method (black solid curve), (3) of the gas mass estimate (black dotted curve), (4) of the stellar mass estimate of the red galaxies (red dash-dotted curve) and (5) of the stellar mass estimate of the blue galaxies (blue dash-dotted-dotted-dotted curve). The dashed curves and error bars denote 1σ intervals. The open star, triangle, diamond and circle indicate the dynamical mass estimates (M_{500}^{B06}) using 53, 48, 24 red and 29 blue cluster members according to the Biviano et al. (2006) method. The open square and cross denote the richness derived mass estimates (M_{200}^{J07} and M_{200}^{H09}) based on photometric data using the definitions of Johnston et al. (2007) and Hansen et al. (2009).

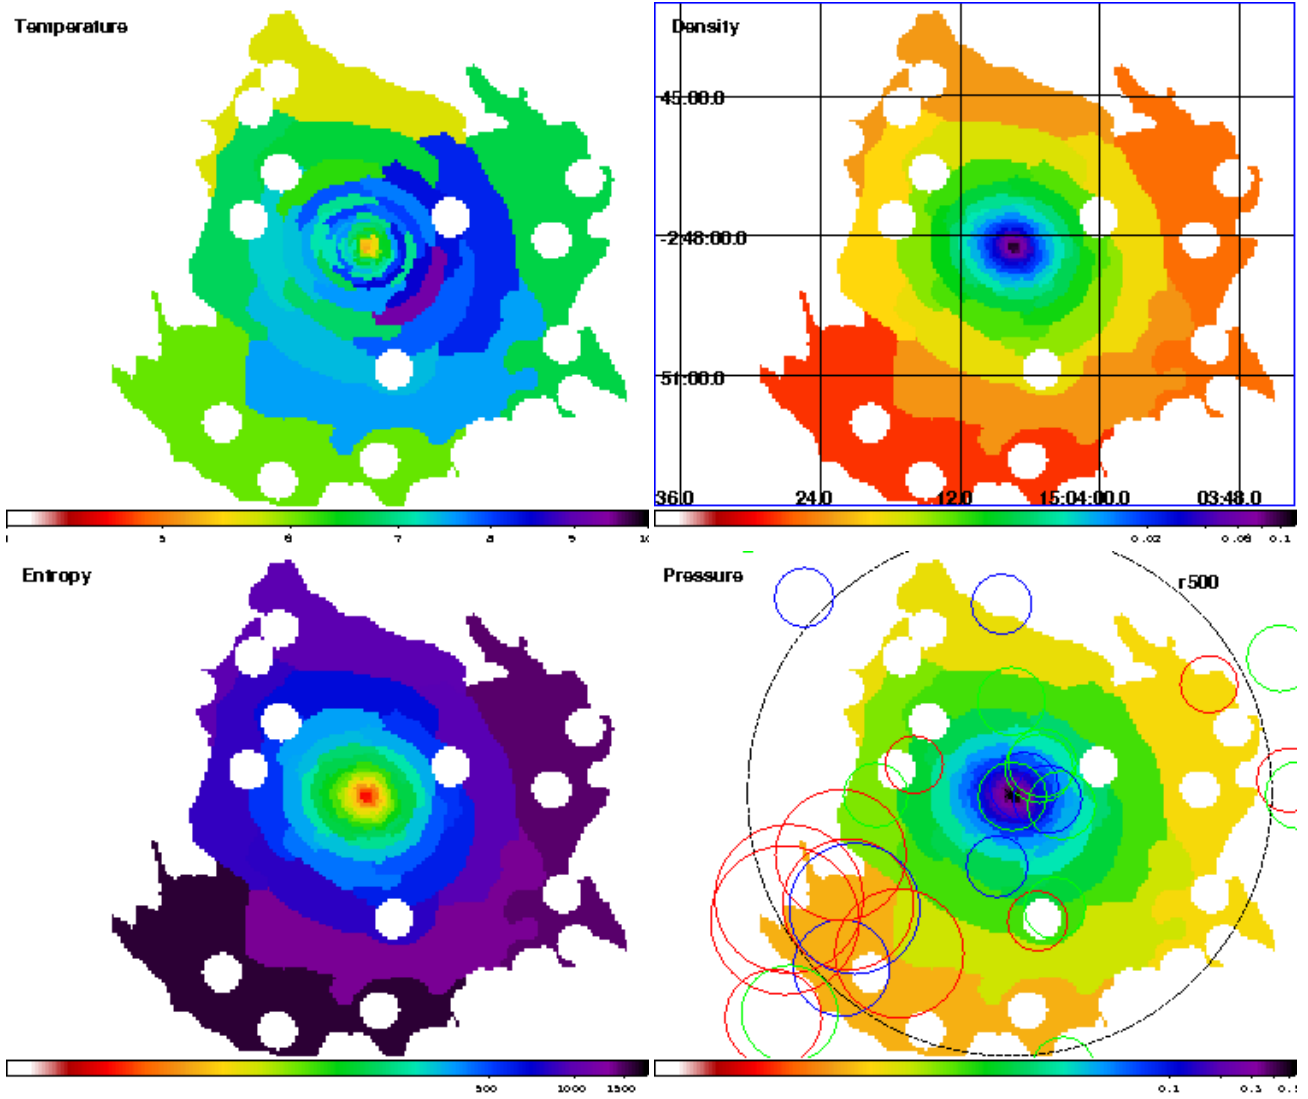

Fig. 4. 2-D X-ray spectrally measured temperature (upper left), electron number density (upper right), entropy (lower left) and pressure (lower right) using the Sanders (2006) binning scheme. Overlaid circles in blue, red and green denote those spectroscopically followed-up cluster galaxies with their cluster centric velocities toward the observer greater than 1000 km s^{-1} , away from the observer greater than 1000 km s^{-1} and smaller than 1000 km s^{-1} , respectively. The radii of these circles are proportional to $\exp[\rho_{\text{DS}}^2]$. The black cross denotes the X-ray flux-weighted centroid and the black dashed circle denotes $r_{500}^{\text{H.E.}}$. The white holes mask X-ray detected point sources. The colour scales logarithmically from 4 to 10 in keV for temperature, from 0.00005 to 0.12 in cm^{-3} for electron number density, from 10 to 1800 in keV cm^2 for entropy and from 0.0001 to 0.54 in keV cm^{-3} for pressure.

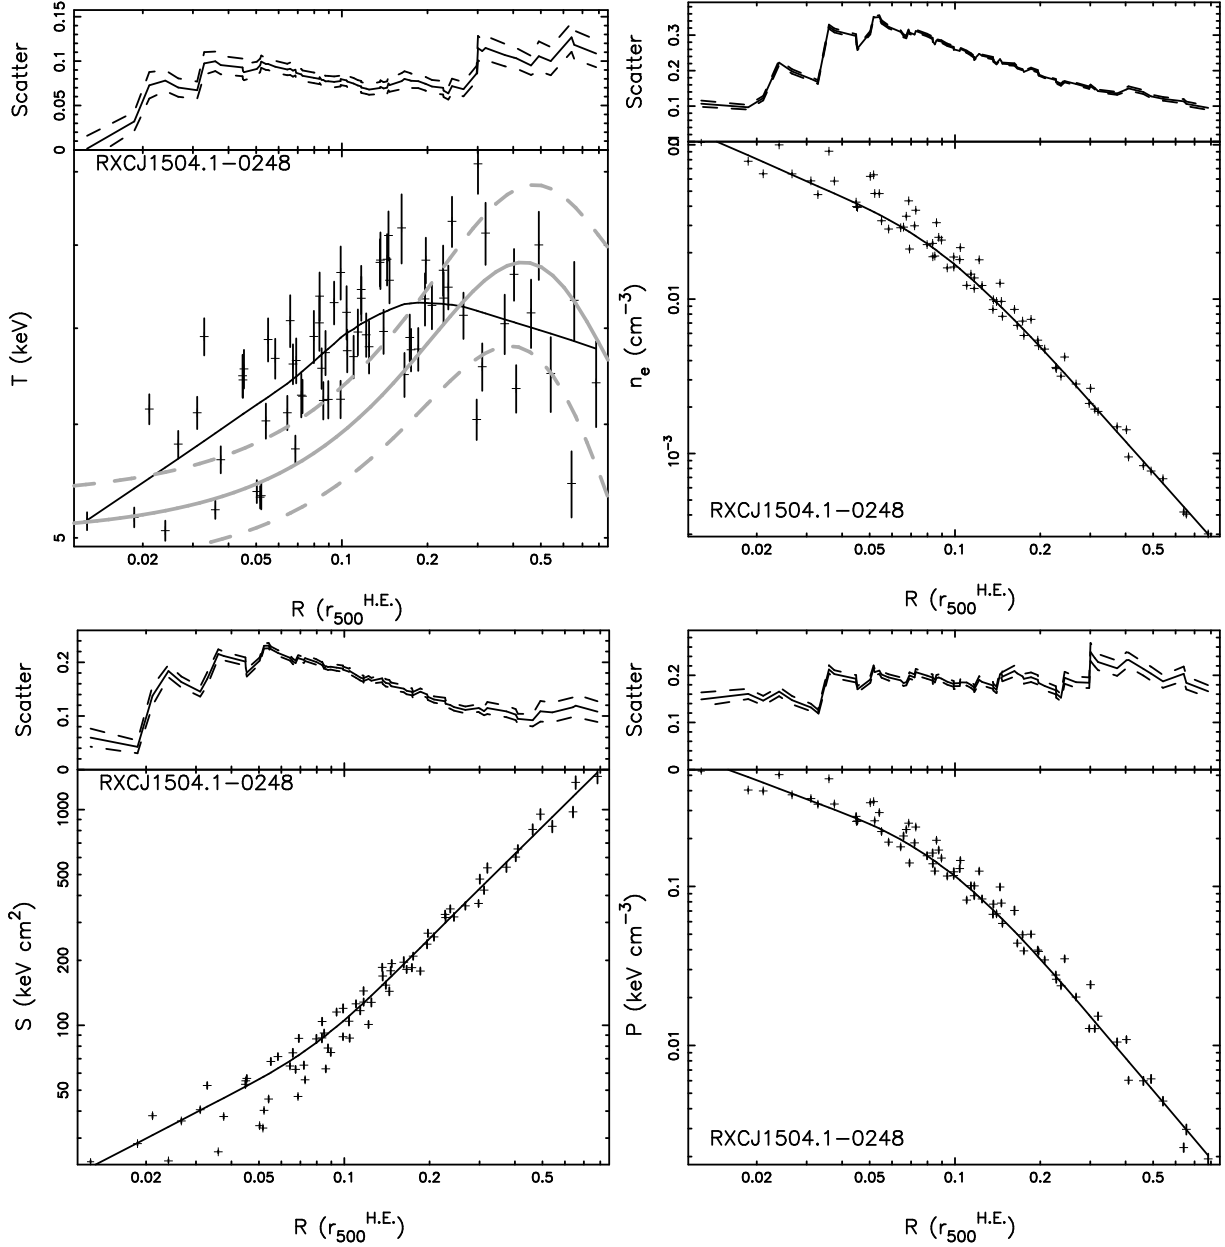

Fig. 5. Temperature (upper left), electron number density (upper right), entropy (lower left) and pressure (lower right) distributions of the spectrally measured 2D maps using the Sanders (2006) binning scheme are shown as crosses with their local regression fits in black curves. The solid and dashed grey curves in the upper left plot show the parametrization of the deprojected temperature profile and its $1-\sigma$ interval derived in Sect. 2.3. Differential scatter and its $1-\sigma$ intervals of the temperature, electron number density, entropy and pressure fluctuations in the 2D maps are shown in solid and dashed black curves in their upper panels.

Fig. 6. Radial distribution of the iron abundance. The vertical line denotes $0.1r_{500}^{\text{H.E.}}$

Fig. 7. *Left:* Histogram of the line-of-sight velocities. Member galaxies of the cluster, member galaxies of the high-velocity group and non-member galaxies are in solid (black), dashed (red) and dash-dotted (grey) lines. The arrow shows the cluster redshift. *Right:* Line-of-sight velocity versus projected radius, in which filled blue diamonds and red stars show blue and red member galaxies in the caustic (black curve), and open boxes show fore- and background galaxies. The grey curve shows the symmetric boundary by choosing the minimum of the values on both sides of the caustic boundary relative to the cluster redshift. The cluster radii, r_{500}^{caustic} and r_{200}^{caustic} , derived from the mass distribution using the caustic method are shown as solid and dashed vertical lines, respectively.

Fig. 8. WFI *B*-band imaging. Overlaid circles in blue, red and green denote those spectroscopically followed-up cluster galaxies with their cluster centric velocities toward the observer greater than 1000 km s^{-1} , away from the observer greater than 1000 km s^{-1} and smaller than 1000 km s^{-1} , respectively. The radii of these circles are proportional to $\exp[\rho_{\text{DS}}^2]$. The black cross denotes the X-ray flux-weighted centroid and the black dashed circle denotes $r_{500}^{\text{H.E.}}$.

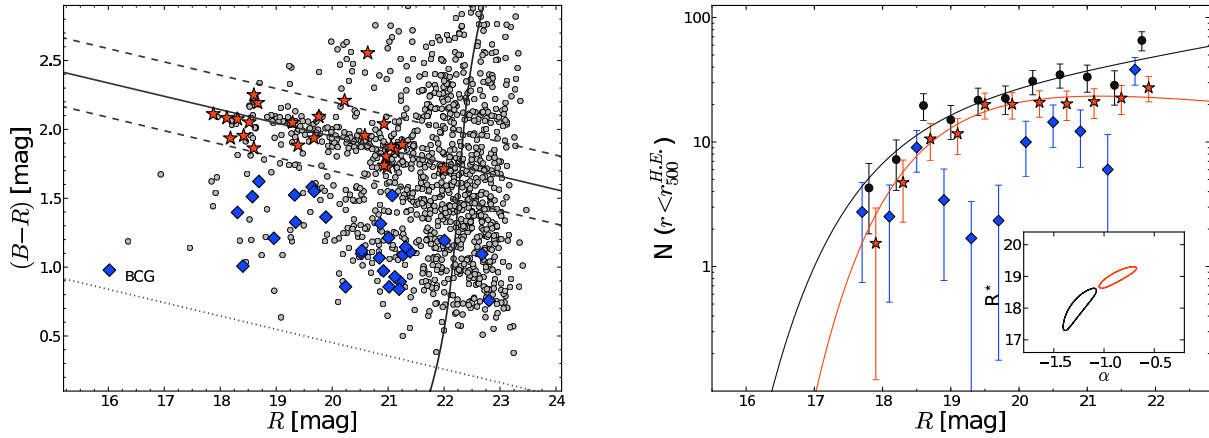

Fig. 9. *Left:* Colour-magnitude diagram with the corresponding red sequence in solid line and its $3\sigma = 0.249$ magnitude intervals in dashed lines. The sample is complete down to the curve at ~ 22 magnitude which varies slightly with the $B - R$ colour. We thus limited the analysis to the galaxies brighter than $R = 22$ magnitude. The dotted line denotes the colour cut that is 1.5 magnitude bluer than the red sequence, below which the objects were considered as foreground contamination. Red stars and blue diamonds indicate red and blue spectroscopic member galaxies regardless of their cluster centric distances. The BCG is extremely blue with $B - R = 0.98$. *Right:* Cluster galaxy luminosity functions for red (red stars), blue (blue diamonds) and all (black circles) members within $r_{500}^{\text{H.E.}}$ derived from the X-ray hydrostatic mass estimate. The membership is statistically determined using control fields with the background contamination statistically subtracted. The best-fit Schechter (1976) functions are shown in red and black curves for the red and all members, respectively. The inset shows the 68% confidence region for the R^* and α parameters of the best-fit Schechter (1976) functions. No fit was possible for the blue members.

Fig. 10. *Left:* Number density profiles with their best-fit NFW models for red member galaxies (red triangles, solid curve) and all members (black circles, dashed curve), respectively. We obtained reduced $\chi^2 = 1.03, 2.24$ for the red and all member galaxies, which indicates that the red galaxies follow well the theoretical profile and the blue galaxies may account for the deviation of the fit for all member galaxies. The bin size is 300 kpc. *Right:* Ratio of blue to all member galaxies as a function of projection distance from the X-ray flux-weighted centroid. The vertical line remarks $r_{500}^{\text{H.E.}}$.

Appendix A: X-ray 2-D spectrally measured maps

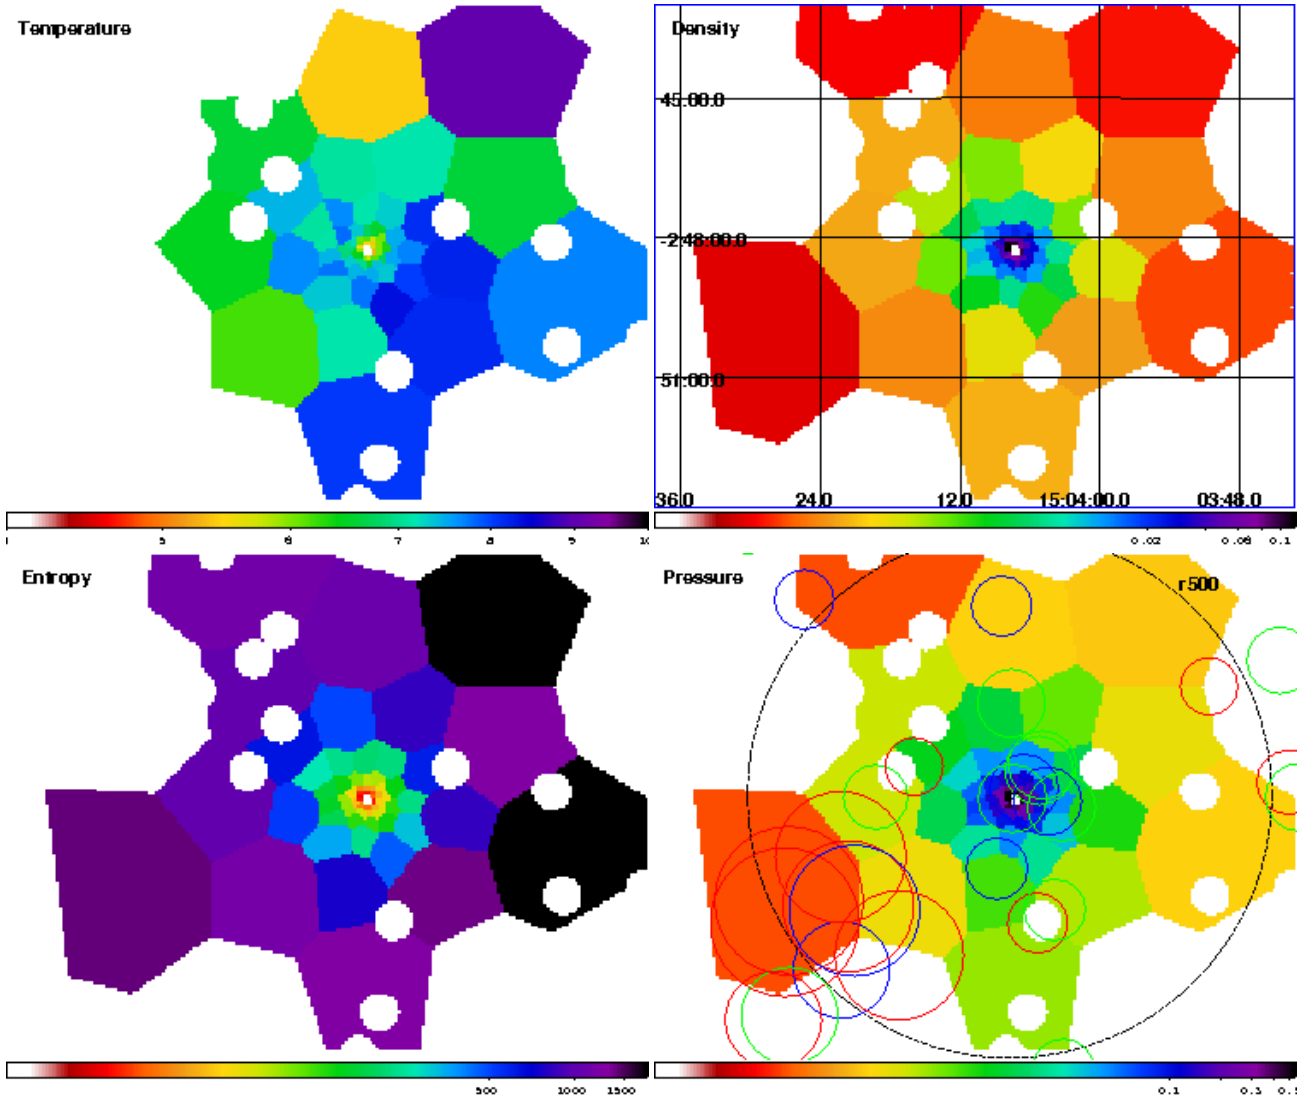

Fig. A.1. 2-D X-ray spectrally measured temperature (upper left), electron number density (upper right), entropy (lower left) and pressure (lower right) maps using the Cappellari & Copin (2003) binning scheme. Overlaid circles in blue, red and green denote those spectroscopically followed-up cluster galaxies with their cluster centric velocities toward the observer greater than 1000 km s^{-1} , away from the observer greater than 1000 km s^{-1} and smaller than 1000 km s^{-1} , respectively. The radii of these circles are proportional to $\exp[\rho_{\text{DS}}^2]$. The black cross denotes the X-ray flux-weighted centroid and the black dashed circle denotes $r_{500}^{\text{H.E.}}$. The white holes mask X-ray detected point sources. The colour scales logarithmically from 4 to 10 in keV for temperature, from 0.00005 to 0.12 in cm^{-3} for electron number density, from 10 to 1800 in keV cm^2 for entropy and from 0.0001 to 0.54 in keV cm^{-3} for pressure.
