Abstract

We analyze a complex scalar field with ϕ^4 interaction and a chemical potential μ on the lattice. An exact flux representation of the partition sum is used which avoids the complex action problem and based on a generalized worm algorithm we can run Monte Carlo simulations at arbitrary densities. We study thermodynamical quantities as a function of the chemical potential μ for zero- and finite temperature. It is shown that at zero temperature thermodynamical observables are independent of μ up to a critical value μ_c (Silver Blaze phenomenon). In a spectroscopy calculation we cross-check that μ_c agrees with the mass m of the scalar field. The Silver Blaze region ends in a second order phase transition and we show that for low temperatures the second order phase boundary persists and separates a pseudo Silver Blaze region from a condensed phase with strong μ -dependence.

1 Introduction

The QCD phase diagram is a topic which currently sees a lot of attention in experimental and theoretical work. A particularly interesting (and rather unexplored) part is the region at low temperatures and medium to high densities (medium to high values of the chemical potential μ). While for large chemical potential exotic states of matter are conjectured, for small chemical potential and vanishing temperature one expects physics to be independent of μ : As long as the chemical potential is smaller than the mass of the state it couples to no excitations can be generated and physics must be independent of μ . This is an interesting non-perturbative effect which has come to be known as Silver Blaze problem [1].

In principle lattice QCD would be an adequate method to study such non-perturbative phenomena. However, when coupling a chemical potential the fermion determinant becomes complex and cannot be used as a probability weight in a Monte Carlo simulation. This so called complex action problem is a common feature in many field theories at non-zero μ and has considerably held up the study of QCD and other systems at finite density. Using new ideas such as worm algorithms [2], designed for updating systems with local constraints, several interesting models at finite density were rewritten in terms of a flux representation where the complex action problem is avoided and worm-based Monte Carlo simulations are possible (see, e.g., [3, 4, 5, 6, 7, 8, 9, 10] for examples). This opens the possibility to explore the Silver Blaze phenomenon in an ab-initio lattice study.

In this article we analyze the Silver Blaze problem for a charged scalar ϕ^4 field. For scalar fields a suitable flux representation [7, 9, 10] can be found which avoids the complex action problem at finite μ and Monte Carlo simulations at high densities become possible. The model has been analyzed previously using the complex Langevin approach and mean field techniques [11, 12]. In this paper we systematically study the transition at the end of the Silver Blaze region at zero temperature and attempt to follow the transition line for non-zero temperatures. This work sheds light on Silver Blaze type of phenomena and explores new strategies for overcoming the complex action problem in lattice calculations at finite density.

The article is organized as follows: In the next section we present the flux representation and our observables. In Section 3 the worm algorithm is described (see also the appendix for a pseudo-code listing) and tested. The numerical analysis at vanishing temperature is discussed in Section 4, followed by the results for non-zero temperature in Section 5. A summary and discussion section completes the paper.

2 Flux representation for the charged scalar field

In the conventional representation the lattice action of the charged scalar field with a ϕ^4 -interaction is given by

$$S = \sum_{x} \left(\eta |\phi_{x}|^{2} + \lambda |\phi_{x}|^{4} - \sum_{\nu=1}^{4} \left[e^{\mu \,\delta_{\nu,4}} \phi_{x}^{\star} \phi_{x+\widehat{\nu}} + e^{-\mu \,\delta_{\nu,4}} \phi_{x}^{\star} \phi_{x-\widehat{\nu}} \right] \right).$$
(1)

The first sum is over the sites x of a $N_s^3 \times N_t$ lattice with periodic boundary conditions, the second sum is over the four Euclidean directions $\nu = 1, 2, 3, 4$, and $\hat{\nu}$ denotes the unit vector in ν -direction. The degrees of freedom are the complex valued field variables ϕ_x attached to the sites x of the lattice. η denotes the combination $8 + m^2$, where m is the bare mass parameter. The ϕ^4 coupling is denoted by λ and the chemical potential by μ . All parameters are in units of the lattice spacing a, in other words the lattice spacing is set to a = 1 throughout this paper, except for some places where we display a explicitly for clarity. The partition sum Z is obtained by integrating the Boltzmann factor e^{-S} over all field configurations, $Z = \int D[\phi]e^{-S}$. The measure is a product over all lattice sites x, with ϕ_x being integrated over the complex plane, i.e., $D[\phi] = \prod_x \int_{\mathbb{C}} d\phi_x/2\pi$. The normalization with 2π will be useful later.

Note that in its present form the model has a complex action problem: For $\mu \neq 0$ the sum of the temporal nearest neighbor terms is complex. Thus the Boltzmann factor cannot be used as a probability weight in a Monte Carlo simulation. The problem can be overcome by using alternative degrees of freedom, i.e., a flux representation. The first step to obtain the flux representation of the partition sum is an expansion of the Boltzmann factors for the nearest neighbor terms

$$\prod_{x,\nu} \exp\left(e^{\mu\,\delta_{\nu,4}}\phi_x^{\star}\phi_{x+\widehat{\nu}}\right) \exp\left(e^{-\mu\,\delta_{\nu,4}}\phi_x\phi_{x+\widehat{\nu}}^{\star}\right) =$$

$$\sum_{\{n,\overline{n}\}} \left(\prod_{x,\nu} \frac{1}{n_{x,\nu}!\,\overline{n}_{x,\nu}!}\right) \left(\prod_x e^{\mu[n_{x,4}-\overline{n}_{x,4}]}\right) \left(\prod_{x,\nu} \left(\phi_x^{\star}\phi_{x+\widehat{\nu}}\right)^{n_{x,\nu}} \left(\phi_x\phi_{x+\widehat{\nu}}^{\star}\right)^{\overline{n}_{x,\nu}}\right) =$$

$$\sum_{\{n,\overline{n}\}} \left(\prod_{x,\nu} \frac{1}{n_{x,\nu}!\,\overline{n}_{x,\nu}!}\right) \left(\prod_x e^{\mu[n_{x,4}-\overline{n}_{x,4}]} \phi_x^{\star}\sum_{\nu} [n_{x,\nu}+\overline{n}_{x-\widehat{\nu},\nu}]} \phi_x^{\sum_{\nu} [\overline{n}_{x,\nu}+n_{x-\widehat{\nu},\nu}]}\right),$$
(2)

where by $\sum_{\{n,\overline{n}\}}$ we denote the sum over all configurations of the expansion

variables $n_{x,\nu}, \overline{n}_{x,\nu} \in [0,\infty)$, i.e., the multiple sum

$$\sum_{\{n,\overline{n}\}} = \prod_{x,\nu} \sum_{n_{x,\nu}=0}^{\infty} \sum_{\overline{n}_{x,\nu}=0}^{\infty} .$$
(3)

The complex field variables are now written in polar form, $\phi_x = r_x e^{i\theta_x}$. Rewriting also the integration measure in polar coordinates one finds for the partition sum

$$Z = \sum_{\{n,\overline{n}\}} \left(\prod_{x,\nu} \frac{1}{n_{x,\nu}! \,\overline{n}_{x,\nu}!} \right) \left(\prod_{x} \int_{-\pi}^{\pi} \frac{d\theta_x}{2\pi} e^{-i\theta_x \sum_{\nu} [n_{x,\nu} - \overline{n}_{x,\nu} - (n_{x-\widehat{\nu},\nu} - \overline{n}_{x-\widehat{\nu},\nu})]} \right) \\ \times \left(\prod_{x} e^{\mu [n_{x,4} - \overline{n}_{x,4}]} \int_0^{\infty} dr_x \, r_x^{1+\sum_{\nu} [n_{x,\nu} + n_{x-\widehat{\nu},\nu} + \overline{n}_{x,\nu} + \overline{n}_{x-\widehat{\nu},\nu}]} \, e^{-\eta r_x^2 - \lambda r_x^4} \right).$$
(4)

The integrals over the phase give rise to Kronecker deltas, which for notational convenience we will write as $\delta(n)$. The integrals over the modulus we abbreviate as

$$W(n) = \int_0^\infty dr \, r^{n+1} \, e^{-\eta r^2 - \lambda r^4} \,. \tag{5}$$

They can easily be computed numerically. The partition sum now reads:

$$Z = \sum_{\{n,\overline{n}\}} \left(\prod_{x,\nu} \frac{1}{n_{x,\nu}! \,\overline{n}_{x,\nu}!} \right) \left(\prod_{x} \delta \left(\sum_{\nu} \left[n_{x,\nu} - \overline{n}_{x,\nu} - (n_{x-\widehat{\nu},\nu} - \overline{n}_{x-\widehat{\nu},\nu}) \right] \right) \right) \times \left(\prod_{x} e^{\mu [n_{x,4} - \overline{n}_{x,4}]} W \left(\sum_{\nu} \left[n_{x,\nu} + \overline{n}_{x,\nu} + n_{x-\widehat{\nu},\nu} + \overline{n}_{x-\widehat{\nu},\nu} \right] \right) \right).$$
(6)

In this form the complex phase problem is gone. All weight factors for configurations of the n and \overline{n} variables are real and non-negative. However, configurations of the n and \overline{n} can still have weight 0. This is always the case if at a site x the constraint enforced by the Kronecker deltas is violated, i.e., when at least for one x one has $\sum_{\nu} [n_{x,\nu} - \overline{n}_{x,\nu} - (n_{x-\widehat{\nu},\nu} - \overline{n}_{x-\widehat{\nu},\nu})] \neq 0$.

In the current representation the constraints mix both, the n and the \overline{n} variables. The structure of the constraints can be simplified by introducing new variables $k_{x,\nu} \in (-\infty, \infty)$ and $l_{x,\nu} \in [0,\infty)$. They are related to the old variables by

$$n_{x,\nu} - \overline{n}_{x,\nu} = k_{x,\nu}$$
 and $n_{x,\nu} + \overline{n}_{x,\nu} = |k_{x,\nu}| + 2l_{x,\nu}$. (7)

The partition sum turns into

$$Z = \sum_{\{k,l\}} \left(\prod_{x,\nu} \frac{1}{(|k_{x,\nu}| + l_{x,\nu})! \, l_{x,\nu}!} \right) \left(\prod_{x} \delta \left(\sum_{\nu} \left[k_{x,\nu} - k_{x-\hat{\nu},\nu} \right] \right) \right) \\ \times \left(\prod_{x} e^{\mu k_{x,4}} W \left(\sum_{\nu} \left[|k_{x,\nu}| + |k_{x-\hat{\nu},\nu}| + 2(l_{x,\nu} + l_{x-\hat{\nu},\nu}) \right] \right) \right).$$
(8)

In the final form (8), which we now refer to as flux representation, the constraints no longer mix the two types of flux variables. Obviously only the k-fluxes are subject to conservation of flux at each site x, i.e., only they must obey $\sum_{\nu} [k_{x,\nu} - k_{x-\hat{\nu},\nu}] = 0$ for all x.

Also observables need to be mapped to the flux representation. For thermodynamic observables which are obtained as derivatives of $\ln Z$ with respect to the various couplings this is particularly simple. We will need the following observables which we refer to as particle number density n, the particle number susceptibility χ_n , the derivative χ'_n of χ_n with respect to μ , the field expectation value $\langle |\phi^2| \rangle$, the corresponding susceptibility $\chi_{|\phi|^2}$ and its derivative $\chi'_{|\phi|^2}$ with respect to μ . They are defined as

$$n = \frac{T}{V} \frac{\partial \ln Z}{\partial \mu} = \frac{1}{N_s^3 N_t} \frac{\partial \ln Z}{\partial \mu} , \ \chi_n = \frac{\partial n}{\partial \mu} , \ \chi'_n = \frac{\partial \chi_n}{\partial \mu} ,$$
(9)

$$\langle |\phi|^2 \rangle \,=\, \frac{-T}{V} \frac{\partial \,\ln Z}{\partial \eta} \,=\, \frac{-1}{N_s^3 \,N_t} \frac{\partial \,\ln Z}{\partial \eta} \;,\; \chi_{|\phi|^2} \,=\, \frac{-\partial \langle |\phi|^2 \rangle}{\partial \eta} \;,\; \chi_{|\phi|^2}' \,=\, \frac{\partial \,\chi_{|\phi|^2}}{\partial \mu}$$

All observables are normalized by the spatial volume $V = N_s^3$ in order to make them intensive quantities. We remark, that the observables (9) are dimensionful (except $\chi_{|\phi|^2}$). Since we here use a fixed scale approach (the lattice spacing *a* is set by η and λ and kept fixed) and drive the temperature $T = 1/aN_t$ by changing N_t , we will often show results in lattice units. Where a comparison of results at different scales is necessary we make quantities dimensionless using suitable powers of μ_c , the critical value of the chemical potential at zero temperature (see the discussion below).

It is straightforward to work out the derivatives that define the observables (9) also for the flux representation of Z and we only discuss two examples to illustrate the general structure. Particularly simple is the particle number density. One immediately sees that the flux representation of n is given by

$$n = \frac{1}{N_s^3 N_t} \left\langle \sum_x k_{x,4} \right\rangle \,, \tag{10}$$

i.e., the particle number is simply the net flux of k around compactified time (= the 4-direction). The expectation value $\langle ... \rangle$ is now of course understood as a vacuum expectation value in the flux representation. Not much more difficult is the flux representation for $\langle |\phi|^2 \rangle = -\partial/\partial\eta \ln Z/N_s^3 N_t$. Note that η enters only through the weight factors W(n) defined in (5) which have the obvious property $-\partial/\partial\eta W(n) = W(n+2)$. Application of the product rule to the product of the factors W in (8) and subsequent completion of the remaining products to the full Boltzmann factor gives rise to

$$\langle |\phi|^2 \rangle = \frac{1}{N_s^3 N_t} \left\langle \sum_x \frac{W(f_x + 2)}{W(f_x)} \right\rangle, \tag{11}$$

where we use the abbreviation $f_x = \sum_{\nu} [|k_{x,\nu}| + |k_{x-\hat{\nu},\nu}| + 2(l_{x,\nu} + l_{x-\hat{\nu},\nu})]$. In a similar way the other observables listed in (9) can be obtained as higher moments of the fluxes and the sum of ratios of W.

3 Worm algorithm and tests

Having discussed the flux representation of the partition sum and the observables, we now address the task of finding a suitable algorithm. In the final representation (8) of the partition sum we use two different sets of variables. One of them, the variables $l_{x,\nu}$, are not subject to a constraint. For these we simply apply sweeps of local Metropolis updates: Each link (x,ν) is visited and we generate a trial configuration by increasing or decreasing $l_{x,\nu}$ by ± 1 with equal probability. The change is accepted with the usual Metropolis probability given by the ratio of the weights of new and old configuration. A negative trial link is always rejected.

Considerably more interesting is the update of the flux variables $k_{x,\nu}$ where a suitable update needs to take into account the local constraints $\sum_{\nu} [k_{x,\nu} - k_{x-\hat{\nu},\nu}] = 0$. For that purpose we use a generalization of the Prokof'ev-Svistunov worm algorithm [2]. The worm starts at a randomly chosen site of the lattice and then grows by adding links to form a chain of links. At each position x the worm chooses randomly the next link from the 8 links attached to x. For that link it proposes to change the corresponding variable k by ± 1 and accepts that change with a local Metropolis step. At the starting point and the head of the worm the constraint is violated, and the worm must continue until its head reaches the starting point such that along the closed contour of changed links all constraints are intact again. A possible initial configuration for the $k_{x,\nu}$ is to set $k_{x,\nu} = 0$ at all links, a configuration that clearly obeys the constraints. The situation for a worm update of the variables $k_{x,\nu}$ is a little bit tricky: The local weight for a variable $k_{x,\nu}$ not only has factors that live on the link (the factorials in $1/(|k_{x,\nu}| + l_{x,\nu})!$ and the contribution from the chemical potential), but also two factors at the two endpoints of the link, the terms $W(f_x)$ and $W(f_{x+\hat{\nu}})$ (where again $f_x = \sum_{\nu} [|k_{x,\nu}| + |k_{x-\hat{\nu},\nu}| + 2(l_{x,\nu} + l_{x-\hat{\nu},\nu})])$. The contributions from the factors W at the endpoints need to be suitably distributed among subsequent steps of the worm. In the appendix we provide pseudo-code for the initialization of the worm and the subsequent steps, illustrating how we solved the weight assignment for the W contributions. Worms for the variables $k_{x,\nu}$ are alternated with the local Metropolis sweeps for the unconstrained variables $l_{x,\nu}$.

In our simulations we use $N_s^3 \times N_t$ lattices with N_s ranging from 4 to 24, and N_t from 2 to 100. A full update sweep is the combination of one sweep for the $l_{x,\nu}$ variables and one worm for the $k_{x,\nu}$ fluxes. We typically use between 500.000 and 1.000.000 measurements separated by 5 full update sweeps. The number of equilibration sweeps is typically 25.000. All errors we quote are statistical errors determined with the jackknife method. The weights W defined in (5) were evaluated numerically using Mathematica and pre-stored for the Monte Carlo simulation.

The algorithm was thoroughly tested by comparing it to the free case $(\lambda = 0)$ where exact results can be obtained using Fourier transformation, and to a conventional simulation at $\mu = 0$. In Fig. 1 we show examples for the comparison using 8⁴ lattices. The lhs. plot shows the particle number density n as a function of η for different values of the chemical potential μ for the case of $\lambda = 0$. The symbols are the data from our flux simulation and the full curves the results from Fourier transformation. The rhs. plot compares the $\mu = 0$ results for the expectation value $\langle |\phi|^2 \rangle$ from the flux simulation (triangles) to those of a conventional simulation (crosses). We plot $\langle |\phi|^2 \rangle$ as a function of η for different values of λ . The two plots show that the results from the flux simulation very nicely match the exact curves for the free case and the data from a conventional simulation at $\mu = 0$. Further comparisons were done for other observables and more values of the parameters – all with very good agreement.

Finally we performed a comparison with the complex Langevin results at finite μ by Aarts [11], and we found excellent agreement of our data with the complex Langevin results that are available on lattices of sizes 4⁴ to 10⁴. It is interesting to note that these results are very well described also by mean-field theory [12]. In that study the quartic coupling was fixed to $\lambda = 1.0$, and the boson mass M satisfied $(aM)^2 = 1.47$. As a result of this heavy mass, the temperatures reached on lattices $L^4 = 4^4$ to 10⁴ are

Figure 1: Lhs. plot: Comparison of results for the particle number density n from the flux simulation at $\lambda = 0$ (symbols) to the exact result obtained from Fourier transformation (curves). We plot n as a function of η for different values of μ using lattices of size 8⁴. Rhs. plot: Results for the expectation value $\langle |\phi|^2 \rangle$ as a function of η for different values of λ , again on lattices of size 8⁴. The chemical potential is set to $\mu = 0$ and we compare the results from the flux simulation (triangles, circles, squares) to the outcome of a conventional $\mu = 0$ simulation (crosses).

in the range T/M = 0.08, ..., 0.21. At the same time, the system is large, since ML = 5, ..., 12. So the observed mean-field behavior should come as no surprise. Our comparison with [11, 12] confirms the findings by Aarts.

To summarize: Our tests establish that the flux representation is correct, that the algorithm works, and that the observables were correctly mapped to the corresponding expressions in terms of the fluxes.

4 Transition at zero temperature

We begin our study of the phase diagram with an analysis of the situation at zero temperature. For this analysis we set the temporal extent of the lattice to $N_t = 100$, such that in lattice units the temperature is $T = 1/N_t = 0.01$. Although not exactly 0, this is much smaller than all other involved scales. To study the approach of our observables to the thermodynamic limit we analyze different spatial volumes N_s^3 using $N_s = 4, 8, 12, 16, 20$ and 24. We consider two different combinations of the couplings η and λ . The two points in parameter space are $\eta = 9.0$, $\lambda = 1.0$ and $\eta = 7.44$, $\lambda = 1.0$.

Figure 2: Results at T = 0.01 for $\eta = 9.0$ and $\lambda = 1.0$. In the lhs. column of plots we show n, χ_n and χ'_n as a function of μ (top to bottom). In the rhs. column we show $\langle |\phi|^2 \rangle$, $\chi_{|\phi|^2}$ and $\chi'_{|\phi|^2}$. We compare the results for $4^3 \times 100$, $8^3 \times 100$, $12^3 \times 100$, $16^3 \times 100$ and $20^3 \times 100$.

In Fig. 2 we show the η = 9.0, λ = 1.0 results for n, χ_n and χ'_n as a function of μ in the lhs. column of plots, and for $\langle |\phi|^2 \rangle$, $\chi_{|\phi|^2}$ and $\chi'_{|\phi|^2}$ on the rhs. The particle number density n vanishes up to a critical value of $\mu_c = 1.146(1)$ which marks the end of the Silver Blaze region where observables are independent of μ . For values $\mu > \mu_c$ the particle number density rises essentially linearly. Consequently the particle number susceptibility χ_n is discontinuous at μ_c , jumping from $\chi_n = 0$ to a finite value at μ_c . The comparison of the different spatial volumes illustrates how the discontinuity emerges in the thermodynamic limit. Finally, when looking at the third μ -derivative χ'_n of the free energy we observe that for increasing volume a strongly peaked maximum emerges that very precisely marks the value of $\mu_c = 1.146(1)$. Furthermore, the height of the peak grows with increasing volume $V = N_s^3$ (for a quantitative assessment see below), indicating the emergence of a true singularity in the thermodynamic limit. The observables $\langle |\phi|^2 \rangle$, $\chi_{|\phi|^2}$ and $\chi'_{|\phi|^2}$ behave similarly to the derivatives with respect to μ : The expectation value $\langle |\phi|^2 \rangle$ is constant below μ_c and for $\mu > \mu_c$ increases with constant slope. The corresponding susceptibility $\chi_{|\phi|^2}$ thus also develops a step in the thermodynamic limit. Finally, another derivative with respect to μ , i.e., $\chi'_{|\phi|^2}$, shows the corresponding peaks, which again grow with the volume.

The results for the second parameter set, $\eta = 7.44$, $\lambda = 1.0$ are shown in Fig. 3. Again we display $n, \chi_n, \chi'_n, \langle |\phi|^2 \rangle, \chi_{|\phi|^2}$ and $\chi'_{|\phi|^2}$ as a function of μ . In the plots we omit the data at $N_s = 4$ since for these the transition point in μ is shifted out of the μ -range of our plots due to finite volume effects. For the larger volumes the behavior of the observables is the same as for the $\eta = 9.0$ runs, but now the critical value μ_c that marks the end of the Silver Blaze region is lower at $\mu_c = 0.170(1)$ in lattice units. Again we observe scaling of the maxima of the third derivatives with the volume and conclude that also at $\eta = 7.44$, $\lambda = 1.0$ we find a second order transition at $\mu_c = 0.170(1)$. We remark that the drop of $\mu_c = 1.146(1)$ in lattice units at $\eta = 9.0$ to $\mu_c = 0.170(1)$ at $\eta = 7.44$ is due to a considerable decrease of the lattice constant a. This implies that at $\eta = 7.44$ we work with a smaller lattice spacing a and thus with a smaller physical spatial extent aN_s . Thus we expect to see more severe finite volume effects at $\eta = 7.44$ than at $\eta = 9.0$. On the other hand with the finer lattice spacing we will be able to go to higher temperatures (see the next section).

To further confirm the finding of a singularity at μ_c we analyzed loglog plots of the height of the maxima of χ'_n and $\chi'_{|\phi|^2}$ versus the 3-volume $V = N_s^3$. For $\eta = 9.0$ the corresponding figure is Fig. 7 with the $N_t = 100$

Figure 3: Results at T = 0.01 for $\eta = 7.44$ and $\lambda = 1.0$. In the lhs. column of plots we show n, χ_n and χ'_n as a function of μ (top to bottom). In the rhs. column we show $\langle |\phi|^2 \rangle$, $\chi_{|\phi|^2}$ and $\chi'_{|\phi|^2}$. We compare the results for $8^3 \times 100, 12^3 \times 100, 16^3 \times 100$ and $20^3 \times 100$.

data we discuss in this section labeled by $T/\mu_c = 0.0087$, while the $\eta = 7.44$ results are shown in Fig. 9 with the $N_t = 100$ data labeled by $T/\mu_c = 0.058$. The numerical results are represented by the symbols and we fit them with straight lines. The numbers next to the lines give their slope determined from the fits. At $\eta = 9.0$ we find that the maxima of χ'_n and $\chi'_{|\phi|^2}$ nicely follow a straight line with slopes that are close to 0.5, both for χ'_n and $\chi'_{|\phi|^2}$. For $\eta = 7.44$ the finite volume effects are more severe, as discussed above, and we only show the data for our larger volumes, i.e., for $N_s = 12, 16, 20$ and 24. Some of the data show an upward curving trend and if one uses $N_s = 16, 20$ and 24 for the fit, one finds slopes of 0.39(4) for the maxima of χ'_n and 0.43(11) for $\chi'_{|\phi|^2}$. Although for $\eta = 7.44$ the data are not as clean due to finite volume effects (and also the temperature in units of μ_c is not as low as for $\eta = 9.0$) the data indicate that also at $\eta = 7.44$ for the lowest temperature the maxima of χ'_n and $\chi'_{|\phi|^2}$ diverge as $V \to \infty$.

The analysis implies that at zero temperature the third derivatives diverge in the continuum limit and the susceptibilities develop a jump, indicating a second order transition at the end of the Silver Blaze region. In the first derivatives of the free energy the transition is characterized by the onset of a non-vanishing particle number density n at μ_c and a linear response of the expectation value $\langle |\phi|^2 \rangle$ to changing μ for $\mu > \mu_c$.

We conclude the discussion of the T = 0 phenomenology with an important cross-check. The Silver Blaze regions ends at the point where the chemical potential becomes equal to the mass m of the excitation it couples to, in other words one expects $\mu_c = m$. In order to check this we performed a small spectroscopy calculation on $20^3 \times 40$ lattices using the conventional representation at $\mu = 0$. The mass was extracted from the correlator of the zero momentum Fourier transform of ϕ , i.e., the 2-point function

$$C(t) = \langle \hat{\phi}(t) \, \hat{\phi}(0)^* \rangle \quad \text{with} \quad \hat{\phi}(t) = \frac{1}{N_s^3} \sum_{\vec{x}} \phi(\vec{x}, t) \,. \tag{12}$$

In Fig. 4 we show our results for the effective masses $m_{eff}(t + 1/2) = \ln C(t)/C(t+1)$ of that correlator for both, $\eta = 9.0$ and $\eta = 7.44$. The effective masses are represented by the symbols and the horizontal lines are the respective values of μ_c . It is obvious that the effective masses agree very well with the values of μ_c^{-1} . An exponential fit of the correlator for

¹We remark that here the $\eta = 9.0$ data are more difficult to analyze, since the large mass $m = \mu_c = 1.146$ leads to a very rapid exponential decay of the correlator (12) and the relative statistical error quickly overlays the signal. Thus for $\eta = 9.0$ the effective mass plateau is rather short and the errors are large.

Figure 4: Effective masses (symbols) for $\eta = 9.0$ (top set of data) and $\eta = 7.44$ (bottom). The effective masses are compared to the values of the critical chemical potential μ_c (horizontal lines) and we annotate the values for μ_c as well as for the mass m_{fit} obtained from an exponential fit of the 2-point function (12).

 $\eta = 7.44$ gives a mass of $m_{fit} = 0.171(8)$ which is in excellent agreement with $\mu_c = 0.170(1)$. For $\eta = 9.0$ we find $m_{fit} = 1.11(5)$ which agrees with $\mu_c = 1.146(1)$ within error bars. We conclude that we properly understand the Silver Blaze behavior at T = 0.

5 Non-zero temperature

Having studied the transition at zero temperature we now explore how the transition line extends in the temperature direction of the phase diagram. As discussed, we work at fixed values of the couplings (again using our two values $\eta = 9.0$ and $\eta = 7.44$ at $\lambda = 1.0$), and drive the temperature by changing N_t . This has the advantage that we always work at a fixed scale and do not mix temperature and discretization effects, but on the other hand restricts the accessible temperatures to a discrete set. For our finite temperature studies we use the values $N_t = 100, 20, 10, 9, 8, 7, 6, 5, 4, 3$ and

2. In lattice units the temperatures $T = 1/N_t$ thus range between T = 0.01and T = 0.5. More interesting is the range of temperatures in units of the critical chemical potential at T = 0, i.e., the value μ_c which we determined in lattice units in the previous section². For $\eta = 9.0$, where $\mu_c = 1.146(1)$, the largest temperature we can reach with $N_t = 2$ is $T/\mu_c \sim 0.436$. For the finer $\eta = 7.44$ lattices ($\mu_c = 0.170(1)$) we can go considerably higher, up to $T/\mu_c \sim 2.94$, although at the price of more severe finite volume effects.

As the temperature is increased above zero, physics cannot be completely independent of μ below some critical value of the chemical potential. Still, at least for not too large temperatures, one should observe only very weak μ -dependence of physical observables at sufficiently small chemical potential ("pseudo Silver Blaze behavior"). In order to define the curves in the phase diagram that separate the pseudo Silver Blaze behavior from a condensed phase characterized by strong μ -dependence, we determined the position of the maxima of the third derivatives of the free energy as a function of μ for different temperatures, using our $N_s = 20$ lattices for $\eta = 9.0$ and $N_s = 24$ for $\eta = 7.44$. For the $\eta = 9.0$ data we find that the positions of the maxima of χ'_n and $\chi'_{|\phi|^2}$ always agree exactly, while for the $\eta = 7.44$ data, where the finite size effects are more severe, we find agreement only within error bars.

In Fig. 5 we show the positions of the maxima of χ'_n and $\chi'_{|\phi|^2}$ in the μ -T plane. For the $\eta = 9.0$ data we use filled circles connected with dashed lines (the plot also contains points from $\eta = 7.44$ (triangles) which we will discuss below). We express both the temperature T and the chemical potential μ in units of the critical value $\mu_c = 1.146(1)$ determined in the zero temperature runs using $N_t = 100$. In these units the largest temperature we can reach with $\eta = 9.0$ is $T/\mu_c = 0.436$. When turning on the temperature, the phase boundary curves slightly to the right reaching $\mu/\mu_c = 1.045$ at $T/\mu_c = 0.436$, the highest temperature accessible for $\eta = 9.0$. This phase boundary separates pseudo Silver Blaze behavior from strong μ -dependence.

In order to assess the behavior across the phase boundary, in Fig. 6 we show the observables n, χ_n , $\langle |\phi|^2 \rangle$ and $\chi_{|\phi|^2}$ from the $\eta = 9.0$ runs at $N_t = 20$ as a function of μ for several temperatures (again using for T and μ units of μ_c). In other words we show the observables along horizontal slices through the phase boundary in Fig. 5.

While the first derivatives n and $\langle |\phi|^2 \rangle$ were almost perfectly constant up to $\mu_c = 1.146(1)$ for our zero temperature runs (compare Fig. 2), in Fig. 6 we now observe a deviation from constant behavior which becomes more prominent as the temperature is increased. However, the transition at

²Whenever we use μ_c this refers to the critical chemical potential at zero temperature.

Figure 5: Phase diagram determined from the positions of the maxima of χ'_n and $\chi'_{|\phi|^2}$ in the μ -T plane. We combine data from $\eta = 9.0$ runs for $N_s = 20$ (circles connected with dashed lines) and $\eta = 7.44$ runs at $N_s = 24$ (triangles). T and μ are expressed in units of μ_c .

the critical value of μ is still rather pronounced, and the corresponding susceptibilities χ_n and $\chi_{|\phi|^2}$ still seem to develop a discontinuity. The position of the discontinuity shifts towards larger values of μ in agreement with the curvature of the phase boundary in Fig. 5.

In order to analyze the order of the transition also at T > 0 we repeat the analysis of the volume dependence of the maxima of the third derivatives χ'_n and $\chi'_{|\phi|^2}$ as function of the 3-volume V. The results of this analysis (done on $20^3 \times N_t$ lattices) for different temperatures are shown in Fig. 7. The symbols represent the numerical results and we fit them to straight lines, with the numbers next to the lines giving the corresponding slopes. It is obvious that the data are well described by a linear behavior with slopes near 0.45 for χ'_n and slopes slightly above 0.5 for $\chi'_{|\phi|^2}$. The plots show that also for our finite temperature values the third derivatives keep developing singularities in the thermodynamic limit. We conclude that for the temperature range

Figure 6: Results for n, χ_n , $\langle |\phi|^2 \rangle$ and $\chi_{|\phi|^2}$ for $\eta = 9.0$ and $N_s = 20$ as a function of μ for several temperatures corresponding to $N_t = 100, 10, 5, 3$ and 2. For T and μ we use units of μ_c , while n, χ_n , $\langle |\phi|^2 \rangle$ and $\chi_{|\phi|^2}$ are given in lattice units at a fixed scale (set by $\eta = 9.0, \lambda = 1.0$).

we cover with our $\eta = 9.0$ runs, i.e., for temperatures up to $T/\mu_c = 0.436$ a second order transition separates the pseudo Silver Blaze region from the condensed phase with strong μ dependence.

We remark that the scaling behavior of the transition is expected to be different for the T = 0 and T > 0 cases. For T = 0 one expects that the transition is of mean field type, which was indeed confirmed by Aarts in [12] and our dual simulation perfectly reproduces this finding (as already discussed in Section 3). Due to dimensional reduction for T > 0 one expects a behavior in the universality class of the 3-d XY model. However, it seems that it is difficult to explicitly extract this behavior from a lattice simulation

Figure 7: Log-log plot of the maxima of the third derivatives of the free energy versus the 3-volume $V = N_s^3$ for $\eta = 9.0$ and $N_s = 4, 8, 12, 16$ and 20. We compare different temperatures corresponding to $N_t = 100, 10, 5, 3$ and 2. The straight lines are linear fits to the data and the numbers near the lines are the respective slopes.

with the resources available to us. This is reflected in the finding by Aarts [12] that the results on lattices ranging from 4^4 to 10^4 are equally well described by mean field behavior which illustrates that the change in the critical behavior must be very subtle. Also an analysis in the continuum [13] shows that the non-linear contribution to n versus $\mu - \mu_c$ that is predicted for finite T is very small in the range of parameters we can access. The finite volume analysis in Fig. 7 is not accurate enough to extract such a small effect.

An interesting question is of course where the phase boundary continues for larger temperatures. With the data taken at $\eta = 9.0$ we reach a maximal temperature of $T/\mu_c = 0.436$ and found the second order line to persist up to that value. For temperatures above that number we need to use the $\eta = 7.44$ configurations where $\mu_c = 0.170(1)$ in lattice units and temperatures of $T/\mu_c \sim 2.94$ can be reached. However, as we have already discussed, the $\eta = 7.44$ data suffer from more severe finite volume effects which spoil the accuracy of the analysis (e.g., the peaks of the third derivatives of the free energy become wider and it is more difficult to exactly determine the phase boundary and the order of the transition). Nevertheless we try to explore the trend for the behavior along the phase boundary towards larger T.

The phase diagram in Fig. 5 also contains a few points from $\eta = 7.44$ runs on $24^3 \times N_t$ lattices (triangles). As for $\eta = 9.0$ we use the positions of the maxima of the third derivatives χ'_n and $\chi'_{|\phi|^2}$ to determine the phase boundary. However, while for $\eta = 9.0$ the positions of the maxima of χ'_n and $\chi'_{|\phi|^2}$ always match perfectly, for $\eta = 7.44$ this is the case only for temperatures up to $T/\mu_c \sim 0.5$. Consequently, at $\eta = 7.44$ we use different symbols for the maxima of χ'_n (upward pointing triangles) and $\chi'_{|\phi|^2}$ (triangles pointing downward). The two $\eta = 7.44$ points with $T/\mu_c < 0.5$ show matching maxima for χ'_n and $\chi'_{|\phi|^2}$ and fall on the curve set by the $\eta = 9.0$ data. Those points confirm (although with larger error bars) the picture of a second order line up to at least $T/\mu_c = 0.436$ from the $\eta = 9.0$ runs. For the larger temperatures $T/\mu_c > 0.5$ the third derivatives χ'_n and $\chi'_{|\phi|^2}$ peak at slightly different values. However, the positions of the maxima agree within error bars and we attribute the small discrepancy to the more severe finite volume effects for the $\eta = 7.44$ ensembles. The corresponding observables are shown in Fig. 8 where we plot $n, \chi_n, \langle |\phi|^2 \rangle$ and $\chi_{|\phi|^2}$ for $\eta = 7.44$ as a function of μ for several temperatures.

In Fig. 9 we repeat the finite volume study of Fig. 7 now for $\eta = 7.44$. We show the log-log plot of the maxima of χ'_n and $\chi'_{|\phi|^2}$ versus the spatial volume $V = N_s^3$. It is obvious that here the data do not as nicely fall on a straight line as in the corresponding plots for $\eta = 9.0$ shown in Fig. 7. We fit only the data points for the three largest volumes and as in Fig. 7 denote the slopes next to the lines. It is quite interesting to observe that the slope for the maxima of $\chi'_{|\phi|^2}$ remains at values close to 0.5 up to the largest temperatures, indicating that the susceptibility $\chi_{|\phi|^2}$ manages to develop a discontinuity in the thermodynamic limit also for our highest temperatures. The stronger finite volume effects at $\eta = 7.44$ make the analysis more difficult for χ'_n : The slopes for χ'_n are smaller for the smaller volumes but show a tendency towards pointing upwards for larger V, indicating second order behavior for the μ -derivatives also up to the highest temperatures we can access.

One expects that the second order line persists for large T due to the breaking of the U(1) symmetry at the transition to the condensed phase. In Fig. 10 we attempt a plausibility test for this scenario: We plot the height of

Figure 8: Results for n, χ_n , $\langle |\phi|^2 \rangle$ and $\chi_{|\phi|^2}$ for $\eta = 7.44$ and $N_s = 24$ as a function of μ for several temperatures corresponding to $N_t = 100, 20, 10, 8$ and 6. For T and μ we use units of μ_c , while n, χ_n , $\langle |\phi|^2 \rangle$ and $\chi_{|\phi|^2}$ are given in lattice units at a fixed scale (set by $\eta = 7.44, \lambda = 1.0$).

the maxima of the third derivatives χ'_n and $\chi'_{|\phi|^2}$ (both made dimensionless with suitable powers of μ_c) as a function of the inverse temperature in units of μ_c . We find that the maxima are non-zero at finite T and only for $1/T \longrightarrow 0$ the curves reach 0. Furthermore the maxima for the $\eta = 9.0$ runs are larger than those at $\eta = 7.44$ as expected from the larger volume at $\eta = 9.0$. Although this analysis is only an exploratory test at a fixed volume, it supports the existence of a phase transition throughout the phase diagram.

We conclude our presentation of the finite temperature results with the discussion of observables along two vertical cuts in the phase diagram Fig. 5. Using the $\eta = 9.0$ data at $N_s = 20$, in Fig. 11 we show the observables n,

Figure 9: Log-log plot of the maxima of the third derivatives of the free energy versus the 3-volume $V = N_s^3$ for $\eta = 7.44$ and $N_s = 12, 16, 20$ and 24. We compare different temperatures corresponding to $N_t = 100, 10, 6$ and 3. The straight lines are linear fits to the data (using only $N_s = 16, 20, 24$) and the numbers near the lines are the respective slopes.

 χ_n , $\langle |\phi|^2 \rangle$ and $\chi_{|\phi|^2}$ as a function of T/μ_c and compare two different values of the chemical potential. The vertical cut at $\mu/\mu_c = 1.012$ hits the phase boundary at $T/\mu_c \sim 0.2$, while the cut at $\mu/\mu_c = 0.977$ continues all the way to $T/\mu_c = 0$ without entering the condensed phase (compare Fig. 5). This behavior is clearly reflected in the observables: For the $\mu/\mu_c = 0.977$ data the particle number density n and the susceptibility χ_n both drop to zero as the temperature is decreased to $T/\mu_c = 0$, as expected for a value of the chemical potential in the Silver Blaze domain, i.e., $\mu < \mu_c$. The vacuum expectation value $\chi_{|\phi|^2}$ drops towards 0.237, while the corresponding susceptibility $\chi_{|\phi|^2}$ vanishes as $T/\mu_c \to 0$. For the cut at $\mu/\mu_c = 1.012$ the behavior is quite different: When decreasing the temperature down to $T/\mu_c \sim 0.2$, where the cut hits the phase boundary of the condensed phase, the susceptibilities show a drastic increase an then remain essentially constant for

Figure 10: Size of the maxima of the third derivatives χ'_n and $\chi'_{|\phi|^2}$ (both made dimensionless with suitable powers of μ_c) as a function of the inverse temperature in units of μ_c . We compare the results for $\eta = 9.0$ on $20^3 \times N_t$ lattices and $\eta = 7.44$ on $24^3 \times N_t$.

 $T/\mu_c < 0.2$. The particle number density *n* has a non-vanishing value at $T/\mu_c = 0$ and $\langle |\phi|^2 \rangle$ settles at a value of 0.285. The plots nicely demonstrate the temperature driven condensation of the system for $\mu/\mu_c = 1.012$ and its absence at $\mu/\mu_c = 0.977$.

6 Summary and discussion

In this work we have studied a charged scalar ϕ^4 field at finite density using the lattice formulation. The complex action problem of the standard form was overcome by mapping the partition sum to a flux representation where only real and non-negative terms appear. The system was updated with a generalized worm algorithm and we studied thermodynamical observables as a function of temperature and chemical potential.

For zero temperature the system undergoes a second order phase transition at some critical value μ_c that marks the end of the Silver Blaze region. For $\mu < \mu_c$ the observables are independent of μ , while above a strong μ dependence sets in. The critical value μ_c could very cleanly be identified from the narrow peaks of two 3rd derivatives of the free energy and in a small spectroscopy calculation we showed that μ_c coincides with the mass of

Figure 11: Results for n, χ_n , $\langle |\phi|^2 \rangle$ and $\chi_{|\phi|^2}$ for $\eta = 9.0$ and $N_s = 20$ as a function of T/μ_c for two different values of μ/μ_c .

the scalar field. A finite volume analysis established the second order nature of the transition.

Increasing the temperature we found that the critical line bends towards larger values of μ . For temperatures up to $T/\mu_c \sim 0.5$ we could reliably establish the continuation of second order behavior for finite T. At small but non-zero temperatures we found only a very weak dependence of observables on the chemical potential for values of μ below the critical value (pseudo Silver Blaze behavior). At the critical line we saw an abrupt change of physical observables marking the transition into the condensed phase characterized by strong μ -dependence. When studying our observables as a function of the temperature we could nicely illustrate the temperature driven condensation for $\mu/\mu_c = 1.012$ and the absence of condensation at $\mu/\mu_c = 0.977$. For the analysis of temperatures $T/\mu_c > 0.5$ we had to rely on finer lattices ($\eta = 7.44$) which, however, show considerably more severe finite size effects. For small temperatures the results match the results from our coarser ($\eta = 9.0$) lattices very well, but for $T/\mu_c > 0.5$ some of the observables – the ones related to the particle number density – were seriously affected by finite volume effects and thus gave inconclusive results about the nature of the transition between pseudo Silver Blaze behavior and the condensed phase with strong μ -dependence. The observables related to derivatives of the free energy with respect to the mass parameter, i.e., $\langle |\phi|^2 \rangle$, $\chi_{|\phi|^2}$ and $\chi'_{|\phi|^2}$, on the other hand indicate that a second order line could persist to temperatures considerably higher than $T/\mu_c \sim 0.5$. Lattice studies on large and fine lattices will be necessary to settle this issue.

Appendix: Pseudo-code for the worm algorithm

In this appendix we provide pseudo-code for the initialization of the worm and its subsequent steps. The worm algorithm that updates the variables $k_{x,\nu} \in \mathbb{Z}$ is set up in a fixed background of the variables $l_{x,\nu}$ generated with local Metropolis sweeps (see Section 3). The starting point of a worm will be denoted by x_0 , the position of its head by x, and Λ will be used for the set of all lattice sites. Δ is an equally distributed random variable with $\Delta \in \{-1, +1\}$ that determines whether the worm tries to increase or decrease the flux along its path. By $\nu \in \{\pm 1, \pm 2, \pm 3, \pm 4\}$ we denote the direction of the next attempted step of the worm, and in case ν is negative $(\nu = -|\nu|)$ we use the convention $k_{x,-|\nu|} = k_{x-|\widehat{\nu}|,|\nu|}$ for the assignment of the corresponding link variables. As in the main text we use the abbreviation $f_x = \sum_{\nu} [|k_{x,\nu}| + |k_{x-\widehat{\nu},\nu}| + 2(l_{x,\nu} + l_{x-\widehat{\nu},\nu})]$, and by \widetilde{f}_x we denote the same expression but evaluated with the variable $\widetilde{k}_{x,\nu}$ from the trial offer. Finally, rand() denotes a random generator for uniformly distributed random numbers in the interval [0, 1).

Starting the worm

while worm has not started

```
\Delta \in \{-1,+1\} randomly
choose
                x_0 \in \Lambda randomly
choose
choose \nu \in \{\pm 1, \pm 2, \pm 3, \pm 4\} randomly
k_{x_0,\nu} = k_{x_0,\nu} + \Delta * sign(\nu)
      |\widetilde{k}_{x_0,
u}| > |k_{x_0,
u}| then
if
          \rho = \exp\left(sign(\nu)\,\mu\,\Delta\,\delta_{|\nu|,4}\right) \times \left(|\widetilde{k}_{x_0,\nu}| + l_{x_0,\nu}\right)^{-1} \times W(f_{x_0+\widehat{\nu}})^{-1}
else
          \rho = \exp\left(sign(\nu)\,\mu\,\Delta\,\delta_{|\nu|,4}\right) \times \left(|k_{x_0,\nu}| + l_{x_0,\nu}\right) \times W(f_{x_0+\widehat{\nu}})^{-1}
endif
if
          rand() < \rho then
          store f_{x_0}
          k_{x_0,\nu} \longleftarrow k_{x_0,\nu}
          x = x_0 + \hat{\nu}
          worm has started
endif
```

end while

Running the worm
