Two-way Decode-and-Forward for Energy-Efficient Wireless Relaying: Selective Forwarding versus One-bit Soft Forwarding

Qing F. Zhou, Wai Ho Mow, Shengli Zhang and Dimitris Toumpakaris

Abstract

Motivated by applications such as battery-operated wireless sensor networks (WSN), we propose an easy-to-implement energy-efficient two-way relaying scheme. In particular, we address the challenge of improving the standard two-way selective decode-and-forward protocol (TW-SDF) in terms of blockerror-rate (BLER) with minor additional complexity and energy consumption. By following the principle of soft relaying, our solution is the two-way one-bit soft forwarding (TW-1bSF) protocol in which the relay forwards the one-bit quantization of a posterior information metric about the transmitted bits, associated with an appropriately designed reliability parameter.

In WSN-related standards (such as IEEE802.15.6 and Bluetooth), block codes are adopted instead of convolutional and other sophisticated codes, due to their efficient decoder hardware implementation. As the second main contribution, we derive tight upper bounds on the BLER performance for both TW-SDF and TW-1bSF, when the two-way relaying network employs block codes and hard decoding. The error probability analysis confirms the superiority of TW-1bSF. Moreover, we derive the asymptotic performance gain of TW-1bSF over TW-SDF, which further suggests that the proposed protocol is a good choice, especially when long block codes are used.

I. INTRODUCTION

Traditionally, the design of network protocols has mainly focused on how to maximize the throughput or bandwidth efficiency. Recently, the design of energy-efficient (a.k.a. green) wireless networks has generated considerable interest. Instead of the power consumption related to transmission, the term energy efficiency typically refers to the energy consumed by communication units to process signals, including encoding and decoding operations. For example, in some remote monitoring applications using wireless sensor networks (WSNs), the sensor nodes are expected to be of low cost and to have many years of battery life. Therefore, energy efficiency is the most critical design issue for such networks. Motivated by such application scenarios, in this paper we propose an easy-to-implement energy-efficient *two-way* relaying scheme in which two source nodes exchange their messages with the help of an intermediate relay node, and we evaluate its performance.

Applying the idea of network coding [1] to two-way relaying networks is particularly simple and fruitful. This is because network coding over the binary field (i.e. XOR) is sufficient for this topology. Moreover, under the setting of time-division multiple access, exchanging one pair of messages between the two nodes requires only three packet transmissions, instead of four when using routing. Here, the three-transmission relaying method is referred to as *direct network coding* (DNC). Allowing the source nodes to broadcast simultaneously, as proposed in physical-layer network coding (PNC) [2], [3] and analog network coding (ANC) [4], further reduces the number of transmissions to two, resulting in even higher spectral efficiency. However, these two spectrally efficient schemes are not amenable for wireless networks with energy efficiency requirements because of the need for accurate synchronization, sophisticated decoding at the relay, no use of the direct link, and accurate channel estimation [5], [6].

There are two variations of the two-way decode-and-forward protocols that are based on DNC, namely, non-selective and selective. In the non-selective two-way decode-and-forward (DF) protocol, the relay decodes both packets received from the two sources, and then broadcasts the network-coded (XOR) version of the two decoded packets regardless of whether the two decoded packets are erroneous or not. This effect of error propagation may result in serious performance degradation. A modification of the DF protocol is the *two-way selective decode-and-forward* (TW-SDF) protocol. In this protocol, a sufficiently strong CRC code is used to assess the correctness of the two decoded packets at the relay. The relay only processes the two decoded packets if they have both been decoded correctly and then broadcasts their network-coded combination. This approach effectively avoids error propagation, and can successfully recover the loss on the diversity order of the non-selective DF protocol. The decode-and-forward scheme

outperforms its demodulation-and-forward counterpart based on joint network-channel coding [7], [8].

In *one-way* relaying networks, the SDF protocol can be further improved by using the soft relaying technique [9], [10], [11], [12], [13]. Specifically, the relay uses a soft decoder to derive the *a posteriori* probabilities of the code bits, and then forwards the soft information values. At the desired receiver, the forwarded soft information values are exploited as a priori information by source-controlled soft decoders [14] to improve decoding performance. It is shown that performance improvement can be achieved over the SDF protocol with hard decoding, because in many occasions an incorrectly decoded packet contains only a few erroneous bits and the *a posteriori* information forwarded by the relay may help locate the position of the erroneous bits. However, the main disadvantage of the soft relaying protocol is that it requires significant additional bandwidth and/or power consumption, mainly due to the requirement of transmitting soft values or their multiple-bit quantized version and because of the use of complicated soft-input soft-output decoders. The key motivation behind our work is to simplify the soft relaying method by using only a one-bit quantized representation of the soft information, and hence avoid the bandwidth expansion associated with soft signal forwarding and the complexity because of soft decoding. To mitigate the error propagation due to the low-rate quantization, the quantized bit message is forwarded along with a reliability parameter, which is utilized by the decoder to estimate the equivalent LLR of the message from the relay. The so-constructed *one-bit soft forwarding* (1bSF) protocol is almost as easy to implement and as energy efficient as the SDF protocol that employs hard decoding [15] (see also [16]). In [17] preliminary results regarding the effectiveness of the protocol for one-way relay networks were obtained through computer simulation. In this paper, we extend the philosophy to two-way relaying systems by proposing the two-way 1bSF (TW-1bSF) protocol.

In the literature, the performance evaluation of various relaying protocols is typically carried out using the outage probability when applying ideal capacity-approaching codes at the relay(s) [18], [19], or via the symbol error rate (SER) in the absence of channel coding at the relay(s) [20], [21], [22]. To the best of the authors' knowledge, few works have analytically derived the performance of relaying protocols that use practical channel codes. These include the loose lower bound derivation of the BER for a Turbo-coded one-way relay system [23], and the approximate derivation of the block-error-rate (BLER) for a convolutional-coded one-way relay system [24], for an end-to-end coded two-hop detect-and-forward one-way relay system [25], and for a demodulation-and-forward scheme with network coding but no channel coding [26]. However, from the viewpoint of communication engineering, a tight upper bound is of higher practical importance. To bridge this gap, in this paper we derive tight BLER upper bounds for TW-SDF and TW-1bSF, when block codes are employed and hard decoding is used at the receivers.

We further derive the asymptotic performance gain of TW-1bSF over TW-SDF, and discuss the design of the reliability parameter to improve the performance of the proposed TW-1bSF protocol. The error probability analysis confirms the superiority of TW-1bSF. It further shows that the proposed protocol is a good choice, especially when long block codes are used.

II. SYSTEM MODEL AND RELATED WORK

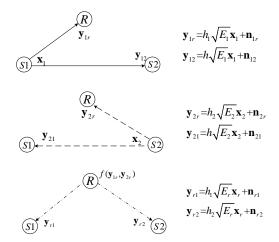

Fig. 1. Two-way relaying based on direct network coding (DNC).

We consider a three-node two-way wireless relaying network. In this network, two sources S1 and S2 exchange their information messages with the help of a relay R. The messages are encoded to protect them against channel impairments. Fig.1 shows the discrete-time model of DNC-based two-way relaying over this network. During the first time slot, S1 broadcasts a vector \mathbf{x}_1 containing the encoded message to R and S2, using power E_1 . The received signal vectors at R and S2 are \mathbf{y}_{1r} and \mathbf{y}_{12} , respectively. During the second time slot, S2 broadcasts \mathbf{x}_2 using power E_2 . The received signal vectors at R and S1 are \mathbf{y}_{2r} and \mathbf{y}_{21} , respectively. After receiving the signals \mathbf{y}_{1r} and \mathbf{y}_{2r} , the relay generates a signal vector $\mathbf{x}_r = f(\mathbf{y}_{1r}, \mathbf{y}_{2r})$ for forwarding, where $f(\cdot, \cdot)$ is a mapping determined by the relaying scheme. Without loss of generality, it is assumed that the power of \mathbf{x}_r is normalized to 1. During the third time slot, R broadcasts \mathbf{x}_r with power E_r . The signal vectors received at S1 and S2 are \mathbf{y}_{r1} and \mathbf{y}_{r2} , respectively.

In this system model, $\mathbf{x}_i = [x_{i,1}, x_{i,2}, \cdots, x_{i,n}]^T \in \mathcal{X}^n$ with $i \in \{1, 2\}$ and $x_{i,m} \in \{+1, -1\} = \mathcal{X}$, i.e., we assume that BPSK modulation is employed. The same encoder, and therefore the same codebook is used by both sources. In addition, $\mathbf{y}_{ij} = \{y_{ij,m}\}_{m=1}^n$ represents the received signal vector at node $j \in \{1, 2, r\}$ (r for R, 1 for S1, 2 for S2) from node i; h, h_1 and h_2 are the channel coefficients of the S1-S2 link (direct link), the S1-R link and the S2-R link, respectively, and all are reciprocal; \mathbf{n}_{ij} are noise vectors at receiver j with independent identically-distributed (i.i.d.) Gaussian entries $\sim \mathcal{N}(0, \sigma_j^2)$. We assume that the channel coefficients are fixed during the three slots of the two-way relaying transmission scheme. Moreover, as can been seen in Fig. 1, flat fading is assumed. We also assume that all noise terms have the same normalized variance $\sigma_r^2 = \sigma_1^2 = \sigma_2^2 = N_0/2 = 1/2$, and that the sources utilize the same power $E_1 = E_2 = E$. Note that in this system model, all terms are real-valued because of the use of BPSK modulation.

In the DNC-based two-way relaying method, it is crucial to carefully design the mapping function $f(\mathbf{y}_{1r}, \mathbf{y}_{2r})$ such that both messages can be decoded by their desired receivers. It is even more desirable to optimize it to achieve the best performance in terms of capacity or bit error rate. Using the concept of SDF to design $f(\mathbf{y}_{1r}, \mathbf{y}_{2r})$ leads to the TW-SDF protocol, which is described in the following.

A. Two-way SDF Relaying Protocol (TW-SDF)

The relay R decodes \mathbf{y}_{1r} and \mathbf{y}_{2r} at the end of the first and the second time slot, respectively, to generate $\hat{\mathbf{x}}_{1r}$ and $\hat{\mathbf{x}}_{2r}$, i.e., the estimates of \mathbf{x}_1 and \mathbf{x}_2 . Then the relay combines $\hat{\mathbf{x}}_{1r}$ and $\hat{\mathbf{x}}_{2r}$ using network coding, and forwards the network-coded vector \mathbf{x}_r to the sources during the third time slot. If any of the $\hat{\mathbf{x}}_{1r}$ and $\hat{\mathbf{x}}_{2r}$ is erroneously decoded, the decoding error will propagate from R to the sources, leading to performance degradation. To eliminate this detrimental effect, TW-SDF does not allow R to forward erroneous information by forming the forwarded signal vector as

$$\mathbf{x}_{r}^{\text{TW-SDF}} = \begin{cases} \mathbf{x}_{1} \circ \mathbf{x}_{2}, & \text{if } \hat{\mathbf{x}}_{1r} = \mathbf{x}_{1} \text{ and } \hat{\mathbf{x}}_{2r} = \mathbf{x}_{2} \\ & \text{Nil}, & \text{otherwise} \end{cases}$$
(1)

where \circ denotes the Hadamard product, which is the element-wise XOR operation in the modulated signal domain¹. In (1), Nil represents no transmission. Note that $\hat{\mathbf{x}}_{ir} = \mathbf{x}_i$ means that no error is detected by, e.g., an error-detection code.

To demonstrate the decoding algorithm at the source nodes, we focus on the receiving process at S2 without loss of generality. After the third time slot, S2 has the received signals y_{12} and y_{r2} . While y_{12} is affected by Gaussian noise only, y_{r2} is distorted by Gaussian noise and the transmitted codeword x_2

¹Let $x_i = (-1)^{b_i}$, $b_i \in \{0, 1\}$ represent BPSK modulation. The value of the XOR operation of two bits is given by $(-1)^{b_i \oplus b_j} = (-1)^{b_i} (-1)^{b_j} = x_i x_j$. So, the XOR operation in the BPSK modulated signal domain is $x_r = x_i x_j$.

from S2. Since S2 knows the transmitted codeword of its own, it can remove the contamination caused by \mathbf{x}_2 from \mathbf{y}_{r2} , and generate a new detection statistic

$$\tilde{\mathbf{y}}_{r2} \triangleq \mathbf{y}_{r2} \circ \mathbf{x}_{2} = h_{2} \sqrt{E_{r}} \mathbf{x}_{r}^{\text{TW-SDF}} \circ \mathbf{x}_{2} + \tilde{\mathbf{n}}_{r2}, \qquad (2)$$

where $\tilde{\mathbf{n}}_{r2} = \mathbf{n}_{r2} \circ \mathbf{x}_2$ is a vector of i.i.d. Gaussian r.v's $\sim \mathcal{N}(0, N_0/2)$. If $\hat{\mathbf{x}}_{ir} = \mathbf{x}_i$, then $\tilde{\mathbf{y}}_{r2} = h_2 \sqrt{E_r} \mathbf{x}_1 + \tilde{\mathbf{n}}_{r2}$. By summing \mathbf{y}_{12} and $\tilde{\mathbf{y}}_{r2}$ using maximal ratio combining (MRC), S2 can decode the codeword \mathbf{x}_1 as

$$\hat{\mathbf{x}}_{1}^{\text{TW-SDF}} = \begin{cases} \mathfrak{Dec}(4h\sqrt{E}\mathbf{y}_{12} + 4h_2\sqrt{E_r}\tilde{\mathbf{y}}_{r2}), & \text{if } \hat{\mathbf{x}}_{ir} = \mathbf{x}_i \\ \\ \mathfrak{Dec}(4h\sqrt{E}\mathbf{y}_{12}), & \text{otherwise} \end{cases}$$
(3)

where \mathfrak{Dec} represents a decoding algorithm.

III. TWO-WAY ONE-BIT SOFT FORWARDING (TW-1BSF) PROTOCOL

In this paper, our aim is to improve the TW-SDF protocol by leveraging the soft relaying principle, while using negligible additional bandwidth and by keeping the decoding algorithm simple such that the energy efficiency requirement can be met. The main idea is to always transmit during the third time slot even when a $\hat{\mathbf{x}}_{ir}$ is in error. Moreover, one indicator bit for the entire forwarded packet is transmitted. As will be shown, this leads to significant performance improvement compared to the TW-SDF protocol. Because the one-bit indicator corresponds to the entire packet of length *n*, the required additional bandwidth is negligible.

A. Design of TW-1bSF

The *a posteriori* soft output for each message/code bit, typically the LLR, is composed of a sign component and a reliability component. Using the entries of the received signal vector $\{y_{ir,m}\}_{m=1}^{n}$, the LLR of $x_{i,m}$ can be calculated as

$$LLR(x_{i,m}|y_{ir,m}) = 4h_i \sqrt{Ey_{ir,m}}.$$
(4)

In (4) we have used the fact that BPSK is employed. In vector form, the LLR of x_i based on y_{ir} is

$$LLR(\mathbf{x}_i|\mathbf{y}_{ir}) = 4h_i \sqrt{E} \mathbf{y}_{ir}.$$
(5)

As shown in [14], the LLR of the network coded vector $\mathbf{x}_1 \circ \mathbf{x}_2$ based on \mathbf{y}_{1r} and \mathbf{y}_{2r} is given by

$$LLR(\mathbf{x}_{1} \circ \mathbf{x}_{2} | \mathbf{y}_{1r}, \mathbf{y}_{2r}) = \left\{ Sign(y_{1r,m}y_{2r,m}) \times \min\{|4h_{1}\sqrt{E}y_{1r,m}|, |4h_{2}\sqrt{E}y_{2r,m}|\} \right\}_{m=1}^{n}.$$
 (6)

Methods of broadcasting the LLR vector of (6) to both end nodes have been studied widely. This is also known as soft network coding (SoftNC) [27], [28]. They are quite similar to analog network coding (ANC), and thus also suffer from large peak-to-average power ratio (PAPR), noise propagation and other drawbacks associated with analog communication. One solution is to quantize each soft value and then broadcast the quantized information using high-level modulation. However, besides quantization errors, high-level modulation incurs larger transmission power in order to meet the BER requirement when using PSK, or larger bandwidth when FSK is employed. Our solution is to quantize each soft output of the relay decoder to one bit, exactly as in the case of TW-SDF. We then form \mathbf{x}_r as the network-coded combination of the two vectors of quantized bits. Thus, $\mathbf{x}_r^{\text{TW-1bSF}} = \hat{\mathbf{x}}_{1r} \circ \hat{\mathbf{x}}_{2r}$. Unlike TW-SDF, $\mathbf{x}_r^{\text{TW-1bSF}}$ is forwarded even when $\hat{\mathbf{x}}_{1r} \neq \mathbf{x}_1$ or $\hat{\mathbf{x}}_{2r} \neq \mathbf{x}_2$.

Furthermore, R generates a scalar value to measure the reliability of the network-coded vector, and then broadcasts it to the receivers (similar to the equivalent SNR approach in [24]), or the receivers calculate the reliability value by themselves. Each receiver uses y_{ri} and the associated reliability value as *a priori* information to enhance the decoding performance of the signal vector received through the direct link. Thus the name *two-way one-bit soft forwarding* (TW-1bSF) for the protocol that uses this relaying approach.

We note here that we can implement the TW-1bSF protocol in several ways. However, in this paper, we use the simple implementation method described above, i.e., $\mathbf{x}_r^{\text{TW-1bSF}} = \hat{\mathbf{x}}_{1r} \circ \hat{\mathbf{x}}_{2r}$ is always forwarded during the third time slot, unlike TW-SDF. An indicator bit is embedded in the overhead of the forwarded frame as, for example, in the COPE protocol [29], [30]. Then the receivers can calculate the reliability value based on the indicator bit and the channel information.

B. Design of reliability value

If \mathbf{x}_1 can be successfully decoded from either of \mathbf{y}_{12} and $\tilde{\mathbf{y}}_{r2}$, then the transmission succeeds. So, in the following we consider the detection of \mathbf{x}_1 at S2 based on both \mathbf{y}_{12} and $\tilde{\mathbf{y}}_{r2}$, assuming that decoding is not successful from either of them. The aim of TW-1bSF is to make \mathbf{y}_{r2} useful even if an error has occurred in $\hat{\mathbf{x}}_{1r}$ or $\hat{\mathbf{x}}_{2r}$. Let \mathbf{L}_{r2} be the LLR vector of the target message \mathbf{x}_1 in TW-1bSF obtained by $\tilde{\mathbf{y}}_{r2}$, i.e., $\mathbf{L}_{r2} = \text{LLR}(\mathbf{x}_1|\tilde{\mathbf{y}}_{r2})$. By regarding \mathbf{L}_{r2} as the LLR of the S1 - R - S2 path and using the decoding method of [14], S2 can decode using the received signal vector \mathbf{y}_{12} as follows

$$\hat{\mathbf{x}}_{1} = \underset{\mathbf{x}\in\mathcal{X}^{c(n)}}{\operatorname{argmax}} \left(\langle 4h\sqrt{E}\mathbf{y}_{12}, \mathbf{x} \rangle + \langle \mathbf{L}_{r2}, \mathbf{x} \rangle \right)$$
$$= \underset{\mathbf{x}\in\mathcal{X}^{c(n)}}{\operatorname{argmax}} \left(4h\sqrt{E}\mathbf{y}_{12}^{T}\mathbf{x} + \mathbf{L}_{r2}^{T}\mathbf{x} \right)$$

$$= \underset{\mathbf{x}\in\mathcal{X}^{c(n)}}{\operatorname{argmin}} \left(-4h\sqrt{E}\mathbf{y}_{12}^{T}\mathbf{x} - \mathbf{L}_{r2}^{T}\mathbf{x} \right)$$
$$= \underset{\mathbf{x}\in\mathcal{X}^{c(n)}}{\operatorname{argmin}} (4h\sqrt{E}\mathbf{y}_{12} + \mathbf{L}_{r2} - \mathbf{x})^{T} (4h\sqrt{E}\mathbf{y}_{12} + \mathbf{L}_{r2} - \mathbf{x})$$
$$= \underset{\mathbf{x}\in\mathcal{X}^{c(n)}}{\operatorname{argmin}} \|4h\sqrt{E}\mathbf{y}_{12} + \mathbf{L}_{r2} - \mathbf{x}\|,$$
(7)

where $\langle \cdot, \cdot \rangle$ represents the inner product, $\|\cdot\|$ represents the l_2 norm, and $(\cdot)^T$ represents the matrix transposition.

Next, to design \mathbf{L}_{r2} we distinguish three different cases, depending on whether a decoding error occurs for $\hat{\mathbf{x}}_{1r}$ and $\hat{\mathbf{x}}_{2r}$ at R, and whether the forwarded network-coded packet \mathbf{x}_r is correctly decoded at the receiver.

Let $\mathfrak{D}(\mathbf{y})$ be a hard-output decoder. Then $\mathfrak{D}(\mathbf{y}) \in \mathcal{X}^n$ for $\forall \mathbf{y}$. We define the following erroneous decoding events

$$\mathcal{E} \triangleq \{ \hat{\mathbf{x}}_1 \neq \mathbf{x}_1 \}, \quad \mathcal{E}_{12} \triangleq \{ \mathfrak{D}(\mathbf{y}_{12}) \neq \mathbf{x}_1 \}, \quad \mathcal{E}_{1r} \triangleq \{ \hat{\mathbf{x}}_{1r} \neq \mathbf{x}_1 \},$$

$$\mathcal{E}_{2r} \triangleq \{ \hat{\mathbf{x}}_{2r} \neq \mathbf{x}_2 \}, \quad \mathcal{E}_{r2} \triangleq \{ \mathfrak{D}(\tilde{\mathbf{y}}_{r2}) \neq \mathbf{x}_r \circ \mathbf{x}_2 \}.$$
(8)

In addition, let A^c denote the complement of an error event A, i.e. the event of correct decoding, for example, $\mathcal{E}^c = {\hat{\mathbf{x}}_1 = \mathbf{x}_1}$.

In the following, we introduce the three cases and the corresponding design of L_{r2} .

Case I: This is the case where x̂_{1r} and x̂_{2r} are both correctly decoded, i.e., x̂_{1r} = x₁ and x̂_{2r} = x₂, but the forwarded signal x_r is not correctly decoded at S2, i.e., D(y_{r2}) ≠ x_r. It is denoted by Θ_I ≜ E₁₂ ∩ E^c_{2r} ∩ E_{r2}. In this case, from (2), ỹ_{r2} = h₂√E_rx₁ + ñ_{r2}, so we simply have

$$\mathbf{L}_{r2} = \{ \mathrm{LLR}(x_{1,m} | \tilde{y}_{r2,m}) \}_{m=1}^{n} = 4h_2 \sqrt{E_r} \tilde{\mathbf{y}}_{r2}.$$
(9)

Comparing (9) with (3) shows that in this case TW-1bSF and TW-SDF have the same decoding results.

Case II: This is the case where at least one of x̂_{1r} and x̂_{2r} is incorrectly decoded, i.e., E_{1r} ∪ E_{2r}, but x_r is correctly decoded at S2, and is denoted by Θ_{II} ≜ E₁₂ ∩ (E_{1r} ∪ E_{2r}) ∩ E^c_{r2}. In this case, we let

$$\mathbf{L}_{r2} = (\mathfrak{D}(\mathbf{y}_{r2}) \circ \mathbf{x}_2)\mathcal{L} = (\mathbf{x}_r \circ \mathbf{x}_2)\mathcal{L}, \tag{10}$$

where \mathcal{L} is a scalar value measuring the reliability of the forwarded vector \mathbf{x}_r . This case can be further decomposed into three disjoint subcases as $\Theta_{II} = \Theta_{IIa} \cup \Theta_{IIb} \cup \Theta_{IIc}$, where $\Theta_{IIa} \triangleq \mathcal{E}_{12} \cap \mathcal{E}_{1r} \cap \mathcal{E}_{2r}^c \cap \mathcal{E}_{r2}^c$, $\Theta_{IIb} \triangleq \mathcal{E}_{12} \cap \mathcal{E}_{1r}^c \cap \mathcal{E}_{2r} \cap \mathcal{E}_{r2}^c$ and $\Theta_{IIc} \triangleq \mathcal{E}_{12} \cap \mathcal{E}_{1r} \cap \mathcal{E}_{2r} \cap \mathcal{E}_{r2}^c$. Case III: This is the case where at least one of x̂_{1r} and x̂_{2r} is incorrectly decoded, and x_r is not correctly decoded at S2 either. It is denoted by Θ_{III} ≜ E₁₂ ∩ (E_{1r} ∪ E_{2r}) ∩ E_{r2}. In this case, we let

$$\mathbf{L}_{r2} = \mathfrak{D}(\tilde{\mathbf{y}}_{r2})\mathcal{L}^{-},\tag{11}$$

where \mathcal{L}^- is the scalar reliability value for Case III. In summary,

$$\mathbf{L}_{r2} = \begin{cases} 4h_2 \sqrt{E_r} \tilde{\mathbf{y}}_{r2}, & \text{for Case I} \\ (\mathbf{x}_r \circ \mathbf{x}_2) \mathcal{L}, & \text{for Case II} \\ \mathfrak{D}(\tilde{\mathbf{y}}_{r2}) \mathcal{L}^-, & \text{for Case III} \end{cases}$$
(12)

We then design \mathcal{L} and \mathcal{L}^- . According to (6), the scalar reliability value \mathcal{L} of Case II should be a function of the reliability values $\{4\sqrt{E}\min\{|h_1y_{1r,m}|, |h_2y_{2r,m}|\}\}_{m=1,2,...,n}$. Note that

$$4\sqrt{E}\min\{|h_1y_{1r,m}|, |h_2y_{2r,m}|\} = \min\left\{\log\frac{\exp(-\frac{(y_{1r,m}-h_1\sqrt{E})^2}{2\sigma_r^2})}{\exp(-\frac{(y_{1r,m}+h_1\sqrt{E})^2}{2\sigma_r^2})}, \log\frac{\exp(-\frac{(y_{2r,m}-h_2\sqrt{E})^2}{2\sigma_r^2})}{\exp(-\frac{(y_{2r,m}+h_2\sqrt{E})^2}{2\sigma_r^2})}\right\}.$$
 (13)

We have a few options on choosing \mathcal{L} , such as taking the arithmetic average of the reliability values. Alternatively, simply exploiting the relationship between the LLR and the raw bit error rate,

$$\frac{1-p_{1r}}{p_{1r}} = \frac{\int_0^\infty \frac{1}{\sqrt{2\pi\sigma_r^2}} \exp\left(-\frac{(y_{1r,m}-h_1\sqrt{E})^2}{2\sigma_r^2}\right) \mathrm{d}y_{1r,m}}{\int_0^\infty \frac{1}{\sqrt{2\pi\sigma_r^2}} \exp\left(-\frac{(y_{1r,m}+h_1\sqrt{E})^2}{2\sigma_r^2}\right) \mathrm{d}y_{1r,m}},\tag{14}$$

and we can set the reliability value for Case II as

$$\mathcal{L} = \min\left(\log\frac{1 - p_{1r}}{p_{1r}}, \log\frac{1 - p_{2r}}{p_{2r}}\right),$$
(15)

where $p_{1r} = Q(\sqrt{2h_1^2 E})$ is the channel bit error rate of the S1-R link, $p_{2r} = Q(\sqrt{2h_2^2 E})$ is the channel bit error rate of the S2-R link, and $Q(\cdot)$ is the Gaussian Q function. In (13), the likelihood is measured using the probability density function, whereas in (14) the likelihood is given by the cumulative density function, which is unrelated to the individual received symbols $y_{1r,m}$ (or $y_{2r,m}$).

Using the same principle as in (15), the reliability value for Case III can be set to

$$\mathcal{L}^{-} = \log \frac{1 - (1 - (1 - p_{1r})(1 - p_{2r}))}{1 - (1 - p_{1r})(1 - p_{2r})} = \log \frac{(1 - p_{1r})(1 - p_{2r})}{1 - (1 - p_{1r})(1 - p_{2r})},$$
(16)

where $1 - (1 - p_{1r})(1 - p_{2r})$ is the probability that at least one of the S1-R and the S2-R links is in error. Here we choose \mathcal{L}^- intuitively. In Section V we will discuss the impact of the choice of \mathcal{L} and \mathcal{L}^- on the error performance.

Remark 1. As in COPE [29], the end nodes use an indicator bit embedded in the overhead and the CRC associated with $\mathbf{x}_r^{\text{TW-1bSF}}$ to identify the cases that the forwarded message belongs to. Specifically, if the

indicator bit is 1, it signals Case I, otherwise Case II or Case III. When the indicator bit is 0, if the received signal vector \mathbf{y}_{r2} passes the CRC check, then the destination proceeds according to Case II, otherwise Case III. Here we assume that each end node knows the channel coefficients h_1 and h_2 . Hence, it can obtain \mathcal{L} and \mathcal{L}^- by calculating p_{1r} and p_{2r} from the link coefficients and then substituting them into (15) and (16).

C. Selection of the Channel Code and the Decoder

Many channel codes are applicable to the proposed TW-1bSF protocol. However, for WSNs with limited energy and computation capability, simple block codes like Hamming or BCH codes are preferable. In particular, BCH codes with a syndrome decoder that uses the Berlekamp-Massey (BM) and Chien's search (CS) algorithm are 15% more energy efficient than the best performing convolutional codes [31]. Therefore, in the sequel, we study the TW-1bSF protocol when Hamming or BCH codes are applied, and hard decoders are employed at the receiving ends. Consequently, the decoder (7) can be rewritten as

$$\hat{\mathbf{x}}_{1}^{\text{TW-1bSF}} = \mathfrak{D}(\mathbf{L}_{d}), \tag{17}$$

where $\mathbf{L}_d \triangleq 4h\sqrt{E}\mathbf{y}_{12} + \mathbf{L}_{r2}$.

For most practical block codes, the minimum distance is an odd number, conventionally denoted by 2t + 1, where t is known as the correcting capacity. Therefore, in the following analysis we consider block codes with minimum distance 2t + 1.

IV. PERFORMANCE ANALYSIS OF TW-SDF AND TW-1BSF

This section analyzes the performance of the TW-SDF and the TW-1bSF protocols in terms of block error rate (BLER). It is assumed that the messages are encoded using block codes, whereas the receiving sources employ hard decoders, as described in Section III.

Without loss of generality, we consider the detection of x_1 at S2. We derive the BLER of the codewords transmitted from S1 to S2, defined as

$$P^{(\mathbf{x}_1)} \triangleq \Pr(\hat{\mathbf{x}}_1 \neq \mathbf{x}_1).$$
(18)

A. Background

Recall that in the two-way relaying network, there are four point-to-point links associated with the transmission of \mathbf{x}_1 , i.e., $S1 \rightarrow S2$, $S1 \rightarrow R$, $S2 \rightarrow R$ and $R \rightarrow S2$, denoted as $\{12, 1r, 2r, r2\}$, respectively. We first derive the BLER of these links based on their raw bit error rates $p_{12} = Q(\sqrt{2h^2 E})$,

 $p_{1r} = Q(\sqrt{2h_1^2 E}), p_{2r} = Q(\sqrt{2h_2^2 E})$ and $p_{r2} = Q(\sqrt{2h_2^2 E_r})$. No matter which specific hard decoding method is applied, we can upper and lower bound the BLER of a link by using the performance of the *bounded distance decoder* (BDD). Assuming that a decoding error occurs if the received word falls *outside* the decoding sphere of the *transmitted* codeword [32], we obtain the upper bound

$$\widehat{P}_i = 1 - \sum_{k=0}^t \binom{n}{k} p_i^k (1 - p_i)^{(n-k)},$$
(19)

where $i \in \{12, 1r, 2r, r2\}$. On the other hand, assuming that a decoding error occurs only if the received words fall *inside* the decoding spheres of the codewords that have not been transmitted, we obtain the lower bound

$$\widetilde{P}'_{i} = \sum_{k=2t+1}^{n} \beta'_{k}(p_{i}) = \sum_{k=2t+1}^{n} A_{k} \sum_{m=0}^{t} \sum_{j=0}^{\min(m,n-k)} \binom{k}{m-j} \binom{n-k}{j} \times p_{i}^{k-m+2j} (1-p_{i})^{n-k+m-2j},$$
(20)

where A_k is the number of the codewords with Hamming weight k; $\beta'_k(p_i)$ lower bounds the probability that the codeword to which the received word is decoded has Hamming distance k from the transmitted codeword. Note that in (20) we have assumed, without loss of generality, that the all-zero codeword has been transmitted. However, except for perfect codes, the lower bound (20) is too loose to accurately predict the BLER of any practical hard decoder. This is because it does not take into account undecodable sequences that are outside the Hamming spheres of any codewords. Among the dominant part of the undecodable received words, i.e., the $\binom{n}{t+1}$ received words of weight t + 1, the lower bound (20) only accounts for $A_{2t+1}\binom{2t+1}{t}$ words that are inside the Hamming spheres of the codewords of weight 2t + 1.

B. A tighter lower bound

Here, we propose a lower bound that is tighter than (20). Suppose, again, that the all-zero codeword is transmitted. Since the correcting capability is t, the received words of Hamming weight t + 1 are not guaranteed to be correctly decoded, and which codewords they will be decoded to depends on the decoding method. We denote the number of the received words of weight t+1 that are decoded to wrong codewords of weight k by W_k . We call W_k , $2t + 1 \le k \le n$ the sphere partitioning function (SPF). The SPF partitions the surface of the radius-(t + 1) sphere centered at the transmitted zero codeword. Note that $W_0 \ne 0$ for almost all codes and hard decoders. If W_k for a given hard decoder $\mathfrak{D}(\cdot)$ is known, the following lemma provides a tighter lower bound on the BLER of the hard decoder.

Lemma 1 (Intrinsic Lower Bound of Hard Decoder). Given a hard decoder $\mathfrak{D}(\cdot)$ of SPF W_k and a link of raw BER p_i , the BLER of the link when $\mathfrak{D}(\cdot)$ is used is lower bounded by (21).

$$\underbrace{\breve{P}_{i}}_{\beta_{2t+1}(p_{i})} = \underbrace{\beta_{2t+1}'(p_{i}) + \left(W_{2t+1} - A_{2t+1}\binom{2t+1}{t}\right) p_{i}^{t+1}(1-p_{i})^{n-t-1}}_{\beta_{2t+1}(p_{i})} + \underbrace{\sum_{k=2t+2}^{n} \beta_{k}(p_{i}) + W_{k}p_{i}^{t+1}(1-p_{i})^{n-t-1}}_{\beta_{k}(p_{i})}}_{\beta_{k}(p_{i})}$$
(21)

Proof: Given the transmission of the zero codeword, consider all the received words of weight t+1. If the hard decoder's SPF W_k is known, it is clear that except for the $A_{2t+1}\binom{2t+1}{t}$ words included in (20), additional $W_{2t+1} - A_{2t+1}\binom{2t+1}{t}$ words are decoded to wrong codewords of weight 2t + 1, and $\sum_{k=2t+2}^{n} W_k$ words are decoded to wrong codewords of weight k > 2t + 1. This concludes the proof of the lemma.

Note that with $\beta_k(p_i)$ defined as in (21), $\beta_k(p_i) > \beta'_k(p_i)$, $k \in \{2t + 1, \dots, n\}$, so the lower bound (21) is tighter than (20).

C. Preliminary results

Recall that all receivers utilize the same energy-efficient hard decoder with SPF W_k . Due to the equiprobability of the codewords and the linearity of block codes, the BLER of \mathbf{x}_1 at S2 equals the conditional BLER given the transmission of $\mathbf{x}_1 = \mathbf{x}_2 = \{+1\}_{m=1}^n = \mathbf{1}$, which are the BPSK modulated signal vectors that correspond to the all-zero codewords. The following analysis is carried out under the assumption that $\mathbf{x}_1 = \mathbf{x}_2 = \mathbf{1}$, which is omitted from now on for simplicity.

By decomposing TW-SDF transmission into disjoint cases, its BLER can be expressed as

$$P_{\text{TW-SDF}}^{(\mathbf{x}_{1})} = P(\mathcal{E}, \Theta_{\text{I}}) + P(\mathcal{E}, \Theta_{\text{II}} \cup \Theta_{\text{III}}) = P(\mathcal{E}, \Theta_{\text{I}}) + P(\Theta_{\text{II}} \cup \Theta_{\text{III}}).$$
(22)

Similarly, for TW-1bSF,

$$P_{\text{TW-lbSF}}^{(\mathbf{x}_{1})} = P(\mathcal{E}, \Theta_{\text{I}} \cup \Theta_{\text{II}} \cup \Theta_{\text{II}}) = P(\mathcal{E}, \Theta_{\text{I}}) + P(\mathcal{E}, \Theta_{\text{II}}) + P(\mathcal{E}, \Theta_{\text{III}}).$$
(23)

We define $d(\mathbf{y}) \triangleq |\{\tau \in \{1, 2, \dots, n\} : y_{\tau} < 0\}|$ as the number of negative elements in a vector (or scalar) **y**. Because $\mathbf{x}_1 = \mathbf{x}_2 = \mathbf{1}$, the following three properties will be used in the following BLER analysis.

- 1) A raw bit is *in error* if the corresponding signal $y_{\tau} < 0$ for $\tau \in \{1, \dots, n\}$, i.e., $d(y_{\tau}) = 1$;
- If the received signal vector y is decoded erroneously, then the decoded codeword has weight at least 2t + 1, i.e., d(D(y)) ≥ 2t + 1;
- 3) When a Bounded Distance Decoder (BDD) is used at receiver *i*, \mathbf{y}_i is correctly decoded iff $d(\mathbf{y}_i) \leq t$.

To distinguish from the events in (8), if a BDD is used, we denote the decoding error event at the receiver of link *i* as $\hat{\mathcal{E}}_i$. Then the probability of this error event is $P(\hat{\mathcal{E}}_i) = \hat{P}_i$ as given by (19). Also denote

$$\dot{\Theta}_j \triangleq \{\Theta_j : \mathfrak{D} \text{ is a BDD for link } i \in \{12, 1r, 2r, r2\}\}$$
(24)

with $j \in \{I, II, III\}$. Specifically, $\dot{\Theta}_{I} = \dot{\mathcal{E}}_{12} \cap \dot{\mathcal{E}}_{1r}^{c} \cap \dot{\mathcal{E}}_{2r}^{c} \cap \dot{\mathcal{E}}_{r2}$, $\dot{\Theta}_{II} = \dot{\mathcal{E}}_{12} \cap (\dot{\mathcal{E}}_{1r} \cup \dot{\mathcal{E}}_{2r}) \cap \dot{\mathcal{E}}_{r2}^{c}$ and $\dot{\Theta}_{III} = \dot{\mathcal{E}}_{12} \cap (\dot{\mathcal{E}}_{1r} \cup \dot{\mathcal{E}}_{2r}) \cap \dot{\mathcal{E}}_{r2}$.

We start with the analysis of $P(\mathcal{E}, \Theta_{\rm I})$, since it is the common term of $P_{\rm TW-SDF}^{(\mathbf{x}_{\rm I})}$ and $P_{\rm TW-IbSF}^{(\mathbf{x}_{\rm I})}$. The event $\Theta_{\rm I}$ is decoder-dependent, and its probability is usually hard to determine, if not impossible. Alternatively, we examine its worst-decoder counterpart, $\dot{\Theta}_{\rm I}$, and derive a upper bound of $P(\mathcal{E}, \dot{\Theta}_{\rm I})$. From the definition of $\dot{\Theta}_{\rm I}$, and the fact that the BDD is the worst hard decoder in terms of error performance, we have

$$P(\mathcal{E}, \dot{\Theta}_{\mathrm{I}}) \le P(\dot{\mathcal{E}}, \dot{\Theta}_{\mathrm{I}}) = P(\dot{\Theta}_{\mathrm{I}}) - P(\dot{\mathcal{E}}^{c}, \dot{\Theta}_{\mathrm{I}}) = \widehat{P}_{12} (1 - \widehat{P}_{1r})(1 - \widehat{P}_{2r}) \ \widehat{P}_{r2} - P(\dot{\mathcal{E}}^{c}, \dot{\Theta}_{\mathrm{I}}).$$
(25)

The term $P(\dot{\mathcal{E}}^c, \dot{\Theta}_I)$ in (25) is given by the following theorem.

Theorem 1. $P(\dot{\mathcal{E}}^c, \dot{\Theta}_I)$ can be calculated as (26),

$$P(\dot{\mathcal{E}}^{c}, \dot{\Theta}_{I}) \triangleq (1 - \hat{P}_{1r})(1 - \hat{P}_{2r}) \sum_{k=t+1}^{n-1} {n \choose k} \sum_{m=\max(0,t+1-(n-k))}^{t} \sum_{i=t+1}^{m+n-k} {k \choose m} {n-k \choose i-m} p_{I}^{n-k-(i-m)} q_{I}^{m}$$
$$\times \sum_{g=0}^{t-m} \sum_{j=0}^{g} {k-m \choose j} \dot{p}_{I}^{j} \dot{q}_{I}^{k-m-j} {i-m \choose g-j} \ddot{p}_{I}^{g-j} \ddot{q}_{I}^{i-m-(g-j)}.$$
(26)

where

$$\begin{cases} p_{\rm I} = (1 - p_{r2}) (1 - p_{12}), & q_{\rm I} = p_{12} p_{r2}, & \dot{p}_{\rm I} = {\rm mvnCDF}([0, 0], \boldsymbol{\mu}_1, \boldsymbol{\Sigma}_1), \\ \dot{q}_{\rm I} = p_{r2} (1 - p_{12}) - \dot{p}_{\rm I}, & \ddot{p}_{\rm I} = {\rm mvnCDF}([0, 0], \boldsymbol{\mu}_2, \boldsymbol{\Sigma}_2), & \ddot{q}_{\rm I} = p_{12} (1 - p_{r2}) - \ddot{p}_{\rm I}. \end{cases}$$
(27)

In (27), mvnCDF(\cdot, \cdot, \cdot) represents the *multivariate normal cumulative distribution function* using Matlab notation, with mean vectors $\boldsymbol{\mu}_1 = [a^2 + b^2, -b]$ and $\boldsymbol{\mu}_2 = [a^2 + b^2, -a]$, and covariance matrices $\boldsymbol{\Sigma}_1 = \frac{1}{2}[a^2 + b^2, -b; -b, 1]$ and $\boldsymbol{\Sigma}_2 = \frac{1}{2}[a^2 + b^2, -a; -a, 1]$, in which $a = h_2\sqrt{E_r}$ and $b = h\sqrt{E}$.

Proof: Recall that $\dot{\Theta}_{I} = \dot{\mathcal{E}}_{12} \cap \dot{\mathcal{E}}_{1r}^{c} \cap \dot{\mathcal{E}}_{2r}^{c} \cap \dot{\mathcal{E}}_{r2}^{c}$. Because of $\dot{\mathcal{E}}_{1r}^{c}$ and $\dot{\mathcal{E}}_{2r}^{c}$, $\tilde{\mathbf{y}}_{r2} = h_2 \sqrt{E_r} \mathbf{x}_1 + \tilde{\mathbf{n}}_{r2}$ according to (2), so $\dot{\mathcal{E}}_{r2}$ means that $\tilde{\mathbf{y}}_{r2}$ has $d(\tilde{\mathbf{y}}_{r2}) = k \ge t+1$ bits in error. Similarly, $\dot{\mathcal{E}}_{12}$ means that \mathbf{y}_{12} has $i \ge t+1$ bits in error. Recall that in Case I, $\mathbf{L}_d = 4h\sqrt{E}\mathbf{y}_{12} + 4h_2\sqrt{E_r}\tilde{\mathbf{y}}_{r2}$. Using the fact that $P(\dot{\mathcal{E}}^c, \dot{\Theta}_I) = P(d(\mathbf{L}_d) \le t, \dot{\Theta}_I)$, we have

$$P(\dot{\mathcal{E}}^{c}, \dot{\Theta}_{I}) = (1 - \hat{P}_{1r})(1 - \hat{P}_{2r}) \sum_{k=t+1}^{n-1} \binom{n}{k} P(d(\mathbf{L}_{d}) \le t, d(\tilde{\mathbf{y}}_{r2}) = k, d(\mathbf{y}_{12}) \ge t+1).$$
(28)

Note that here k = n is omitted because $P(d(\mathbf{L}_d) \leq t, d(\tilde{\mathbf{y}}_{r2}) = n, d(\mathbf{y}_{12}) \geq t + 1) = 0$. A detailed expression for (28) is derived in Appendix A, which proves the theorem.

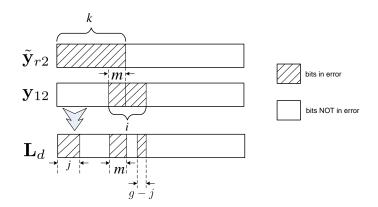

Fig. 2. The alignment between $\tilde{\mathbf{y}}_{r2}$ and \mathbf{y}_{12} for decoding $\mathbf{L}_d = 4h\sqrt{E}\mathbf{y}_{12} + 4h_2\sqrt{E_r}\tilde{\mathbf{y}}_{r2}$ in Case I. The erroneous channel bits are represented by shadowed boxes, whereas the correct channel bits are represented by blank boxes.

As to the numerical evaluation of the lower bound (26), it is accurate enough to calculate only its first few terms, because the first few terms correspond to the received words containing a small number of erroneous bits (referring to k and i in Fig. 2) and thus dominate the error event. This truncated calculation results in the obtained value being slightly loose, but the difference is negligible, and the truncated results are still valid lower bounds. In particular, our experiments show that the calculation based on truncation gives accurate results when truncating at k, i = 10 when the code length $n \le 127$.

D. Performance of TW-SDF

The *one-way* SDF protocol has been well studied in terms of outage probability, symbol error rate and ergodic capacity for the scenario where no channel coding is applied at the relays, but few results are available for scenarios where channel coding is employed by the relaying networks. In [24], a pair of loose BLER bounds is derived for the cooperative DF protocol [33] when convolutional codes and *soft* decoders are used. In this section, we contribute new results for relaying networks that use channel coding by deriving a tight upper bound for the DNC-based TW-SDF protocol that uses block codes and *hard* decoders.

Theorem 2. Suppose that all nodes apply a hard decoder whose performance is at least as good as BDD. Then the BLER of the TW-SDF protocol can be upper bounded as

$$P_{\text{TW-SDF}}^{(\mathbf{x}_1)} \leq \widehat{P}_{\text{TW-SDF}}^{(\mathbf{x}_1)} \triangleq P(\dot{\Theta}_{\text{II}} \cup \dot{\Theta}_{\text{III}}) + P(\dot{\mathcal{E}}, \dot{\Theta}_{\text{I}}),$$
(29)

where $P(\dot{\mathcal{E}}, \dot{\Theta}_{I})$ is given by (25).

Proof: See Appendix B.

Note that $\Theta_{I} \nsubseteq \dot{\Theta}_{I}$, so the proof of inequality (29) is not straightforward. Also note that the upper bound $\hat{P}_{TW-SDF}^{(\mathbf{x}_{1})}$ is not related with the sphere partition function (SPF) W_{k} ; thus it is decoder-independent.

From the definitions $\dot{\Theta}_{\text{II}} = \dot{\mathcal{E}}_{12} \cap (\dot{\mathcal{E}}_{1r} \cup \dot{\mathcal{E}}_{2r}) \cap \dot{\mathcal{E}}_{r2}^c$ and $\dot{\Theta}_{\text{III}} = \dot{\mathcal{E}}_{12} \cap (\dot{\mathcal{E}}_{1r} \cup \dot{\mathcal{E}}_{2r}) \cap \dot{\mathcal{E}}_{r2}, P(\dot{\Theta}_{\text{II}} \cup \dot{\Theta}_{\text{III}}) = P(\dot{\Theta}_{\text{II}}) + P(\dot{\Theta}_{\text{III}})$ in (29) can be derived using $P(\dot{\Theta}_{\text{II}}) = \hat{P}_{12} (\hat{P}_{1r} + \hat{P}_{2r} - \hat{P}_{1r}\hat{P}_{2r})(1 - \hat{P}_{r2})$ and $P(\dot{\Theta}_{\text{III}}) = \hat{P}_{12} (\hat{P}_{1r} + \hat{P}_{2r} - \hat{P}_{1r}\hat{P}_{2r}) \hat{P}_{r2}$. Simulation results in Section V will verify the tightness of the upper bound of Theorem 2.

E. Performance of TW-1bSF

In general, deriving the exact BLER performance of the TW-1bSF protocol for a given hard decoder is a formidable task, except for some specific cases of special hard decoders like BDD. Alternatively, we resort to deriving upper bounds on the performance. We can simply universally upper bound $P_{\text{TW-1bSF}}^{(\mathbf{x}_1)} =$ $P(\mathcal{E}, \Theta_{\text{I}} \cup \Theta_{\text{II}} \cup \Theta_{\text{II}})$ by $\max_{\mathfrak{D}} P(\mathcal{E}, \Theta_{\text{I}} \cup \Theta_{\text{II}}) = P(\mathcal{E}, \Theta_{\text{I}} \cup \Theta_{\text{II}} \cup \Theta_{\text{II}})|_{\mathfrak{D}=\text{BDD}}$, in which all links and \mathbf{L}_d are decoded using BDD. However, this upper bound is very loose for most practical decoders. In the following, we derive a tighter upper bound.

Lemma 2 (Upper Bound for the BLER of TW-1bSF). Given any hard decoder, we have

$$P_{\text{TW-1bSF}}^{(\mathbf{x}_{1})} = P(\mathcal{E}, \Theta_{\text{I}} \cup \Theta_{\text{II}} \cup \Theta_{\text{II}}) \le P(\mathcal{E}, \dot{\Theta}_{\text{I}}) + P(\mathcal{E}, \dot{\Theta}_{\text{II}a}) + P(\mathcal{E}, \dot{\Theta}_{\text{II}b}) + P(\dot{\Theta}_{\text{II}c}) + P(\dot{\Theta}_{\text{II}c}).$$
(30)

Proof: Recall that no hard decoder \mathfrak{D} performs worse than the BDD, so it is clear that $\check{\mathcal{E}}_{i}^{c} \subseteq \mathcal{E}_{i}^{c}$ and $\mathcal{E}_{i} \subseteq \check{\mathcal{E}}_{i}$, for all *i*. Therefore, $\Theta_{\mathrm{I}} \cup \Theta_{\mathrm{II}} \cup \Theta_{\mathrm{II}} = (\mathcal{E}_{1r}^{c} \cap \mathcal{E}_{2r}^{c} \cap \mathcal{E}_{r2}^{c})^{c} \cap \mathcal{E}_{12} \subseteq (\check{\mathcal{E}}_{1r}^{c} \cap \check{\mathcal{E}}_{2r}^{c} \cap \check{\mathcal{E}}_{r2}^{c})^{c} \cap \check{\mathcal{E}}_{12} = \check{\Theta}_{\mathrm{I}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} \subseteq \check{\Theta}_{\mathrm{I}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} = (\mathcal{E}_{1r}^{c} \cap \mathcal{E}_{2r}^{c} \cap \mathcal{E}_{r2}^{c})^{c} \cap \check{\mathcal{E}}_{2r}^{c} \cap \check{\mathcal{E}}_{2r}^{c})^{c} \cap \check{\mathcal{E}}_{12} = \check{\Theta}_{\mathrm{I}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}}) \leq P(\mathcal{E}, \check{\Theta}_{\mathrm{I}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}}) \leq P(\mathcal{E}, \check{\Theta}_{\mathrm{I}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}} \cup \check{\Theta}_{\mathrm{II}}) + P(\check{\mathcal{E}}, \check{\Theta}_{\mathrm{I}}) + P(\check{\mathcal{E}}, \check{\Theta}_{\mathrm{II}}) + P(\check{\Theta}_{\mathrm{IIc}}) + P(\check{\Theta}_{\mathrm{III}})$, which proves the lemma.

In the following, we analyze the terms on the right-hand side of (30) except for the first one, which is given by (25).

1) $P(\mathcal{E}, \dot{\Theta}_{IIa})$: We obtain an upper bound of $P(\mathcal{E}, \dot{\Theta}_{IIa}) = P(\dot{\Theta}_{IIa}) - P(\mathcal{E}^c, \dot{\Theta}_{IIa})$ by deriving a lower bound of $P(\mathcal{E}^c, \dot{\Theta}_{IIa})$ as follows.

Theorem 3. Given a hard decoder of SPF W_k , $P(\mathcal{E}^c, \dot{\Theta}_{IIa})$ can be lower bounded by

$$\begin{split} & \stackrel{\widetilde{P}}{=} (\mathcal{E}^{c}, \dot{\Theta}_{\mathrm{II}a}) \\ & \triangleq (1 - \widehat{P}_{2r})(1 - \widehat{P}_{r2}) \sum_{k=2t+1}^{n-1} \beta_{k}(p_{1r}) \sum_{m=\max(0,t+1-(n-k))}^{t} \\ & \times \sum_{i=t+1}^{m+(n-k)} \binom{k}{m} \binom{n-k}{i-m} p_{\mathrm{II}}^{n-k-(i-m)} p_{\mathrm{I2}}^{m} \sum_{g=0}^{t-m} \sum_{j=0}^{g} \binom{k-m}{j} \dot{p}_{\mathrm{II}}^{j} \dot{q}_{\mathrm{II}}^{k-m-j} \binom{i-m}{g-j} \ddot{p}_{\mathrm{II}}^{j-j} \ddot{q}_{\mathrm{II}}^{i-m-(g-j)} , \end{split}$$

where $\beta_k(p_{1r})$ is given by (21), and

$$p_{\mathrm{II}} = 1 - p_{12}, \quad \dot{p}_{\mathrm{II}} = Q(-\sqrt{2h^{2}E}) - Q\left(\sqrt{2E}(\mathcal{L}/4hE - h)\right),$$

$$\dot{q}_{\mathrm{II}} = Q\left(\sqrt{2E}(\mathcal{L}/4hE - h)\right), \quad \ddot{p}_{\mathrm{II}} = Q\left(\sqrt{2E}(\mathcal{L}/4hE + h)\right),$$

$$\ddot{q}_{\mathrm{II}} = Q(\sqrt{2h^{2}E}) - Q\left(\sqrt{2E}(\mathcal{L}/4hE + h)\right).$$
(32)

Proof: Using the inequality $\widehat{P}_{1r} \ge \widecheck{P}_{1r} = \sum_{k=2t+1}^{n} \beta_k(p_{1r})$ of Lemma 1, we have

$$P(\mathcal{E}^{c}, \dot{\Theta}_{\mathrm{II}a}) \ge (1 - \widehat{P}_{2r})(1 - \widehat{P}_{r2}) \sum_{k=2t+1}^{n-1} \beta_{k}(p_{1r}) P(\mathcal{E}^{c}, d(\mathbf{y}_{12}) \ge t+1 \mid d(\hat{\mathbf{x}}_{1r}) = k, \dot{\mathcal{E}}_{2r}^{c}, \dot{\mathcal{E}}_{r2}^{c}).$$
(33)

Note that the term k = n is omitted at (33) because $P(\mathcal{E}^c, \dot{\mathcal{E}}_{12} \mid d(\hat{\mathbf{x}}_{1r}) = n, \dot{\mathcal{E}}_{2r}^c, \dot{\mathcal{E}}_{r2}^c) = 0$. The detailed derivation of (31) from (33) which proves the theorem is given in Appendix C.

Using $P(\dot{\Theta}_{IIa}) = \hat{P}_{12}\hat{P}_{1r}$ $(1 - \hat{P}_{2r})(1 - \hat{P}_{r2})$ and Theorem 3, we conclude that $P(\mathcal{E}, \dot{\Theta}_{IIa})$ can be upper bounded as follows

$$\widehat{P}\left(\mathcal{E}, \dot{\Theta}_{\mathrm{II}a}\right) \triangleq \widehat{P}_{12}\widehat{P}_{1r}\left(1 - \widehat{P}_{2r}\right)\left(1 - \widehat{P}_{r2}\right) - \widecheck{P}\left(\mathcal{E}^{c}, \dot{\Theta}_{\mathrm{II}a}\right).$$
(34)

Unlike $P(\dot{\mathcal{E}}^c, \dot{\Theta}_I)$ in (26), $\breve{P}(\mathcal{E}^c, \dot{\Theta}_{IIa})$ in Theorem 3 is related with the SPF W_k .

2) $P(\mathcal{E}, \dot{\Theta}_{IIb})$: Similarly, we upper bound $P(\mathcal{E}, \dot{\Theta}_{IIb}) = P(\dot{\Theta}_{IIb}) - P(\mathcal{E}^c, \dot{\Theta}_{IIb})$ by finding a lower bound of $P(\mathcal{E}^c, \dot{\Theta}_{IIb})$ as shown below.

Corollary 1. Given a hard decoder with SPF W_k , $P(\mathcal{E}^c, \dot{\Theta}_{IIb})$ can be lower bounded by (35).

$$\widetilde{P}\left(\mathcal{E}^{c}, \widetilde{\Theta}_{\Pi b}\right) \triangleq (1 - \widehat{P}_{1r})(1 - \widehat{P}_{r2}) \sum_{k=2t+1}^{n-1} \beta_{k}(p_{2r}) \sum_{m=\max(0,t+1-(n-k))}^{t} \sum_{i=t+1}^{m+(n-k)} \binom{k}{m} \binom{n-k}{i-m} \\
\times p_{\Pi}^{n-k-(i-m)} p_{12}^{m} \sum_{g=0}^{t-m} \sum_{j=0}^{g} \binom{k-m}{j} \dot{p}_{\Pi}^{j} \dot{q}_{\Pi}^{k-m-j} \binom{i-m}{g-j} \ddot{p}_{\Pi}^{g-j} \ddot{q}_{\Pi}^{i-m-(g-j)}.$$
(35)

Proof: This corollary is proven through a direct use of Theorem 3 by exchanging the roles of \mathcal{E}_{1r} and \mathcal{E}_{2r} .

Thus, by the corollary, $P(\mathcal{E}, \dot{\Theta}_{IIb})$ is upper bounded by

$$\widehat{P}\left(\mathcal{E}, \dot{\Theta}_{\mathrm{II}b}\right) \triangleq \widehat{P}_{12}\left(1 - \widehat{P}_{1r}\right) \widehat{P}_{2r}\left(1 - \widehat{P}_{r2}\right) - \widecheck{P}\left(\mathcal{E}^{c}, \dot{\Theta}_{\mathrm{II}b}\right).$$
(36)

3) Upper bound for $P_{TW-IbSF}^{(\mathbf{x}_1)}$: Substituting (26) into (25), (31) into (34), and (35) into (36), gives expressions for $P(\dot{\mathcal{E}}, \dot{\Theta}_{\mathrm{I}})$, $\hat{P}(\mathcal{E}, \dot{\Theta}_{\mathrm{II}a})$ and $\hat{P}(\mathcal{E}, \dot{\Theta}_{\mathrm{II}b})$, respectively. Then, by substituting these upper bounds, $P(\dot{\Theta}_{\mathrm{II}c}) = \hat{P}_{12}\hat{P}_{1r}\hat{P}_{2r}$ $(1 - \hat{P}_{r2})$ and $P(\dot{\Theta}_{\mathrm{III}}) = \hat{P}_{12}(1 - (1 - \hat{P}_{1r})(1 - \hat{P}_{2r}))\hat{P}_{r2}$ into (30), we obtain an upper bound for $P(\mathcal{E}, \Theta_{\mathrm{I}} \cup \Theta_{\mathrm{II}} \cup \Theta_{\mathrm{III}})$, i.e., $P_{\mathrm{TW-IbSF}}^{(\mathbf{x}_1)}$:

$$\widehat{P}_{\text{TW-1bSF}}^{(\mathbf{x}_{1})} \triangleq P(\dot{\mathcal{E}}, \dot{\Theta}_{\text{I}}) + \widehat{P}(\mathcal{E}, \dot{\Theta}_{\text{II}a}) + \widehat{P}(\mathcal{E}, \dot{\Theta}_{\text{II}b}) + P(\dot{\Theta}_{\text{II}c}) + P(\dot{\Theta}_{\text{III}}).$$
(37)

Remark 2 (Performance of Perfect Codes). For perfect codes, the sphere decoder is exactly the optimal hard decoder. It has $W_{2t+1} = A_{2t+1} {\binom{2t+1}{t}} = {\binom{n}{t+1}}$ and $W_k = 0$ for all k > 2t + 1. Then the lower bound given by (20) and the upper bound given by (19) are equal, and also equal to the lower bound (21) of this paper. Thus, the upper bound of TW-SDF given by (29) is exact. Furthermore, the upper bound derived for TW-1bSF is asymptotically tight because the results for $P(\mathcal{E}, \dot{\Theta}_{I})$, $P(\mathcal{E}, \dot{\Theta}_{IIa})$ and $P(\mathcal{E}, \dot{\Theta}_{IIb})$ are exact, whereas $P(\dot{\Theta}_{IIc})$ and $P(\dot{\Theta}_{III})$ are asymptotically negligible.

V. ASYMPTOTIC PERFORMANCE ANALYSIS OF TW-SDF AND TW-1BSF

The analytical comparison of the BLER performance of the TW-1bSF and the TW-SDF protocols is prohibitive because of the fairly long BLER expressions. To gain insight, we derive and compare their asymptotic performance as $E \to \infty$ and $E_r \to \infty$. In the following analysis, $f_A(E, E_r)$ and $f_B(E, E_r)$ are said to be asymptotically equal with respect to E and E_r , denoted as $f_A(E, E_r) \sim f_B(E, E_r)$, if $\log_{E\to\infty,E_r\to\infty} f_A(E, E_r)/f_B(E, E_r) = 1$. We first present a lemma that will be used in the asymptotic analysis afterwards.

Lemma 3. Let $z_1 \sim \mathcal{N}(\mu_1 \sqrt{E}, 1)$ and $z_2 \sim \mathcal{N}(\mu_2 \sqrt{E}, 1)$ be two independent Gaussian random variables. If $\Lambda_1 = \Pr(z_1 + z_2 > 0, z_1 > 0, z_2 < 0)$ and $\Lambda_2 = \Pr(z_1 + z_2 < 0, z_1 > 0, z_2 < 0)$, then $\Lambda_1 / \Lambda_2 \to \infty$ as $E \to \infty$.

Proof: A detailed proof is given in Appendix D.

A. Asymptotic performance of TW-SDF

When $E \to \infty$ and $E_r \to \infty$, i.e., $p_i \to 0$, the upper bound (19) converges to $\hat{P}_i \sim \binom{n}{t+1} p_i^{t+1}$. We start by analyzing $P(\dot{\mathcal{E}}, \dot{\Theta}_I)$ in (25).

Case I): Since $\hat{P}_{12} (1 - \hat{P}_{1r})(1 - \hat{P}_{2r}) \hat{P}_{r2} \sim \hat{P}_{12} \hat{P}_{r2}$ $\sim {\binom{n}{t+1}} p_{12}^{t+1} {\binom{n}{t+1}} p_{r2}^{t+1}$, asymptotically $P(\hat{\mathcal{E}}, \dot{\Theta}_{\rm I}) \sim {\binom{n}{t+1}} p_{12}^{t+1} {\binom{n}{t+1}} p_{r2}^{t+1} - P(\hat{\mathcal{E}}^c, \dot{\Theta}_{\rm I})$. Regarding $P(\hat{\mathcal{E}}^c, \dot{\Theta}_{\rm I})$ given by (26), it is clear from Lemma 3 that $\dot{q}_{\rm I}/\dot{p}_{\rm I} \rightarrow \infty$ and $\ddot{q}_{\rm I}/\ddot{p}_{\rm I} \rightarrow \infty$, and hence $\dot{q}_{\rm I} \sim p_{r2}(1-p_{12}) \sim p_{r2}$ and $\ddot{q}_{\rm I} \sim p_{12}(1-p_{r2}) \sim p_{12}$. Thus, $P(\hat{\mathcal{E}}^c, \dot{\Theta}_{\rm I})$ is dominated by the terms in which $\dot{p}_{\rm I}^j = \ddot{p}_{\rm I}^{g-j} = 1$, i.e., j = g = 0, i = t+1 and k = t+1. Therefore

$$P(\dot{\mathcal{E}}^{c}, \dot{\Theta}_{\mathrm{I}}) \sim {\binom{n}{t+1}} \sum_{m=0}^{t} {\binom{t+1}{m}} {\binom{n-(t+1)}{t+1-m}} p_{r2}^{m} p_{12}^{m} \dot{q}_{\mathrm{I}}^{t+1-m} \ddot{q}_{\mathrm{I}}^{t+1-m} \sim {\binom{n}{t+1}} p_{r2}^{t+1} p_{12}^{t+1} \sum_{m=0}^{t} {\binom{t+1}{m}} {\binom{n-(t+1)}{t+1-m}}.$$
(38)

Thus,

$$P(\hat{\mathcal{E}}, \hat{\Theta}_{\mathrm{I}}) \sim {\binom{n}{t+1}}^2 p_{12}^{t+1} p_{r2}^{t+1} - {\binom{n}{t+1}} p_{r2}^{t+1} p_{12}^{t+1} \sum_{m=0}^t {\binom{t+1}{m}} {\binom{n-(t+1)}{t+1-m}} \\ \sim p_{12}^{t+1} p_{r2}^{t+1} {\binom{n}{t+1}}.$$
(39)

To derive (39), we used the fact that $\binom{n}{t+1} - \sum_{r=0}^{t} \binom{t+1}{r} \binom{n-(t+1)}{t+1-r} = \binom{t+1}{t+1} = 1.$

Finally, by substituting this asymptotic form and $P(\dot{\Theta}_{II} \cup \dot{\Theta}_{III}) \sim \hat{P}_{12} (\hat{P}_{1r} + \hat{P}_{2r})$ into (29), we obtain

$$\widehat{P}_{\text{TW-SDF}}^{(\mathbf{x}_1)} \sim \widehat{P}_{\text{TW-SDF,asym}}^{(\mathbf{x}_1)} \triangleq \binom{n}{t+1} p_{12}^{t+1} p_{r2}^{t+1} + \binom{n}{t+1}^2 [p_{1r}^{t+1} + p_{2r}^{t+1}] p_{12}^{t+1}.$$
(40)

B. Asymptotic performance of TW-1bSF

Among the terms of $\hat{P}_{\text{TW-1bSF}}^{(\mathbf{x}_1)}$ in (37), we have derived an asymptotic expression for $P(\check{\mathcal{E}}, \check{\Theta}_{\text{I}})$ in (39). In the following, we derive the remaining terms for Case II and Case III.

Case II): In $\widehat{P}(\mathcal{E}, \Theta_{\Pi a})$ given by (31), \dot{q}_{Π} is the probability that an erroneous bit *i* from the relay with $\hat{x}_{1r,i} = -1$ can be corrected by $y_{12,i} > 0$, as shown in Fig. 8. To optimize the performance of TW-1bSF, \dot{q}_{Π} should be maximized. Therefore it is desirable that $\dot{q}_{\Pi} > \dot{p}_{\Pi}$, and we want $\frac{\mathcal{L}}{4hE} \sim \frac{\min(h_{1}^{2},h_{2}^{2})}{4h} < h$ to hold. Here, to derive the asymptotic form of \mathcal{L} we have used the approximation $Q(x) \sim \frac{1}{2} \exp(-\frac{1}{2}x^{2})$ and $1 - Q(x) \sim 1$.

If the desired condition is satisfied, then $\dot{q}_{\Pi}/\dot{p}_{\Pi} \to \infty$ as $E \to \infty$, and therefore $\dot{q}_{\Pi} \sim 1$. Note that $\frac{\mathcal{L}}{4hE} \sim \frac{\min(h_1^2,h_2^2)}{4h} < h$ holds when $h = h_1 = h_2 = 1$, for instance. Furthermore, it is clear that $\ddot{q}_{\Pi}/\ddot{p}_{\Pi} \to \infty$, and so $\ddot{q}_{\Pi} \sim Q(\sqrt{2h^2E}) = p_{12}$. Based on the asymptotic analysis for \dot{q}_{Π} , \dot{p}_{Π} , \ddot{q}_{Π} and \ddot{p}_{Π} , we conclude that in $\hat{P}(\mathcal{E}, \dot{\Theta}_{\Pi a})$ the dominant events happen when i = t + 1, g = 0, and j = 0, for all k with $W_k \ge 0$, so $P(d(\mathbf{L}_d) \le t, d(\mathbf{y}_{12}) \ge t + 1 \mid d(\hat{\mathbf{x}}_{1r}) = k, \mathfrak{D}(\tilde{\mathbf{y}}_{r2}) = \hat{\mathbf{x}}_{1r}) \sim \sum_{m=0}^t {k \choose m} {n-k \choose t+1-m} p_{12}^{t+1} \dot{q}_{\Pi}^{k-m}$ in (63). Therefore, by substituting the asymptotic form of (63) and $\beta_k(p_{1r}) \sim W_k p_{1r}^{t+1}$ into (31), and then into (34), we get

$$\widehat{P}\left(\mathcal{E}, \dot{\Theta}_{\Pi a}\right) \sim {\binom{n}{t+1}}^2 p_{12}^{t+1} p_{1r}^{t+1} - \sum_{k=2t+1}^n W_k p_{1r}^{t+1} p_{12}^{t+1} \sum_{m=0}^t {\binom{k}{m}} {\binom{n-k}{t+1-m}} \dot{q}_{\Pi}^{k-m} \\ \sim p_{1r}^{t+1} p_{12}^{t+1} \left[{\binom{n}{t+1}}^2 - \sum_{k=2t+1}^n W_k \left({\binom{n}{t+1}} - {\binom{k}{t+1}} \right) \right].$$
(41)

For the derivation of the last step, we have used the fact that $\sum_{m=0}^{t} {\binom{k}{m} \binom{n-k}{t+1-m}} = {\binom{n}{t+1}} - {\binom{k}{t+1}}$.

By replacing p_{1r} with p_{2r} in the asymptotic equation (41), we have

$$\widehat{P}\left(\mathcal{E}, \widehat{\Theta}_{\mathrm{IIb}}\right) \sim p_{2r}^{t+1} p_{12}^{t+1} \left[\binom{n}{t+1}^2 - \sum_{k=2t+1}^n W_k\left(\binom{n}{t+1} - \binom{k}{t+1}\right) \right].$$
(42)

From $P(\dot{\Theta}_{\mathrm{II}c}) = \widehat{P}_{12}\widehat{P}_{1r}\widehat{P}_{2r}$ $(1 - \widehat{P}_{r2})$, it is clear that $P(\dot{\Theta}_{\mathrm{II}c}) \sim {\binom{n}{t+1}}^3 (p_{1r}p_{2r})^{t+1} p_{12}^{t+1}$. By comparing $P(\dot{\Theta}_{\mathrm{II}c}) \sim O((p_{1r}p_{2r})^{t+1}p_{12}^{t+1})$ with $\widehat{P}(\mathcal{E},\dot{\Theta}_{\mathrm{II}a})$ and $\widehat{P}(\mathcal{E},\dot{\Theta}_{\mathrm{II}b})$, which are $O(p_{12}^{t+1}p_{1r}^{t+1})$ and $O(p_{12}^{t+1}p_{2r}^{t+1})$, we find that $P(\dot{\Theta}_{\mathrm{II}c})$ is asymptotically negligible.

Case III): Using similar arguments as applied to derive the asymptotic form of $P(\dot{\Theta}_{IIc})$, we also find that $P(\dot{\Theta}_{III})$ is asymptotically negligible compared with $\hat{P}(\mathcal{E}, \dot{\Theta}_{I}), \hat{P}(\mathcal{E}, \dot{\Theta}_{IIa})$ and $\hat{P}(\mathcal{E}, \dot{\Theta}_{IIb})$.

Finally, by substituting (39), (41) and (42) into (37), we obtain the following asymptotic expression for $\hat{P}_{\text{TW-lbsf}}^{(\mathbf{x}_1)}$

$$\widehat{P}_{\text{TW-1bSF,asym}}^{(\mathbf{x}_{1})} \triangleq p_{12}^{t+1} p_{r2}^{t+1} \binom{n}{t+1} + (p_{1r}^{t+1} + p_{2r}^{t+1}) p_{12}^{t+1} \left[\binom{n}{t+1}^{2} - \sum_{k=2t+1}^{n} W_{k} \left(\binom{n}{t+1} - \binom{k}{t+1} \right) \right] . (43)$$

C. Asymptotic Performance Comparison

Comparing the asymptotic performance of TW-SDF and TW-1bSF given by (40) and (43), respectively, we note that they have the same first term, but the second term of (43) is smaller than the second term of (40). This observation means that TW-1bSF has a performance gain over TW-SDF if the error events of Case II are dominant over the error events of Case I, which happens if $p_{r2} \le p_{1r}$ or $p_{r2} \le p_{2r}$. Now, suppose that $E_r = E$ and $h = h_1 = h_2 = 1$, which satisfy both conditions $p_{r2} \le p_{2r}$ and $\dot{q}_{II} \sim 1$. Then the asymptotic performance gain of the TW-1bSF protocol over the TW-SDF protocol is given by

$$\frac{\widehat{P}_{\text{TW-SDF,asym}}^{(\mathbf{x}_1)}}{\widehat{P}_{\text{TW-1bSF,asym}}^{(\mathbf{x}_1)}} = \frac{\binom{n}{t+1}^2}{\binom{n}{t+1}^2 - \sum_{k=2t+1}^n W_k\left(\binom{n}{t+1} - \binom{k}{t+1}\right)}.$$
(44)

If perfect codes like Hamming codes are applied, then $W_{2t+1} = \binom{n}{t+1}$ and $W_k = 0$ for k = 0 and k > 2t + 1. Then the asymptotic gain (44) can be further simplified to

$$\frac{\widehat{P}_{\text{TW-SDF,pc,asym}}^{(\mathbf{x}_1)}}{\widehat{P}_{\text{TW-1bSF,pc,asym}}^{(\mathbf{x}_1)}} = \binom{n}{t+1} / \binom{2t+1}{t+1} .$$
(45)

This asymptotic ratio for perfect codes shows that the performance gain increases with the codeword length n.

Remark 3 (*Redesign of the Reliability Value*). From the asymptotic analysis above, in order to maximize the performance gain of the TW-1bSF protocol over the TW-SDF protocol, two conditions need to be

met: (1) $\mathcal{L}/4hE < h$ in order for $\dot{q}_{\text{II}} \sim 1$; (2) $p_{r2} \leq p_{1r}$ or $p_{r2} \leq p_{2r}$ so that the rate of error events in Case II dominates over the rate of error events in Case I. Condition (2) can be easily satisfied, since $p_{r2} = p_{2r}$ when $E_r = E$. Regarding Condition (1), the original choice for $\mathcal{L} \sim \min(h_1^2 E, h_2^2 E)$ provides no guarantee on whether the condition is met. For instance, the condition is violated if h = 1, $h_1 = h_2 = 2$. In order to satisfy the condition, the reliability value can be chosen as

$$\mathcal{L}^* = \min\left(\log\frac{1-p_{1r}}{p_{1r}}, \log\frac{1-p_{2r}}{p_{2r}}, \log\frac{1-p_{12}}{p_{12}}\right).$$
(46)

The superiority of this design choice will be illustratively verified in Section VI through simulations. On the other hand, the design of \mathcal{L}^- is not as critical as \mathcal{L} since the choice of \mathcal{L}^- does not influence the asymptotic performance.

Remark 4 (Decoding Energy Consumption Comparison). Let ϵ be the energy consumption that is needed to decode a codeword. We first consider the consumption at S2. Given that \mathbf{y}_{12} is in error, in the TW-SDF protocol, if R decodes the received signals correctly and forwards the network-coded word, S2 will consume 3ϵ to decode \mathbf{y}_{12} , $\tilde{\mathbf{y}}_{r2}$ and $(4h\sqrt{E}\mathbf{y}_{12} + 4h_2\sqrt{E_r}\tilde{\mathbf{y}}_{r2})$; otherwise, R forwards nothing, and S2 merely decodes \mathbf{y}_{12} consuming ϵ . Therefore, the decoding energy consumed at S2 by the TW-SDF protocol is

$$E_{\text{TW-SDF},S2} = \epsilon P(\mathcal{E}_{12}^c) + 3\epsilon P(\mathcal{E}_{12}, \mathcal{E}_{1r}^c, \mathcal{E}_{2r}^c) + \epsilon (P(\mathcal{E}_{12}) - P(\mathcal{E}_{12}, \mathcal{E}_{1r}^c, \mathcal{E}_{2r}^c))$$
$$\approx \epsilon (1 - \widehat{P}_{12}) + 3\epsilon P(\Theta_{\text{I}}) + \epsilon P(\Theta_{\text{II}} \cup \Theta_{\text{III}}).$$
(47)

In the TW-1bSF protocol, if \mathbf{y}_{12} is in error, no matter whether R can decode the received signals correctly, it will forward \mathbf{x}_r , so S2 consumes $3\epsilon P(\Theta_{II} \cup \Theta_{III})$. The decoding energy consumed by the TW-1bSF protocol is given by

$$E_{\text{TW-1bSF},S2} \approx \epsilon (1 - \hat{P}_{12}) + 3\epsilon P(\Theta_{\text{I}}) + 3\epsilon P(\Theta_{\text{II}} \cup \Theta_{\text{III}}).$$
(48)

Due to the symmetry of the model and $\hat{P}_{12}=\hat{P}_{21}$, the decoding energy consumption at S1 is given by $E_{\text{TW-SDF},S1} = E_{\text{TW-SDF},S2}$, and $E_{\text{TW-1bSF},S1} = E_{\text{TW-1bSF},S2}$. As to the relay, no matter whether TW-SDF or TW-1bSF is applied, it decodes the messages from S1 and S2, and thus consumes energy $E_{\text{TW-SDF},R} = E_{\text{TW-1bSF},R} = 2\epsilon$. Finally, regarding the whole system including S1, S2 and R, the decoding energy consumption for TW-SDF and TW-1bSF is given, respectively, by

$$E_{\text{TW-SDF}} = 2\epsilon(2 - \hat{P}_{12}) + 6\epsilon P(\Theta_{\text{I}}) + 2\epsilon P(\Theta_{\text{II}} \cup \Theta_{\text{III}}),$$
(49)

$$E_{\text{TW-1bSF}} = 2\epsilon(2 - \hat{P}_{12}) + 6\epsilon P(\Theta_{\text{I}}) + 6\epsilon P(\Theta_{\text{II}} \cup \Theta_{\text{III}}).$$
(50)

Since $P(\Theta_{\rm I}) \sim \hat{P}_{12} \hat{P}_{r2}$ and $P(\Theta_{\rm II} \cup \Theta_{\rm III}) \sim \hat{P}_{12} (\hat{P}_{1r} + \hat{P}_{2r})$, we have $E_{\rm TW-SDF} \sim E_{\rm TW-1bSF} \sim 2\epsilon(2-\hat{P}_{12})$, which means that the TW-1bSF protocol consumes almost the same decoding energy as TW-SDF.

Remark 5 (Transmission Energy Consumption Comparison). In TW-1bSF, both sources transmit a message with power E, while the relay forwards a network-coded message with power E_r during the third timeslot if any of the two direct links fails, i.e., \mathcal{E}_{12} or \mathcal{E}_{21} . Therefore, to exchange a pair of messages, the overall transmission energy consumed by TW-1bSF is

$$T_{\text{TW-1bSF}} \approx 2E + E_r (\hat{P}_{12} + \hat{P}_{21}).$$
 (51)

In order for the relay at TW-SDF to forward, besides \mathcal{E}_{12} or \mathcal{E}_{21} as in TW-1bSF, \mathcal{E}_{1r}^c and \mathcal{E}_{2r}^c should hold. Therefore

$$T_{\text{TW-SDF}} \approx 2E + E_r (\hat{P}_{12} + \hat{P}_{21})(1 - \hat{P}_{1r})(1 - \hat{P}_{2r}).$$
 (52)

Therefore, $T_{\text{TW-SDF}} \sim T_{\text{TW-1bSF}} \sim 2E + 2E_r \hat{P}_{12}$, which means that the TW-1bSF protocol consumes almost the same transmission energy as the TW-SDF protocol.

VI. RESULTS AND DISCUSSION

The proposed TW-1bSF protocol is simple in terms of signal processing complexity, and hence consumes relatively little power. Hence, it is suitable for use in communication systems with stringent power constraints such as Bluetooth (IEEE 802.15.1) [34], IEEE 802.15.6 [35] and WBAN (IEEE 802.15.6) [35]. Therefore, in order to assess the performance of the TW-1bSF protocol we use channel codes utilized by these standards. As an example of perfect codes, the (15,11) Hamming code is adopted by Bluetooth [34], and so it is studied in this section. Let r_c be the code rate and E_b/N_0 be the SNR of the information bits. Then the SNR of the code bits is $E/N_0 = r_c E_b/N_0$. In sensor networks, in general all nodes can switch their mode between acting as a transmitter and as a relay, so it is natural to assume that $E = E_r$. In the rest of analysis, it is also assumed that $h = h_1 = h_2 = 1$, because the channel changes slowly and we can always use power control to compensate for the effects of fading. In this setting, both conditions in Remark 3 that render TW-1bSF preferable are satisfied.

Fig. 3 shows the simulated and analytical BLER performance for TW-SDF and TW-1bSF when the (15,11) Hamming code is employed. It can be seen that the simulation results are very close to the upper bound derived for TW-1bSF, and match perfectly with the derived upper bound for TW-SDF. This comparison verifies the accuracy of the performance analysis presented in Section IV. It also shows that

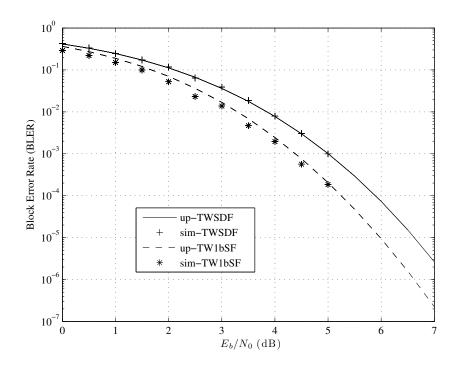

Fig. 3. Simulation results vs analytical results for TW-1bSF and TW-SDF in the two-way network setting for the (15,11) Hamming code. "sim" stands for simulation, whereas "up" stands for the derived BLER upper bounds (29) and (37).

TABLE IVALUES OF THE SPHERE PARTITION FUNCTION (SPF) W_k for two-error-correcting ($t = 2, d_{\min} = 5$) BCH codesWITH CODE LENGTH n = 15, 31, 63, 127, 255, and 511.

W_k	n = 15	n = 31	n = 63	n = 127	n = 255	n = 511
k = 0	36	71	170	164	336	362
$k = d_{\min}$	281	2123	19316	161664	1351834	10949163
$k = d_{\min} + 1$	89	540	2557	5399	19172	42719

for BLERs ranging from 10^{-2} to 10^{-3} , the SNR gain of TW-1bSF over TW-SDF is around 0.6 dB, which offers power savings of about $10^{0.6/10} - 1 \approx 15\%$.

As an extension of Hamming codes, BCH codes are capable of correcting multiple error bits and hence are also widely adopted by small-area communication systems [31], [35]. For the simulations of this paper, the BCH codewords are generated by a systematic encoder, and the received words are decoded by a Berlekamp-Massey decoder; both the encoder and the decoder are provided by the Matlab Communication Toolbox. It is worthwhile to note that in the Matlab BCH decoder, if a decoding failure

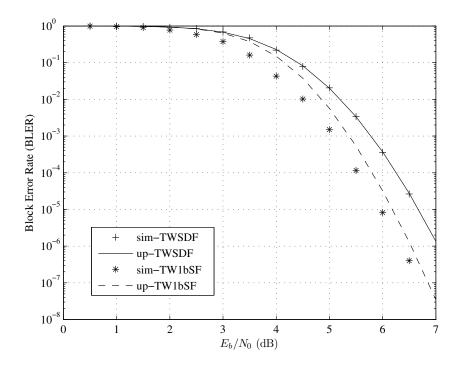

Fig. 4. Performance of TW-SDF and TW-1bSF for the two-way network using the (127,113) BCH code.

happens, then the first k received bits are decoded as the estimate of the transmitted information message if the code rate is k/n. The SPF W_k associated with the Matlab encoder/decoder is shown in Table I for some typical BCH codes. The BLER results obtained for the (127,113) code by simulation and using the analytical upper bound for TW-1bSF and TW-SDF are shown in Fig. 4. Again, the simulation results are tightly upper bounded by the derived bound for TW-SDF, and well bounded by the bound for TW-1bSF, which is asymptotically tight. The simulation results also show that, when the BLER is in the range between 10^{-2} and 10^{-3} , the SNR gain attained by TW-1bSF is about 0.8 dB, which corresponds to power savings of $10^{0.8/10} \approx 20\%$. Fig. 3 and 4 indicate that the asymptotic tightness of the derived upper bounds for the TW-SDF and the TW-1bSF protocols holds for any hard decoders with negligible W_0 . This is because these decoders can be approximated by the BDD, which has $W_0 = 0$, and by which the upper bounds are achieved. As can be seen in Table. I, the Matlab BCH decoder that is employed has very small W_0 .

Fig. 5 displays the upper bound curves as a function of the SNR to illustrate the impact of the codeword length and the error-correcting capability of the code on the performance gain of TW-1bSF over TW-SDF. By comparing the performance when the (7,4) Hamming and the (127,113) Hamming code are used, it

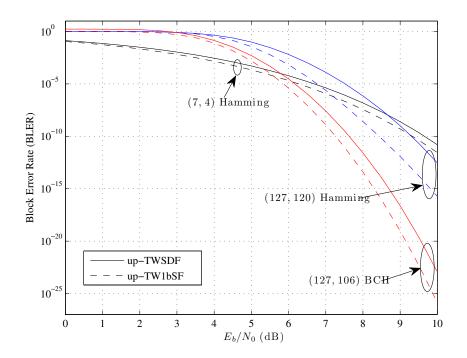

Fig. 5. Performance comparison of TW-SDF and TW-1bSF for different codes in terms of the block error rate (BLER). "(7,4) Hamming" represents the (7,4) Hamming code, "(127,120) Hamming" represents the (127,120) Hamming code and "(127,106) BCH" represents the (127,106) BCH code.

can be seen that for fixed error-correcting capability t, the performance gain increases with the codeword length n. However, the comparison between the (127,120) Hamming code and the (127,113) BCH code shows that, for fixed codeword length n, higher error-correcting capability t may reduce the performance gain. For BCH codes, Fig. 6 quantitatively depicts the asymptotic performance gain (44) as a function of the codeword length n, and the error-correcting capability t. It also presents the simulated performance gain obtained when $E_b/N_0 = 5$ dB. In the figure, the asymptotic performance gain and the simulated performance gain demonstrate similar functional trends over the error-correcting capability t, and both increase with the codeword length n. However, they are not monotonically related with t.

Finally, Fig. 7 verifies the conclusion in Remark 3 that the reliability value design of (46) is better than (15). Fig. 7(a) shows the BLER performance for the two choices of the reliability value as a function of the channel gain of the direct link h, for fixed $E_b/N_0 = 7$ dB. When h is small, which can be interpreted as a setting with no direct link, the performance of TW-SDF and TW-1bSF is the same for both reliability designs. The reliability value (46) starts to show performance gains over TW-SDF when h = 0.4, and

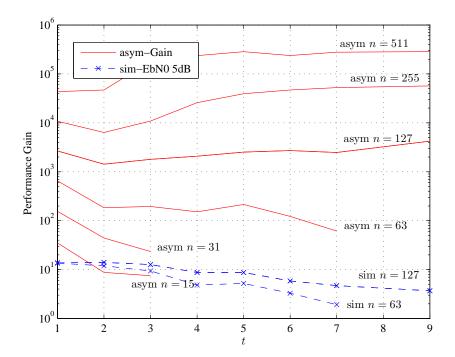

Fig. 6. Asymptotic and simulated performance gain of TW-1bSF over TW-SDF versus the error-correcting capability t when using BCH codes with different codeword length n. "asym-Gain" results are derived from (44), while "sim-EbN0 5dB" results are the values of $P_{\text{TW-SDF}}^{(\mathbf{x}_1)}/P_{\text{TW-IbSF}}^{(\mathbf{x}_1)}$ obtained by simulation.

the performance gains keep increasing as h grows further. By contrast, when the reliability value (15) is used, the performance is not superior to SDF until h = 0.5, where Condition (2) begins to hold. The performance improvement of design (46) over design (15) is appealing between h = 0.6 and h = 0.7. Furthermore, Fig. 7(b) shows the BLER performance of the two reliability value designs as a function of the SNR, for h = 0.6. It can be seen that, in the BLER range from 10^{-2} to 10^{-4} , the TW-1bSF protocol based on design (46) achieves a 0.6 dB gain over TW-SDF, which is much better than the negligible gain when design (15) is employed.

VII. CONCLUSIONS

In this paper, we proposed an energy-efficient two-way one-bit soft forwarding (TW-1bSF) protocol to improve the performance of the TW-SDF protocol in DNC-based two-way relay networks. The idea is to always forward the network-coded packet during the third time slot even when it contains erroneous bits, instead of discarding it by the relay as in the TW-SDF protocol. The key ingredient of TW-1bSF is to also assign a reliability value to the sources. This value is used to weigh the erroneous network-coded

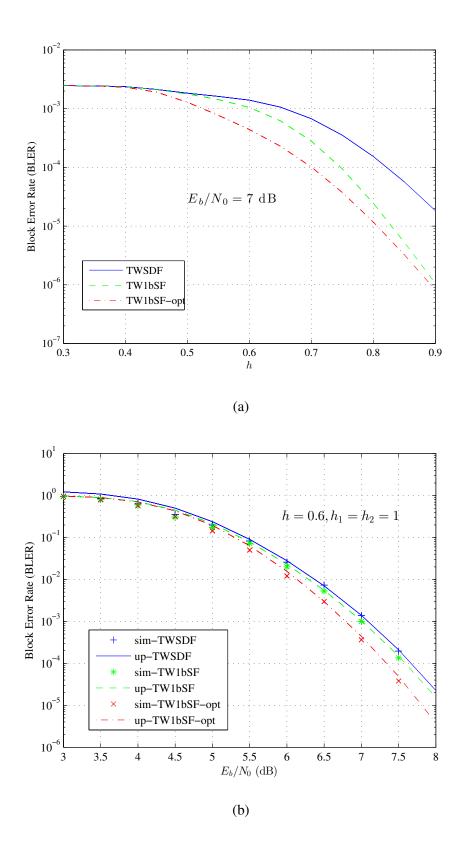

Fig. 7. (a) Comparison of reliability value designs. The (127,113) BCH code is employed. "TW1bSF-opt" stands for the results derived using the reliability value design (46), whereas "TW1bSF" stands for the results derived using the reliability value design (15); (b) BLER performance versus the SNR for h = 0.6 and $h_1 = h_2 = 1$.

packet, and improve the BLER. We prove theoretically, by carefully designing the reliability parameter, that the TW-1bSF protocol benefits from the superior performance of the soft relaying approach while preserving the simplicity of the TW-SDF protocol. Moreover, the bandwidth requirements are negligible, as only a one-bit indicator is sent along with the network-coded packet. Both theoretic and simulation results show that TW-1bSF attains a 0.6 dB gain over TW-SDF in practical settings. We also derive tight upper bounds on the BLER of the TW-1bSF and the TW-SDF protocols when block codes are used and hard decoding is applied at the receiving ends, and we verify the bounds by simulation. Further analysis shows that the asymptotic performance gain of the TW-1bSF protocol can attain an impressive performance improvement compared to TW-SDF, especially when codes with long lengthes are used. In future work, we intend to study the performance of TW-1bSF in two-way relaying networks with multiple relays and slow fading.

APPENDIX A

PROOF OF THEOREM 1

As shown in Fig. 2, suppose that among the *i* erroneous bits of \mathbf{y}_{12} there are *m* bits overlapping with the erroneous bits of $\tilde{\mathbf{y}}_{r2}$. Then $m \leq t$ must hold so that $d(\mathbf{L}_d) \leq t$ be possible. Note that Fig. 2 only shows a special case of consecutive erroneous bits, but the following proof is general. Let $(\tilde{\mathbf{y}}_{r2}, \mathbf{y}_{12})_{(k,m,i)}$ denote the event that $\tilde{\mathbf{y}}_{r2}$ and \mathbf{y}_{12} have *k* and *i* erroneous channel bits, respectively, *m* erroneous bits of which overlap. Given the signal $\tilde{\mathbf{y}}_{r2}$ of weight *k*, the number of such \mathbf{y}_{12} that correspond to the pair (m, i) is $\binom{k}{m}\binom{n-k}{i-m}$. Therefore,

$$P(d(\mathbf{L}_d) \le t, d(\tilde{\mathbf{y}}_{r2}) = k, d(\mathbf{y}_{12}) \ge t+1) = \sum_{m=\max(0,t+1-(n-k))}^{t} \sum_{i=t+1}^{m+n-k} \binom{k}{m} \binom{n-k}{i-m} P(d(\mathbf{L}_d) \le t, (\tilde{\mathbf{y}}_{r2}, \mathbf{y}_{12})_{(k,m,i)}) (53)$$

To derive $P(d(\mathbf{L}_d) \leq t, (\tilde{\mathbf{y}}_{r2}, \mathbf{y}_{12})_{(k,m,i)})$ we first observe that $d(\mathbf{L}_d) \leq t$ occurs if there are $g \leq t - m$ erroneous channel bits among the bits $\{\tau : \tilde{y}_{r2,\tau} < 0, y_{12,\tau} > 0\}$ and $\{\tau : \tilde{y}_{r2,\tau} > 0, y_{12,\tau} < 0\}$. Suppose that j of the g erroneous bits are within the set $\{\tau : \tilde{y}_{r2,\tau} < 0, y_{12,\tau} > 0\}$, and that the remaining g - jerroneous bits are within the set $\{\tau : \tilde{y}_{r2,\tau} < 0, y_{12,\tau} < 0\}$, as shown in Fig. 2. For the τ -th channel bit, let

$$p_{\rm I} = P(\tilde{y}_{r2,\tau} > 0, y_{12,\tau} > 0) = (1 - p_{r2})(1 - p_{12})$$
(54a)

$$q_{\rm I} = P(\tilde{y}_{r2,\tau} < 0, y_{12,\tau} < 0) = p_{12}p_{r2} \tag{54b}$$

$$\dot{p}_{\mathrm{I}} = P(\ell_{d,\tau} < 0, \tilde{y}_{r2,\tau} < 0, y_{12,\tau} > 0) = \Pr(h_2 \sqrt{E_r} \tilde{y}_{r2,\tau} + h \sqrt{E} y_{12,\tau} < 0, y_{12,\tau} > 0)$$
(54c)

$$\dot{q}_{\rm I} = P(\ell_{d,\tau} > 0, \tilde{y}_{r2,\tau} < 0, y_{12,\tau} > 0) = p_{r2}(1 - p_{12}) - \dot{p}_{\rm I}$$
(54d)

$$\ddot{p}_{\rm I} = P(\ell_{d,\tau} < 0, \tilde{y}_{r2,\tau} > 0, y_{12,\tau} < 0) = \Pr(h_2 \sqrt{E_r} \tilde{y}_{r2,\tau} + h \sqrt{E} y_{12,\tau} < 0, \tilde{y}_{r2,\tau} > 0)$$
(54e)

$$\ddot{q}_{\rm I} = P(\ell_{d,\tau} > 0, \tilde{y}_{r2,\tau} > 0, y_{12,\tau} < 0) = p_{12}(1 - p_{r2}) - \ddot{p}_{\rm I},\tag{54f}$$

where $\ell_{d,\tau} = 4h\sqrt{E}y_{12,\tau} + 4h_2\sqrt{E_r}\tilde{y}_{r2,\tau}$ with $y_{12,\tau} \sim \mathcal{N}(h\sqrt{E},\frac{1}{2})$ and $\tilde{y}_{r2,\tau} \sim \mathcal{N}(h_2\sqrt{E_r},\frac{1}{2})$. By counting all combinations of g and j, we get

$$P(d(\mathbf{L}_{d}) \leq t, (\tilde{\mathbf{y}}_{r2}, \mathbf{y}_{12})_{(k,m,i)}) = p_{\mathrm{I}}^{n-k-(i-m)} q_{\mathrm{I}}^{m} \sum_{g=0}^{t-m} \sum_{j=0}^{g} {\binom{k-m}{j}} \dot{p}_{\mathrm{I}}^{j} \dot{q}_{\mathrm{I}}^{k-m-j} {\binom{i-m}{g-j}} \ddot{p}_{\mathrm{I}}^{g-j} \ddot{q}_{\mathrm{I}}^{i-m-(g-j)}.$$
(55)

Finally, substituting (55) into (53), and then into (28), we get (26), which proves the theorem.

APPENDIX B

PROOF OF THEOREM 2

We first prove two inequalities. The first one is

$$\Theta_{\mathrm{I}} \cup \Theta_{\mathrm{II}} = [\mathcal{E}_{12} \cap \mathcal{E}_{1r}^{c} \cap \mathcal{E}_{2r}^{c} \cap \mathcal{E}_{r2}] \cup [\mathcal{E}_{12} \cap (\mathcal{E}_{1r} \cup \mathcal{E}_{2r})] = \mathcal{E}_{12} \cap (\mathcal{E}_{1r}^{c} \cap \mathcal{E}_{2r}^{c} \cap \mathcal{E}_{r2}^{c})^{c}$$
$$\subseteq \dot{\mathcal{E}}_{12} \cap (\dot{\mathcal{E}}_{1r}^{c} \cap \dot{\mathcal{E}}_{2r}^{c} \cap \dot{\mathcal{E}}_{r2}^{c})^{c} = \dot{\Theta}_{\mathrm{I}} \cup \dot{\Theta}_{\mathrm{II}} \cup \dot{\Theta}_{\mathrm{II}},$$
(56)

which is derived using the facts $\mathcal{E}_{12} \subseteq \dot{\mathcal{E}}_{12}$, $\dot{\mathcal{E}}_{1r}^c \subseteq \mathcal{E}_{1r}^c$, $\dot{\mathcal{E}}_{2r}^c \subseteq \mathcal{E}_{2r}^c$ and $\dot{\mathcal{E}}_{r2}^c \subseteq \mathcal{E}_{r2}^c$. The other is

$$\Theta_{\mathrm{II}} \cup \Theta_{\mathrm{III}} = \mathcal{E}_{12} \cap (\mathcal{E}_{1r} \cup \mathcal{E}_{2r}) \subseteq \dot{\mathcal{E}}_{12} \cap (\dot{\mathcal{E}}_{1r} \cup \dot{\mathcal{E}}_{2r}) = \dot{\Theta}_{\mathrm{II}} \cup \dot{\Theta}_{\mathrm{III}}.$$
(57)

We then decompose Θ_{I} as

$$\Theta_{\mathrm{I}} = \underbrace{\mathcal{E}_{12} \cap \dot{\mathcal{E}}_{1r}^{c} \cap \dot{\mathcal{E}}_{2r}^{c} \cap \mathcal{E}_{r2}}_{\Theta_{\mathrm{I},a}} + \underbrace{\mathcal{E}_{12} \cap (\mathcal{E}_{1r}^{c} \setminus \dot{\mathcal{E}}_{1r}^{c}) \cap (\mathcal{E}_{2r}^{c} \setminus \dot{\mathcal{E}}_{2r}^{c}) \cap \mathcal{E}_{r2}}_{\Theta_{\mathrm{I},b}}.$$
(58)

Because $\Theta_{I,b} \cup \Theta_{II} \cup \Theta_{III} \subseteq \Theta_I \cup \Theta_{II} \cup \Theta_{III} \subseteq \dot{\Theta}_I \cup \dot{\Theta}_{II} \cup \dot{\Theta}_{II}$ and $(\Theta_{I,b} \cup \Theta_{II} \cup \Theta_{III}) \cap \dot{\Theta}_I = \emptyset$, we conclude that $\Theta_{I,b} \cup \Theta_{II} \cup \Theta_{III} \subseteq \dot{\Theta}_{II} \cup \dot{\Theta}_{III}$, and thus

$$P(\dot{\Theta}_{\mathrm{II}} \cup \dot{\Theta}_{\mathrm{III}}) \ge P(\Theta_{\mathrm{I},b} \cup \Theta_{\mathrm{II}} \cup \Theta_{\mathrm{III}}) = P(\Theta_{\mathrm{I},b}) + P(\Theta_{\mathrm{II}} \cup \Theta_{\mathrm{III}}).$$
(59)

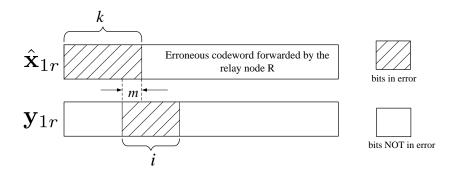

Fig. 8. Error position alignment between the received signals from the R-S2 link and the S1-S2 link for Case II.a.

Combining (59) with $\Theta_{I.a} \subseteq \dot{\Theta}_{I}$, we have

$$P_{\text{TW-SDF}}^{(\mathbf{x}_{1})} = P(\mathcal{E}, \Theta_{\text{I}}) + P(\Theta_{\text{II}} \cup \Theta_{\text{III}}) = P(\mathcal{E}, \Theta_{\text{I}.a}) + P(\mathcal{E}, \Theta_{\text{I}.b}) + P(\Theta_{\text{II}} \cup \Theta_{\text{III}})$$

$$\leq P(\mathcal{E}, \Theta_{\text{I}.a}) + P(\Theta_{\text{I}.b}) + P(\Theta_{\text{II}} \cup \Theta_{\text{III}}) \leq P(\mathcal{E}, \dot{\Theta}_{\text{I}}) + P(\dot{\Theta}_{\text{II}} \cup \dot{\Theta}_{\text{III}})$$

$$\leq P(\dot{\mathcal{E}}, \dot{\Theta}_{\text{I}}) + P(\dot{\Theta}_{\text{II}} \cup \dot{\Theta}_{\text{III}}), \qquad (60)$$

which proves the theorem.

APPENDIX C

PROOF OF THEOREM 3

In the subcase $\hat{\Theta}_{\Pi a}$, note that $\mathfrak{D}(\tilde{\mathbf{y}}_{r2}) = \hat{\mathbf{x}}_{1r}$ because $\hat{\mathcal{E}}_{r2}^c \Rightarrow \mathfrak{D}(\tilde{\mathbf{y}}_{r2}) = \hat{\mathbf{x}}_{1r} \circ \hat{\mathbf{x}}_{2r} \circ \mathbf{x}_2$ and $\hat{\mathcal{E}}_{2r}^c \Rightarrow \hat{\mathbf{x}}_{2r} = \mathbf{x}_2 = \mathbf{1}$. Using this fact and the inequality $P(\mathcal{E}^c) \ge P(d(\mathbf{L}_d) \le t)$ with $\mathbf{L}_d = 4h\sqrt{E}\mathbf{y}_{12} + \hat{\mathbf{x}}_{1r}\mathcal{L}$, we have

$$P\left(\mathcal{E}^{c}, d(\mathbf{y}_{12}) \geq t+1 \mid d(\hat{\mathbf{x}}_{1r}) = k, \check{\mathcal{E}}^{c}_{2r}, \check{\mathcal{E}}^{c}_{r2}\right)$$

$$\geq P(d(\mathbf{L}_{d}) \leq t, d(\mathbf{y}_{12}) \geq t+1 \mid d(\hat{\mathbf{x}}_{1r}) = k, \mathfrak{D}(\tilde{\mathbf{y}}_{r2}) = \hat{\mathbf{x}}_{1r}).$$
(61)

Now, given $d(\hat{\mathbf{x}}_{1r}) = k$ and $d(\mathbf{y}_{12}) = i$ as shown in Fig. 8, the inequality $d(\mathbf{L}_d) \leq t$ holds only if the cardinality of $\{\tau : \hat{x}_{1r,\tau} = -1, y_{12,\tau} < 0\}$ does not exceed t, i.e., $m \leq t$, and among the bits $\{\tau : \hat{x}_{1r,\tau} = -1, y_{12,\tau} > 0\}$ and $\{\tau : \hat{x}_{1r,\tau} = 1, y_{12,\tau} < 0\}$ there are only $g \leq t - m$ erroneous channel bits. Suppose that j erroneous bits are within the set $\{\tau : \hat{x}_{1r,\tau} = -1, y_{12,\tau} > 0\}$, and that the remaining g-j erroneous bits are within the set $\{\tau : \hat{x}_{1r,\tau} = 1, y_{12,\tau} < 0\}$. For the τ -th channel bit, let

$$p_{\rm II} = P(y_{12,\tau} > 0) = 1 - p_{12},\tag{62a}$$

$$q_{\rm II} = P(y_{12,\tau} < 0) = p_{12},\tag{62b}$$

$$\dot{p}_{\mathrm{II}} = P(\ell_{d,\tau} < 0, y_{12,\tau} > 0 \mid \hat{x}_{1r,\tau} = -1) = \Pr(4h\sqrt{E}y_{12,\tau} - \mathcal{L} < 0, y_{12,\tau} > 0),$$
(62c)

$$\dot{q}_{\Pi} = P(\ell_{d,\tau} > 0, y_{12,\tau} > 0 \mid \hat{x}_{1r,\tau} = -1) = \Pr(4h\sqrt{E}y_{12,\tau} - \mathcal{L} > 0, y_{12,\tau} > 0),$$
(62d)

$$\ddot{p}_{\mathrm{II}} = P(\ell_{d,\tau} < 0, y_{12,\tau} < 0 \mid \hat{x}_{1r,\tau} = 1) = \Pr(4h\sqrt{E}y_{12,\tau} + \mathcal{L} < 0, y_{12,\tau} < 0),$$
(62e)

$$\ddot{q}_{\mathrm{II}} = P(\ell_{d,\tau} > 0, y_{12,\tau} < 0 \mid \hat{x}_{1r,\tau} = 1) = \Pr(4h\sqrt{E}y_{12,\tau} + \mathcal{L} > 0, y_{12,\tau} < 0).$$
(62f)

Then by summing the probability of correct detection $p_{\text{II}}^{n-k-(i-m)}q_{\text{II}}^{m}\dot{p}_{\text{II}}^{j}\dot{q}_{\text{II}}^{k-m-j}\ddot{p}_{\text{II}}^{g-j}\ddot{q}_{\text{II}}^{i-m-(g-j)}$ over the combinations of the 5-tuples (k, i, m, g, j), we have

$$P(d(\mathbf{L}_{d}) \leq t, d(\mathbf{y}_{12}) \geq (t+1) \mid d(\hat{\mathbf{x}}_{1r}) = k, \mathfrak{D}(\tilde{\mathbf{y}}_{r2}) = \hat{\mathbf{x}}_{1r})$$

$$= \sum_{m=\max(0,t+1-(n-k))}^{t} \sum_{i=t+1}^{m+(n-k)} \binom{k}{m} \binom{n-k}{i-m}$$

$$\times p_{\mathrm{II}}^{n-k-(i-m)} p_{12}^{m} \sum_{g=0}^{t-m} \sum_{j=0}^{g} \binom{k-m}{j} \dot{p}_{\mathrm{II}}^{j} \dot{q}_{\mathrm{II}}^{k-m-j} \binom{i-m}{g-j} \ddot{p}_{\mathrm{II}}^{g-j} \ddot{q}_{\mathrm{II}}^{i-m-(g-j)}.$$
(63)

Finally, substituting (63) into (61) and then into (33), we obtain (31), and thus prove the theorem.

APPENDIX D

Proof of Lemma 3

Let $0 < \epsilon < \min\{\mu_1, \mu_2\}$ be a small positive value. We can lower bound Λ_1 as

$$\begin{split} \Lambda_1 &= \left(\int_{-(\mu_1 - \epsilon)\sqrt{E}}^{0} + \int_{-\infty}^{-(\mu_1 - \epsilon)\sqrt{E}} \right) \left(1 - Q((\mu_1\sqrt{E} + z_2)\sqrt{2}) \right) f(z_2) dz_2 \\ &\geq \left(1 - Q(\epsilon\sqrt{2E}) \right) \left(Q(\mu_2\sqrt{2E}) - Q((\mu_2 + \mu_1 - \epsilon)\sqrt{2E}) \right), \end{split}$$

which is derived by lower bounding the second integral by 0, and the first integral using the fact that

$$\left(1 - Q((\mu_1\sqrt{E} + z_2)\sqrt{2})\right)\big|_{z_2 \in [0, -(\mu_1 - \epsilon)\sqrt{E}]} \ge \left(1 - Q((\mu_1\sqrt{E} + z_2)\sqrt{2})\right)\big|_{z_2 = -(\mu_1 - \epsilon)\sqrt{E}}.$$

On the other hand, we can upper bound Λ_2 as

$$\begin{split} \Lambda_2 &= \left(\int_{-(\mu_1 - \epsilon)\sqrt{E}}^{0} + \int_{-\infty}^{-(\mu_1 - \epsilon)\sqrt{E}} \right) \left(Q((\mu_1\sqrt{E} + z_2)\sqrt{2}) - Q(\mu_1\sqrt{2E}) \right) f(z_2) dz_2 \\ &\leq \left(Q(\epsilon\sqrt{2E}) - Q(\mu_1\sqrt{2E}) \right) \left(Q(\mu_2\sqrt{2E}) - Q((\mu_2 + \mu_1 - \epsilon)\sqrt{2E}) \right) + Q(-\mu_1\sqrt{2E}) Q((\mu_2 + \mu_1 - \epsilon)\sqrt{2E}) dz_2 \end{split}$$

Thus when $E \to \infty$, we have $Q(-\mu_1\sqrt{2E}) \to 1$, $Q(\epsilon\sqrt{2E})/Q(\mu_1\sqrt{2E}) \to \infty$ and $Q(\mu_2\sqrt{2E})/Q((\mu_2 + \mu_1 - \epsilon)\sqrt{2E}) \to \infty$, and finally

$$\frac{\Lambda_1}{\Lambda_2} \ge \frac{(1 - Q(\epsilon\sqrt{2E}))Q(\mu_2\sqrt{2E})}{Q(\epsilon\sqrt{2E})Q(\mu_2\sqrt{2E}) + Q((\mu_2 + \mu_1 - \epsilon)\sqrt{2E})} \to \infty,$$

which proves the lemma.
