

Polar Write Once Memory Codes

David Burshtein, *Senior Member, IEEE* and Alona Strugatski

Abstract

A coding scheme for write once memory (WOM) using polar codes is presented. It is shown that the scheme achieves the capacity region of noiseless WOMs when an arbitrary number of multiple writes is permitted. The encoding and decoding complexities scale as $O(N \log N)$ where N is the blocklength. For N sufficiently large, the error probability decreases sub-exponentially in N . The results can be generalized from binary to generalized WOMs, described by an arbitrary directed acyclic graph, using nonbinary polar codes. In the derivation we also obtain results on the typical distortion of polar codes for lossy source coding. Some simulation results with finite length codes are presented.

Index Terms

Polar codes, write once memory codes (WOMs).

I. INTRODUCTION

The model of a write once memory (WOM) was proposed by Rivest and Shamir in [1]. In write once memories writing may be irreversible in the sense that once a memory cell is in some state it cannot easily convert to a preceding state. Flash memory is an important example since the charge level of each memory cell can only increase, and it is not possible to erase a single memory cell. It is possible to erase together a complete block of cells which comprises a large number of cells, but this is a costly operation and it reduces the life cycle of the device.

Consider a binary write-once memory (WOM) which is comprised of N memory cells. Suppose that we write on the device t times, and denote the number of possible messages in the i th write by M_i ($1 \leq i \leq t$). The number of bits that are written in the i th write is $k_i = \log_2 M_i$ and the corresponding code rate is $R_i = k_i/N$. Let \mathbf{s}_l denote the N dimensional state vector of the WOM at time (generation) l for $0 \leq l \leq t$, and suppose that $\mathbf{s}_0 = \mathbf{0}$. For $l = 1, 2, \dots, t$, the binary message vector is \mathbf{a}_l ($N R_l$ bits). Given \mathbf{a}_l and the memory state \mathbf{s}_{l-1} , the encoder computes $\mathbf{s}_l = \mathbf{E}_l(\mathbf{s}_{l-1}, \mathbf{a}_l)$ using an encoding function \mathbf{E}_l and writes the result \mathbf{s}_l on the WOM. The WOM constraints can be expressed by $\mathbf{s}_l \geq \mathbf{s}_{l-1}$ where the vector inequality applies componentwise. Since the WOM is binary, \mathbf{s}_{l-1} and \mathbf{s}_l are binary vectors, so that if $s_{l-1,j} = 1$ for some component j , then $s_{l,j} = 1$. The decoder uses a decoding function \mathbf{D}_l to compute the decoded message $\hat{\mathbf{a}}_l = \mathbf{D}_l(\mathbf{s}_l)$. The goal is to design a low complexity

read-write scheme that satisfies the WOM constraints and achieves $\hat{\mathbf{a}}_l = \mathbf{a}_l$ for $l = 1, 2, \dots, t$ with high probability for any set of t messages $\mathbf{a}_l, l = 1, 2, \dots, t$. As is commonly assumed in the literature (see e.g. [2] where it is explained why this assumption does not affect the WOM rate), we also assume that the generation number on each write and read is known.

The capacity region of the WOM is [3]

$$C_t = \left\{ (R_1, \dots, R_t) \in \mathbb{R}_+^t \mid R_1 < h(\epsilon_1), \right. \\ \left. R_2 < (1 - \epsilon_1)h(\epsilon_2), \dots, R_{t-1} < \left[\prod_{j=1}^{t-2} (1 - \epsilon_j) \right] h(\epsilon_{t-1}), \right. \\ \left. R_t < \prod_{j=1}^{t-1} (1 - \epsilon_j), \text{ where } 0 \leq \epsilon_1, \epsilon_2, \dots, \epsilon_{t-1} \leq 1/2 \right\} \quad (1)$$

(\mathbb{R}_+^t denotes a t -dimensional vector with positive elements; $h(x) = -x \log_2 x - (1 - x) \log_2 (1 - x)$ is the binary entropy function). Note that this is both the zero-error capacity region and the ϵ -error capacity region (see the comment after the statement of Theorem 4 in [3]). We also define the maximum average rate,

$$\bar{C}_t = \sup_{(R_1, \dots, R_t) \in C_t} \frac{1}{t} \sum_{j=1}^t R_j$$

The maximum average rate was shown to be [3] $\bar{C}_t = \log_2(t + 1)/t$. This means that the total number of bits that can be stored on N WOM cells in t writes is $N \log_2(t + 1)$ which is significantly higher than N . The maximum fixed rate was also obtained [3]. WOM codes were proposed in the past by various authors, e.g. [1], [4], [5], [6], [7], [8], [2], [9] and references therein. For the case where there are two writes, $t = 2$, the method in [9] can approach capacity in polynomial in the blocklength computational complexity. To the best of our knowledge, this was the first solution with this property.

In this work, which is an expanded version of [10], we propose a new family of WOM codes based on polar codes [11]. The method relies on the fact that polar codes are asymptotically optimal for lossy source coding [12] and can be encoded and decoded efficiently ($O(N \log N)$ operations where N is the blocklength). We show that our method can achieve any point in the capacity region of noiseless WOMs when an arbitrary number of multiple writes is permitted. The encoding and decoding complexities scale as $O(N \log N)$. For N sufficiently large, the error probability is at most 2^{-N^β} for any $0 < \beta < 1/2$. We demonstrate that this method can be used to construct actual practical WOM codes. We also show that our results also apply to generalized WOMs, described by an arbitrary directed acyclic graph (DAG), using nonbinary polar codes. In the derivation we also obtain results on the typical distortion of polar codes for lossy source coding.

Recently, another WOM code was proposed [13], that can approach any point in the capacity region of noiseless WOMs in computational complexity that scales polynomially with the blocklength. On the one hand, the method in [13] is deterministic and guarantees zero error, while our method is probabilistic and only guarantees a vanishing with the blocklength error probability. On the other hand, the method in [13] requires a very long blocklength to

closely approach capacity, and it is not clear whether it can be used in practice. In an actual WOM (e.g., flash memory) there is also some channel noise. Hence, there is some small inevitable error.

The rest of this paper is organized as follows. In Section II we provide some background on polar codes for channel and lossy source coding. In Section III we provide extended results on polar codes for lossy source coding that will be required later. In Section IV we present the new proposed polar WOM code for the binary case and analyze its performance. In Section V we present a generalization of our solution to generalized WOMs, described by an arbitrary DAG, using nonbinary polar codes. In Section VI we present some simulation results. Finally, Section VII concludes the paper.

II. BACKGROUND ON POLAR CODES

In his seminal work [11], Arikan has introduced Polar codes for channel coding and showed that they can achieve the symmetric capacity (i.e. the capacity under uniform input distribution) of an arbitrary binary-input channel. In [14] it was shown that the results can be generalized to arbitrary discrete memoryless channels. We will follow the notation in [12]. Let $G_2 = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$ and let its n th Kronecker product be $G_2^{\otimes n}$. Also denote $N = 2^n$. Let \mathbf{u} be an N -dimensional binary $\{0, 1\}$ message vector, and let $\mathbf{x} = \mathbf{u}G_2^{\otimes n}$ where the matrix multiplication is over $\text{GF}(2)$. Suppose that we transmit \mathbf{x} over a memoryless binary-input channel with transition probability $W(y|x)$ and channel output vector \mathbf{y} . If \mathbf{u} is chosen at random with uniform probability then the resulting probability distribution $P(\mathbf{u}, \mathbf{x}, \mathbf{y})$ is given by

$$P(\mathbf{u}, \mathbf{x}, \mathbf{y}) = \frac{1}{2^N} \mathbb{1}_{\{\mathbf{x}=\mathbf{u}G_2^{\otimes n}\}} \prod_{i=0}^{N-1} W(y_i | x_i) \quad (2)$$

Define the following N sub-channels,

$$W_N^{(i)}(\mathbf{y}, \mathbf{u}_0^{i-1} | u_i) = P(\mathbf{y}, \mathbf{u}_0^{i-1} | u_i) = \frac{1}{2^{N-1}} \sum_{\mathbf{u}_{i+1}^{N-1}} P(\mathbf{y} | \mathbf{u})$$

Denote by $I(W)$ the symmetric capacity of the channel W (it is the channel capacity when the channel is memoryless binary-input output symmetric (MBIOS)) and by $Z(W_N^{(i)})$ the Bhattacharyya parameters of the sub-channels $W_N^{(i)}$. In [11], [15] it was shown that asymptotically in N , a fraction $I(W)$ of the sub-channels satisfy $Z(W_N^{(i)}) < 2^{-2^{n\beta}}$ for any $0 < \beta < 1/2$. Based on this result the following communication scheme was proposed. Let R be the code rate. Denote by F the set of $N(1 - R)$ sub-channels with the highest values of $Z(W_N^{(i)})$ (denoted in the sequel as the *frozen set*), and by F^c the remaining $N \cdot R$ sub-channels. Fix the input to the sub-channels in F to some arbitrary frozen vector \mathbf{u}_F (known both to the encoder and to the decoder) and use the channels in F^c to transmit information. The encoder then transmits $\mathbf{x} = \mathbf{u}G_2^{\otimes n}$ over the channel. The decoder applies the following successive cancelation (SC) scheme. For $i = 0, 1, 2, \dots, N - 1$, if $i \in F$ then $\hat{u}_i = u_i$ (\mathbf{u}_F is common knowledge), otherwise

$$\hat{u}_i = \begin{cases} 0 & \text{if } L_N^{(i)} > 1 \\ 1 & \text{if } L_N^{(i)} \leq 1 \end{cases}$$

where

$$L_N^{(i)}(\mathbf{y}, \mathbf{u}_0^{i-1}) = \frac{W_N^{(i)}(\mathbf{y}, \hat{\mathbf{u}}_0^{i-1} | u_i = 0)}{W_N^{(i)}(\mathbf{y}, \hat{\mathbf{u}}_0^{i-1} | u_i = 1)}$$

Asymptotically, reliable communication under SC decoding is possible for any $R < I(W)$. The error probability is upper bounded by 2^{-N^β} for any $\beta < 1/2$, and the SC decoder can be implemented in complexity $O(N \log N)$.

Polar codes can also be used for lossy source coding [12]. Consider a binary symmetric source (BSS), i.e. a random binary vector \mathbf{Y} uniformly distributed over all N -dimensional binary vectors. Let $d(\mathbf{x}, \mathbf{y})$ be a distance measure between two binary vectors, \mathbf{x} and \mathbf{y} , such that $d(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^N d(x_i, y_i)$ where $d(0, 0) = d(1, 1) = 0$ and $d(0, 1) = d(1, 0) = 1$. Define a binary symmetric channel (BSC) $W(y|x)$ with crossover parameter D and construct a polar code with frozen set F that consists of the $(1-R) \cdot N$ sub-channels with the largest values of $Z(W_N^{(i)})$. This code uses some arbitrary frozen vector \mathbf{u}_F which is known both to the encoder and to the decoder (e.g. $\mathbf{u}_F = 0$) and has rate $R = |F^c|/N$. Given $\mathbf{Y} = \mathbf{y}$ the SC encoder applies the following scheme. For $i = 0, 1, \dots, N-1$, if $i \in F$ then $\hat{u}_i = u_i$, otherwise

$$\hat{u}_i = \begin{cases} 0 & \text{w.p. } L_N^{(i)} / (L_N^{(i)} + 1) \\ 1 & \text{w.p. } 1 / (L_N^{(i)} + 1) \end{cases} \quad (3)$$

(w.p. denotes with probability) The complexity of this scheme is $O(N \log N)$. Since $\hat{\mathbf{u}}_F = \mathbf{u}_F$ is common knowledge, the decoder only needs to obtain $\hat{\mathbf{u}}_{F^c}$ from the encoder ($|F^c|$ bits). It can then reconstruct the approximating source codeword \mathbf{x} using $\mathbf{x} = \hat{\mathbf{u}}G_2^{\otimes n}$. Let $Ed(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N$ be the average distortion of this polar code (the averaging is over both the source vector, \mathbf{Y} , and over the approximating source codeword, $\mathbf{X}(\mathbf{Y})$, which is determined at random from \mathbf{Y}). Also denote by $R(D) = 1 - h(D)$ the rate distortion function. In [12] it was shown, given any $0 < D < 1/2$, $0 < \delta < 1 - R(D)$ and $0 < \beta < 1/2$, that for N (i.e., n) sufficiently large, $R = |F^c|/N = R(D) + \delta$, and any frozen vector \mathbf{u}_F , the polar code with rate R under SC encoding satisfies

$$Ed(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N \leq D + O(2^{-N^\beta}) \quad (4)$$

In fact, as noted in [12], the proof of (4) is not restricted to a BSS and extends to general sources, e.g. a binary erasure source [12].

III. EXTENDED RESULTS FOR POLAR SOURCE CODES

Although the result in [12] is concerned only with the average distortion, one may strengthen it by combining it with the strong converse result of the rate distortion theorem in [16, p. 127]. The strong converse asserts that for any $\delta_1 > 0$, if $\delta > 0$ is chosen sufficiently small and $R < R(D) + \delta$ then $P(d(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N < D - \delta_1)$ can be made arbitrarily small by choosing N sufficiently large. Combining this with (4), we can conclude, for a polar code designed for a BSC(D), with $R = |F^c|/N \leq R(D) + \delta$ and $\delta > 0$ sufficiently small, that

$$\lim_{N=2^n, n \rightarrow \infty} P(d(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N > D + \delta_2) = 0 \quad (5)$$

for any $\delta_2 > 0$.

We now extend the result in (5) in order to obtain an improved upper bound estimate (as a function of N) on the considered probability. The following discussion is valid for an arbitrary discrete MBIOS, $W(y|x)$, in (2). As in [12] we construct a source polar code with frozen set defined by,

$$F = \left\{ i \in \{0, \dots, N-1\} : Z \left(W_N^{(i)} \right) \geq 1 - 2\delta_N^2 \right\} \quad (6)$$

(note that F depends on N , however for simplicity our notation does not show this dependence explicitly) and

$$\delta_N = 2^{-N^\beta} / (2N) \quad (7)$$

By [12, Theorem 19 and Equation (22)] (see also [12, Equation (12)]),

$$\lim_{N=2^n, n \rightarrow \infty} |F|/N = 1 - I(W)$$

Hence, for any $\epsilon > 0$, if N is large enough then the rate R of the code satisfies,

$$R = 1 - |F|/N \leq I(W) + \epsilon$$

Let \mathbf{y} be a source vector produced by a sequence of independent identically distributed (i.i.d.) realizations of Y . If \mathbf{u}_F is chosen at random with uniform probability then the vector \mathbf{u} produced by the SC encoder (that utilizes (3)) has a conditional probability distribution given by [12]

$$Q(\mathbf{u} | \mathbf{y}) = \prod_{i=0}^{N-1} Q(u_i | \mathbf{u}_0^{i-1}, \mathbf{y}) \quad (8)$$

where

$$Q(u_i | \mathbf{u}_0^{i-1}, \mathbf{y}) = \begin{cases} 1/2 & \text{if } i \in F \\ P(u_i | \mathbf{u}_0^{i-1}, \mathbf{y}) & \text{if } i \in F^c \end{cases} \quad (9)$$

On the other hand, the conditional probability of \mathbf{u} given \mathbf{y} corresponding to (2) is,

$$P(\mathbf{u} | \mathbf{y}) = \prod_{i=0}^{N-1} P(u_i | \mathbf{u}_0^{i-1}, \mathbf{y})$$

In the sequel we employ standard strong typicality arguments. Similarly to the notation in [17, Section 10.6, pp. 325-326], we define an ϵ -strongly typical sequence $\mathbf{x} \in \mathcal{X}^N$ with respect to a distribution $p(x)$ on the finite set \mathcal{X} , and denote it by $A_\epsilon^{*(N)}(X)$ (or $A_\epsilon^{*(N)}$ for short) as follows. Let $C(a | \mathbf{x})$ denote the number of occurrences of the symbol a in the sequence \mathbf{x} . Then $\mathbf{x} \in A_\epsilon^{*(N)}(X)$ if the following two conditions hold. First, for all $a \in \mathcal{X}$ with $p(a) > 0$, $|C(a | \mathbf{x})/N - p(a)| < \epsilon$. Second, for all $a \in \mathcal{X}$ with $p(a) = 0$, $C(a | \mathbf{x}) = 0$. Similarly we define ϵ -strongly typical sequences $\mathbf{x}, \mathbf{y} \in \mathcal{X}^N \times \mathcal{Y}^N$ with respect to a distribution $p(x, y)$ on the finite set $\mathcal{X} \times \mathcal{Y}$, and denote it by $A_\epsilon^{*(N)}(X, Y)$ (or $A_\epsilon^{*(N)}$ for short). We denote by $C(a, b | \mathbf{x}, \mathbf{y})$ the number of occurrences of a, b in \mathbf{x}, \mathbf{y} , and require the following. First, for all $a, b \in \mathcal{X} \times \mathcal{Y}$ with $p(a, b) > 0$, $|C(a, b | \mathbf{x}, \mathbf{y})/N - p(a, b)| < \epsilon$. Second, for all $a, b \in \mathcal{X} \times \mathcal{Y}$ with $p(a, b) = 0$, $C(a, b | \mathbf{x}, \mathbf{y}) = 0$. The definition of ϵ -strong typicality can be extended to more than two sequences in the obvious way.

In our case $\mathbf{x} = \mathbf{x}(\mathbf{u}) \triangleq \mathbf{u}G_2^{\otimes n}$. Note that $G_2^{\otimes n}$ is a full rank matrix. Therefore each vector \mathbf{u} corresponds to exactly one vector \mathbf{x} . We say that $\mathbf{u}, \mathbf{y} \in A_\epsilon^{*(N)}(U, Y)$ if $\mathbf{x}(\mathbf{u}), \mathbf{y} \in A_\epsilon^{*(N)}(X, Y)$ with respect to the probability distribution $p(x, y) = W(y | x)/2$ (see (2)).

Theorem 1: Consider a discrete MBIOS, $W(y | x)$. Suppose that the input binary random variable X is uniformly distributed (i.e., $X \in \{0, 1\}$ w.p. $(1/2, 1/2)$), and denote the channel output random variable by Y . Let the source vector random variable \mathbf{Y} be created by a sequence of N i.i.d. realizations of Y . Consider a polar code for source coding [12] with block length $N = 2^n$ and a frozen set defined by (6)-(7) (whose rate approaches $I(W)$ asymptotically) as described above. Let \mathbf{U} be the random variable denoting the output of the SC encoder. Then for any $0 < \beta < 1/2$, $\epsilon > 0$ and N (i.e., n) sufficiently large, $\mathbf{U}, \mathbf{Y} \in A_\epsilon^{*(N)}(U, Y)$ w.p. at least $1 - 2^{-N^\beta}$.

Recall that the SC encoder's output \mathbf{u} has conditional probability distribution $Q(\mathbf{u} | \mathbf{y})$ given by (8)-(9). Hence, Theorem 1 asserts that, for N sufficiently large, $Q\left(A_\epsilon^{*(N)}(U, Y)\right) > 1 - 2^{-N^\beta}$.

Proof: To prove the theorem we use the following result of [12, Lemma 5 and Lemma 7],

$$\sum_{\mathbf{u}, \mathbf{y}} |Q(\mathbf{u}, \mathbf{y}) - P(\mathbf{u}, \mathbf{y})| \leq 2|F|\delta_N \quad (10)$$

Hence,

$$\begin{aligned} & \left| \sum_{\mathbf{u}, \mathbf{y} \in A_\epsilon^{*(N)}} Q(\mathbf{u}, \mathbf{y}) - \sum_{\mathbf{u}, \mathbf{y} \in A_\epsilon^{*(N)}} P(\mathbf{u}, \mathbf{y}) \right| \\ & \leq \sum_{\mathbf{u}, \mathbf{y} \in A_\epsilon^{*(N)}} |Q(\mathbf{u}, \mathbf{y}) - P(\mathbf{u}, \mathbf{y})| \leq 2|F|\delta_N \end{aligned} \quad (11)$$

In addition we claim the following,

$$\sum_{\mathbf{u}, \mathbf{y} \in A_\epsilon^{*(N)}} P(\mathbf{u}, \mathbf{y}) = P\left(A_\epsilon^{*(N)}\right) \geq 1 - e^{-N^\gamma} \quad (12)$$

for some constant γ (that can depend on ϵ). We now prove (12).

$$\begin{aligned} P\left(A_\epsilon^{*(N)}\right) &= \\ & P\left(\forall a, b : \left| \frac{1}{N} C(a, b | \mathbf{X}(\mathbf{U}), \mathbf{Y}) - p(a, b) \right| < \epsilon\right) = \\ & 1 - P\left(\exists a, b : \left| \frac{1}{N} C(a, b | \mathbf{X}(\mathbf{U}), \mathbf{Y}) - p(a, b) \right| \geq \epsilon\right) \end{aligned} \quad (13)$$

In the first equality we have used the fact that $p(a, b) = 0$ implies $C(a, b | \mathbf{X}(\mathbf{U}), \mathbf{Y}) = 0$. Let Z be a binary $\{0, 1\}$ random variable such that $Z_i = 1$ if $(X_i(\mathbf{U}), Y_i) = (a, b)$ and $Z_i = 0$ otherwise. Then,

$$P(Z_i = 1) = p(a, b) \quad , \quad C(a, b | \mathbf{X}(\mathbf{U}), \mathbf{Y}) = \sum_{i=1}^N Z_i$$

Therefore,

$$\begin{aligned} & P\left\{ \left| \frac{1}{N} C(a, b | \mathbf{X}(\mathbf{U}), \mathbf{Y}) - p(a, b) \right| \geq \epsilon \right\} = \\ & P\left\{ \left| \frac{1}{N} \sum_{i=1}^N Z_i - p(a, b) \right| \geq \epsilon \right\} \leq 2e^{-2\epsilon^2 N} \end{aligned} \quad (14)$$

where the inequality is due to Hoeffding's inequality (using the fact $0 \leq Z_i \leq 1$). Hence,

$$P \left\{ \exists a, b : \left| \frac{1}{N} C(a, b | \mathbf{X}(\mathbf{U}), \mathbf{Y}) - p(a, b) \right| \geq \epsilon \right\} \leq 2|\mathcal{X}||\mathcal{Y}|e^{-2\epsilon^2 N}$$

which, together with (13), proves (12). From (11)

$$P \left(A_\epsilon^{*(N)} \right) \leq Q \left(A_\epsilon^{*(N)} \right) + 2|F|\delta_N$$

Combining this with (12) we get

$$Q \left(A_\epsilon^{*(N)} \right) \geq 1 - e^{-N\gamma} - 2|F|\delta_N$$

Recalling the definition of δ_N , (7), the theorem follows immediately. \square

Although not needed in the rest of the paper, we can now improve the inequality (5) using the following Theorem.

Theorem 2: Let \mathbf{Y} be a random vector, uniformly distributed over all N -dimensional binary $\{0, 1\}$ vectors. Consider a polar code for source coding [12] designed for a BSC with crossover parameter D . Let $\mathbf{X}(\mathbf{Y})$ be the reconstructed source codeword given \mathbf{Y} . Then for any $\delta > 0$, $0 < \beta < 1/2$ and N sufficiently large,

$$Q(d(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N \geq D + \delta) < 2^{-N^\beta} \quad (15)$$

The code rate approaches the rate distortion function, $R(D) = 1 - h(D)$, for N sufficiently large.

Proof: Since $d(\mathbf{X}(\mathbf{Y}), \mathbf{Y}) = \sum_{i=0}^N d(X_i, Y_i)$ then,

$$\begin{aligned} Q(d(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N \geq D + \delta) &= \\ Q([C(0, 1 | \mathbf{X}(\mathbf{Y}), \mathbf{Y}) + C(1, 0 | \mathbf{X}(\mathbf{Y}), \mathbf{Y})]/N \geq D + \delta) \end{aligned}$$

Denote by \mathcal{A} , \mathcal{B} and \mathcal{E} the events

$$\begin{aligned} \mathcal{A} &= \{C(0, 1 | \mathbf{X}(\mathbf{Y}), \mathbf{Y})/N < D/2 + \delta/2\} \\ \mathcal{B} &= \{C(1, 0 | \mathbf{X}(\mathbf{Y}), \mathbf{Y})/N < D/2 + \delta/2\} \\ \mathcal{E} &= \{[C(0, 1 | \mathbf{X}(\mathbf{Y}), \mathbf{Y}) + C(1, 0 | \mathbf{X}(\mathbf{Y}), \mathbf{Y})]/N < D + \delta\} \end{aligned}$$

Then for N sufficiently large,

$$\begin{aligned} Q(\mathcal{E}) &> Q(\mathcal{A} \cap \mathcal{B}) = 1 - Q(\bar{\mathcal{A}} \cup \bar{\mathcal{B}}) \\ &\geq 1 - Q(\bar{\mathcal{A}}) - Q(\bar{\mathcal{B}}) > 1 - 2 \cdot 2^{-N^\beta} \end{aligned} \quad (16)$$

The last inequality is due to Theorem 1. This proves (15) (since (16) holds for any $0 < \beta < 1/2$) \square

IV. THE PROPOSED POLAR WOM CODE

Consider the binary WOM problem that was defined in Section I. Given some set of parameters $0 \leq \epsilon_1, \epsilon_2, \dots, \epsilon_{t-1} \leq 1/2$, $\epsilon_0 \equiv 0$ and $\epsilon_t \equiv 1/2$, we wish to show that we can construct a reliable polar coding scheme for any set of WOM rates $(R_1, \dots, R_t) \in \mathbb{R}_+^t$ in the capacity region (1). That is, the rates satisfy

$$R_l < \alpha_{l-1} h(\epsilon_l) \quad \forall l = 1, 2, \dots, t$$

where

$$\alpha_{l-1} = \prod_{j=0}^{l-1} (1 - \epsilon_j) \tag{17}$$

For that purpose we consider the following t test channels. The input set of each channel is $\{0, 1\}$. The output set is $\{(0, 0), (0, 1), (1, 0), (1, 1)\}$. Denote the input random variable by X and the output by (S, V) . The probability transition function of the l th channel is defined by,

$$P_l((S, V) = (s, v) | X = x) = f_l(s, x \oplus v) \tag{18}$$

where

$$f_l(s, b) = \begin{cases} \alpha_{l-1}(1 - \epsilon_l) & \text{if } s = 0, b = 0 \\ \alpha_{l-1}\epsilon_l & \text{if } s = 0, b = 1 \\ (1 - \alpha_{l-1}) & \text{if } s = 1, b = 0 \\ 0 & \text{if } s = 1, b = 1 \end{cases} \tag{19}$$

This channel is also shown in Figure 1. It is easy to verify that the capacity of this channel is $1 - \alpha_{l-1} h(\epsilon_l)$ and that the capacity achieving input distribution is symmetric, i.e., $P(X = 0) = P(X = 1) = 1/2$.

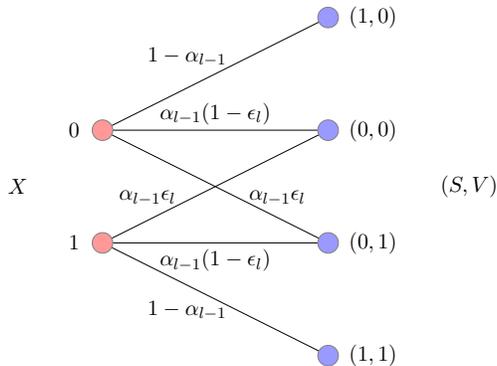

Fig. 1. The probability transition function of the l th channel

For each channel l we design a polar code with blocklength N and frozen set of sub-channels F_l defined by (6). The rate is

$$R'_l = 1 - \alpha_{l-1} h(\epsilon_l) + \delta_l \tag{20}$$

where $\delta_l > 0$ is arbitrarily small for N sufficiently large. This code will be used as a source code.

Denote the information sequence by $\mathbf{a}_1, \dots, \mathbf{a}_t$ and the sequence of WOM states by $\mathbf{s}_0 \equiv 0, \mathbf{s}_1, \dots, \mathbf{s}_t$. Hence $\mathbf{s}_l = \mathbf{E}_l(\mathbf{s}_{l-1}, \mathbf{a}_l)$ and $\hat{\mathbf{a}}_l = \mathbf{D}_l(\mathbf{s}_l)$, where $\mathbf{E}_l(\mathbf{s}, \mathbf{a})$ and $\mathbf{D}_l(\mathbf{s})$ are the l th encoding and decoding functions, respectively, and $\hat{\mathbf{a}}_1, \dots, \hat{\mathbf{a}}_t$ is the retrieved information sequence. We define $\mathbf{E}_l(\mathbf{s}, \mathbf{a})$ and $\mathbf{D}_l(\mathbf{s})$ as follows.

Encoding function, $\hat{\mathbf{s}} = \mathbf{E}_l(\mathbf{s}, \mathbf{a})$:

- 1) Let $\mathbf{v} = \mathbf{s} \oplus \mathbf{g}$ where \oplus denotes bitwise XOR and \mathbf{g} is a sample from an N dimensional uniformly distributed random binary $\{0, 1\}$ vector. The vector \mathbf{g} is a common randomness source (dither), known both to the encoder and to the decoder.
- 2) Let $y_j = (s_j, v_j)$ and $\mathbf{y} = (y_1, y_2, \dots, y_N)$. Compress the vector \mathbf{y} using the l th polar code with $\mathbf{u}_{F_l} = \mathbf{a}_l$. This results in a vector \mathbf{u} and a vector $\mathbf{x} = \mathbf{u}G_2^{\otimes n}$.
- 3) Finally $\hat{\mathbf{s}} = \mathbf{x} \oplus \mathbf{g}$.

Decoding function, $\hat{\mathbf{a}} = \mathbf{D}_l(\hat{\mathbf{s}})$:

- 1) Let $\mathbf{x} = \hat{\mathbf{s}} \oplus \mathbf{g}$.
- 2) $\hat{\mathbf{a}} = \left(\mathbf{x} (G_2^{\otimes n})^{-1} \right)_{F_l}$ where $(\mathbf{z})_{F_l}$ denotes the elements of the vector \mathbf{z} in the set F_l .

Note that the information is embedded within the set F_l . Hence, when considered as a WOM code, our code has rate $R_l = |F_l|/N = (N - |F_l^c|)/N = 1 - R_l'$, where R_l' is the rate of the polar source code.

For the sake of the proof we slightly modify the coding scheme as follows:

- (M1) The definition of the l th channel is modified such that in (19) we use $\epsilon_l - \zeta$ instead of ϵ_l where $\zeta > 0$ will be chosen sufficiently small. We will show that any set of rates $(R_1, \dots, R_t) \in \mathbb{R}_+^t$ that satisfy

$$R_l < \alpha_{l-1} h(\epsilon_l - \zeta) \quad \forall l = 1, 2, \dots, t$$

is achievable in our scheme. Setting ζ sufficiently small then shows that any point in the capacity region (1) is achievable using polar WOM codes.

- (M2) The encoder sets $\mathbf{u}_{F_l} = \mathbf{a}_l \oplus \mathbf{g}'_l$ instead of $\mathbf{u}_{F_l} = \mathbf{a}_l$, where \mathbf{g}'_l is $|F_l|$ dimensional uniformly distributed binary (dither) vector known both at the encoder and decoder. In this way, the assumption that \mathbf{u}_{F_l} is uniformly distributed holds. Similarly, the decoder modifies its operation to $\hat{\mathbf{a}} = \left(\mathbf{x} (G_2^{\otimes n})^{-1} \right)_{F_l} \oplus \mathbf{g}'_l$.
- (M3) We assume a random permutation of the input vector \mathbf{y} prior to quantization in each polar code. These random permutations are known both at the encoder and decoder. More precisely, in step 2 the encoder applies the permutation, π , on \mathbf{y} . Then it compresses the permuted \mathbf{y} and obtains some polar codeword. Finally it applies the inverse permutation, π^{-1} , on this codeword to produce \mathbf{x} and proceeds to step 3. The decoder, in the end of step 1, uses the permutation, π , to permute \mathbf{x} , and then uses this permuted \mathbf{x} (instead of \mathbf{x}) in step 2.
- (M4) Denote the Hamming weight of the WOM state \mathbf{s}_l after l writes by $\gamma_l = w_H(\mathbf{s}_l)$. Also denote the binomial distribution with N trials and success probability $1 - \alpha$ by $B(N, 1 - \alpha)$, such that $\Upsilon \sim B(N, 1 - \alpha)$ if for $k = 0, 1, \dots, N$, $\Pr(\Upsilon = k) = \binom{N}{k} (1 - \alpha)^k \alpha^{N-k}$. After the l th write we draw at random a number η from the distribution $B(N, 1 - \alpha_l)$. If $\gamma_l < \eta$ then we flip $\eta - \gamma_l$ elements in \mathbf{s}_l from 0 to 1.

Theorem 3: Consider an arbitrary information sequence $\mathbf{a}_1, \dots, \mathbf{a}_t$ with rates R_1, R_2, \dots, R_t that are inside the capacity region (1) of the binary WOM. For any $0 < \beta < 1/2$ and N sufficiently large, the coding scheme described above can be used to write this sequence reliably over the WOM w.p. at least $1 - 2^{-N^\beta}$ in encoding and decoding complexities $O(N \log N)$.

To prove the theorem we need the following lemma¹. Consider an i.i.d. source (S, V) with the following probability distribution,

$$P((S, V) = (s, v)) = \begin{cases} (1 - \alpha_{l-1})/2 & \text{if } s = 1, v = 0 \\ \alpha_{l-1}/2 & \text{if } s = 0, v = 0 \\ \alpha_{l-1}/2 & \text{if } s = 0, v = 1 \\ (1 - \alpha_{l-1})/2 & \text{if } s = 1, v = 1 \end{cases} \quad (21)$$

Note that this source has the marginal distribution of the output of the l th channel defined by (18)-(17) under a symmetric input distribution.

Lemma 1: Consider a polar code designed for the l th channel defined by (18)-(17) as described above. The code has rate R'_l defined in (20), a frozen set of sub-channels, F_l , and some frozen vector \mathbf{U}_{F_l} which is uniformly distributed over all $|F_l|$ dimensional binary vectors. The code is used to encode a random vector (\mathbf{S}, \mathbf{V}) drawn by i.i.d. sampling from the distribution (21) using the SC encoder. Denote by \mathbf{X} the encoded codeword. Then for any $\delta > 0$, $0 < \beta < 1/2$ and N sufficiently large, the following holds w.p. at least $1 - 2^{-N^\beta}$,

$$|\{k : S_k = 0 \text{ and } X_k \oplus V_k = 1\}| < (\alpha_{l-1}\epsilon_l + \delta) N \quad (22)$$

$$\{k : S_k = 1 \text{ and } X_k \oplus V_k = 1\} = \emptyset \quad (23)$$

Proof: According to Theorem 1, for N (i.e., n) large enough,

$$(\mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) \in A_{\delta/2}^{*(N)}(X, (S, V))$$

w.p. at least $1 - 2^{-N^\beta}$. Consider all possible triples χ, ξ, ν , where $\chi \in \{0, 1\}$, $\xi \in \{0, 1\}$ and $\nu \in \{0, 1\}$. From the definition of $A_{\delta/2}^{*(N)}$, if $p(\chi, (\xi, \nu)) > 0$ then (w.p. at least $1 - 2^{-N^\beta}$),

$$|C(\chi, (\xi, \nu) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) / N - p(\chi, (\xi, \nu))| < \delta/2 \quad (24)$$

and if $p(\chi, (\xi, \nu)) = 0$ then

$$C(\chi, (\xi, \nu) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) = 0 \quad (25)$$

In addition, using $P(X = 0) = P(X = 1) = 1/2$ and the channel definition (18)-(17) we have,

$$p(0, (0, 1)) = p(1, (0, 0)) = \alpha_{l-1}\epsilon_l/2$$

¹This Lemma is formulated for the original channel with parameter ϵ_l , and not for the (M1) modified channel with parameter $\epsilon_l - \zeta$.

Combining this with (24) we obtain

$$C(0, (0, 1) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) < (\alpha_{l-1}\epsilon_l/2 + \delta/2)N$$

$$C(1, (0, 0) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) < (\alpha_{l-1}\epsilon_l/2 + \delta/2)N$$

Hence,

$$\begin{aligned} & |\{k : S_k = 0 \text{ and } X_k \oplus V_k = 1\}| = \\ & C(0, (0, 1) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) + \\ & C(1, (0, 0) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) < (\alpha_{l-1}\epsilon_l + \delta)N \end{aligned}$$

This proves (22). Similarly (23) is due to (25) since $p(0, (1, 1)) = p(1, (1, 0)) = 0$ from the definition of the channel. \square

We proceed to the proof of Theorem 3. We denote by $\mathbf{S}_l, \mathbf{S}, \hat{\mathbf{S}}, \mathbf{V}, \mathbf{G}, \mathbf{X}$ and Γ_l the random variables corresponding to $s_l, \mathbf{s}, \hat{\mathbf{s}}, \mathbf{v}, \mathbf{g}, \mathbf{x}$ and $\gamma_l = w_H(\mathbf{s}_l)$.

Proof of Theorem 3: Note that we only need to prove successful encoding since the WOM is noiseless.

Recall our definition $\Gamma_l = w_H(\mathbf{S}_l)$. Suppose that $\Gamma_{l-1} \sim B(N, 1 - \alpha_{l-1})$. Our first claim is that under this assumption, for $\rho > 0$ sufficiently small and N sufficiently large, w.p. at least $1 - 2^{-N^\beta}$, the encoding will be successful and $\Gamma_l/N < 1 - \alpha_l - \rho$. For notational simplicity we use \mathbf{S} instead of \mathbf{S}_{l-1} , and $\hat{\mathbf{S}}$ instead of \mathbf{S}_l . Considering step 1 of the encoding we see that $\mathbf{Y} = (\mathbf{S}, \mathbf{V})$, after the random permutation described in (M3), can be considered as i.i.d. sampling of the source (S, V) defined in (21) (by the fact that $w_H(\mathbf{S}) \sim B(N, 1 - \alpha_{l-1})$, and since \mathbf{G} is uniformly distributed). Hence, by Lemma 1 and (M1), the compression of this vector in step 2 satisfies the following for any $\delta > 0$ and N sufficiently large w.p. at least $1 - 2^{-N^\beta}$.

1) If $S_k = 1$ then $X_k = V_k = S_k \oplus G_k = G_k \oplus 1$.

2) For at most $[(\epsilon_l - \zeta)\alpha_{l-1} + \delta]N$ components k we have $S_k = 0$ and $X_k = V_k \oplus 1 = S_k \oplus G_k \oplus 1 = G_k \oplus 1$.

Hence, in step 3 of the encoding, if $S_k = 1$ then $\hat{S}_k = X_k \oplus G_k = 1$ (i.e. the WOM constraints are satisfied). In addition there are at most $[(\epsilon_l - \zeta)\alpha_{l-1} + \delta]N$ components k for which $S_k = 0$ and $\hat{S}_k = 1$. Therefore, w.p. at least $1 - 2^{-N^\beta}$, the vectors \mathbf{S} and $\hat{\mathbf{S}}$ satisfy the WOM constraints and

$$\begin{aligned} \Gamma_l = w_H(\hat{\mathbf{S}}) & < [1 - \alpha_{l-1} + (\epsilon_l - \zeta)\alpha_{l-1} + 2\delta]N \\ & = [1 - \alpha_l - \zeta\alpha_{l-1} + 2\delta]N \end{aligned} \tag{26}$$

(in the first inequality we have used the fact that for N sufficiently large, $\Gamma_{l-1} < (1 - \alpha_{l-1} + \delta)N$ w.p. at least $1 - e^{-N^\epsilon}$ for some $\epsilon > 0$ independent of N). Setting $\rho = \zeta\alpha_{l-1} - 2\delta$ yields our first claim.

From (26) we know that η in (M4) will indeed satisfy the condition $\eta > \Gamma_l$ w.p. at least $1 - 2^{-N^\beta}$. The proof of the theorem now follows by using induction on l to conclude that (w.p. at least $1 - 2^{-N^\beta}$) the l th encoding is successful and $\Gamma_l \sim B(N, 1 - \alpha_l)$. The complexity claim is due to the results in [11]. \square

Notes:

- 1) The test channel in the first write is actually a BSC (since $\alpha_{l-1} = 1$ in Figure 1). Similarly, in the last (t) write we can merge together the source symbols $(0, 0)$ and $(0, 1)$ (note that $\epsilon_t = 1/2$ so that X and V are statistically independent given $S = 0$), thus obtaining a test channel which is a binary erasure channel (BEC).
- 2) Consider for example a flash memory device. In practice, the dither, \mathbf{g} , can be determined from the address of the word (e.g. the address is used as a seed value to a random number generator).
- 3) In the rare event where an encoding error has occurred, the encoder may re-apply the encoding using another dither vector value. Furthermore, the decoder can realize which value of dither vector should be used in various ways. One possibility is that this information is communicated, similarly to the assumption that the generation number is known. Another possibility is that the decoder will switch to the next value of the dither value upon detecting decoding failure, e.g. by using CRC information. By repeating this procedure of re-encoding upon a failure event at the encoder several times, one can reduce the error probability as much as required.

V. GENERALIZATION TO NONBINARY POLAR WOM CODES

A. Nonbinary polar codes

Nonbinary polar codes over a q -ary alphabet ($q > 2$) for channel coding over arbitrary discrete memoryless channels were proposed in [14]. Nonbinary polar codes over a q -ary alphabet for lossy source coding of a memoryless source were proposed in [18]. First suppose that q is prime. Similarly to the binary case, the codeword \mathbf{x} of a q -ary polar code is related to the N -dimensional ($N = 2^n$) message vector \mathbf{u} by the relation $\mathbf{x} = \mathbf{u}G_2^{\otimes n}$, where the matrix $G_2^{\otimes n}$ is the same as in the binary case. However, now $\mathbf{u} \in \mathcal{X}^N$, $\mathbf{x} \in \mathcal{X}^N$ where $\mathcal{X} = \{0, 1, \dots, q-1\}$. Suppose that we transmit \mathbf{x} over a memoryless channel with transition probability $W(y | x)$ and channel output vector \mathbf{y} . If \mathbf{u} is chosen at random with uniform probability over \mathcal{X}^N then the resulting probability distribution $P(\mathbf{u}, \mathbf{x}, \mathbf{y})$ is given by

$$P(\mathbf{u}, \mathbf{x}, \mathbf{y}) = \frac{1}{q^N} \mathbb{1}_{\{\mathbf{x}=\mathbf{u}G_2^{\otimes n}\}} \prod_{i=0}^{N-1} W(y_i | x_i) \quad (27)$$

Define the following N sub-channels,

$$W_N^{(i)}(\mathbf{y}, \mathbf{u}_0^{i-1} | u_i) = P(\mathbf{y}, \mathbf{u}_0^{i-1} | u_i) = \frac{1}{q^{N-1}} \sum_{\mathbf{u}_{i+1}^{N-1}} P(\mathbf{y} | \mathbf{u})$$

We denote by $I(W)$ and $I(W_N^{(i)})$, respectively, the symmetric capacity parameters of W and $W_N^{(i)}$. In [14] it was shown that the sub-channels $W_N^{(i)}$ polarize as in the binary case with the same asymptotic polarization rate. The frozen set is chosen similarly to the binary case. Asymptotically, reliable communication under SC decoding is possible for any rate $R < I(W)$. The error probability is upper bounded by 2^{-N^β} for any $\beta < 1/2$, and the decoder can be implemented in complexity $O(N \log N)$.

Nonbinary polar codes were also proposed for lossy source coding [18]. Consider some random variable $Y \in \mathcal{Y}$. For simplicity we assume that \mathcal{Y} is finite. Also denote $\mathcal{X} = \{0, 1, \dots, q-1\}$. Let the source vector random variable

\mathbf{Y} be created by a sequence of N i.i.d. realizations of Y . Let $d(x, y)$ be some (finite) distance measure between $x \in \mathcal{X}$ and $y \in \mathcal{Y}$. Furthermore, for $\mathbf{x} \in \mathcal{X}^N$ and $\mathbf{y} \in \mathcal{Y}^N$, we define $d(\mathbf{x}, \mathbf{y}) = \sum_{i=1}^N d(x_i, y_i)$. Given some distortion level, $D > 0$, let $W(y|x)$ be the test channel that achieves the symmetric rate distortion bound, $R_s(D)$, (i.e., the rate distortion bound under the constraint that X is uniformly distributed over \mathcal{X}) for the source Y at distortion level D . Using that channel, $W(y|x)$, we construct a polar code with frozen set defined by [18]

$$F = \left\{ i \in \{0, \dots, N-1\} : I\left(W_N^{(i)}\right) \leq \delta'_N \right\} \quad (28)$$

where $\delta'_N = 2^{-N^\beta}$. Given $\mathbf{Y} = \mathbf{y}$ the SC encoder applies the following scheme. For $i = 0, 1, \dots, N-1$, if $i \in F$ then $\hat{u}_i = u_i$, otherwise

$$\hat{u}_i = m \quad \text{w.p.} \quad \frac{W_N^{(i)}(\mathbf{y}, \hat{\mathbf{u}}_0^{i-1} | m)}{\sum_{m'=0}^{q-1} W_N^{(i)}(\mathbf{y}, \hat{\mathbf{u}}_0^{i-1} | m')}$$

The complexity of this scheme is $O(N \log N)$. It was shown [18] that

$$\lim_{N \rightarrow \infty} |F|/N = 1 - I(W)$$

Hence, for N sufficiently large, the rate of the code, $R = |F^c|/N$, approaches $I(W) = R_s(D)$. Furthermore, for any frozen vector, \mathbf{u}_F ,

$$\text{Ed}(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N \leq D + O(2^{-N^\beta})$$

under SC encoding, where $\text{Ed}(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N$ is the average distortion.

In fact, using the results in [18], the statements in Section III immediately extend to the nonbinary case. Consider a polar code constructed using some discrete channel $W(y|x)$ with frozen set defined in (28). Suppose that \mathbf{u}_F is chosen at random with uniform probability. Then, similarly to (8)-(9), the vector \mathbf{u} produced by the SC encoder has a conditional probability distribution given by

$$Q(\mathbf{u} | \mathbf{y}) = \prod_{i=0}^{N-1} Q(u_i | \mathbf{u}_0^{i-1}, \mathbf{y}) \quad (29)$$

where

$$Q(u_i | \mathbf{u}_0^{i-1}, \mathbf{y}) = \begin{cases} 1/q & \text{if } i \in F \\ P(u_i | \mathbf{u}_0^{i-1}, \mathbf{y}) & \text{if } i \in F^c \end{cases} \quad (30)$$

On the other hand, the conditional probability of \mathbf{u} given \mathbf{y} corresponding to (27) is

$$P(\mathbf{u} | \mathbf{y}) = \prod_{i=0}^{N-1} P(u_i | \mathbf{u}_0^{i-1}, \mathbf{y})$$

Similarly to (10) above, it was shown in [18, Lemma 2 and Lemma 5] that

$$\sum_{\mathbf{u}, \mathbf{y}} |Q(\mathbf{u}, \mathbf{y}) - P(\mathbf{u}, \mathbf{y})| \leq |F| \cdot \sqrt{2 \log_q e \cdot \delta'_N} \quad (31)$$

Combining (31) with exactly the same arguments that were presented in Theorem 1, yields the following generalization to Theorem 1.

Theorem 4: Consider a discrete channel, $W(y|x)$ where $x \in \mathcal{X} = \{0, 1, \dots, q-1\}$ and where q is prime. Suppose that the input random variable X is uniformly distributed over \mathcal{X} , and denote the channel output random

variable by Y . Let the source vector random variable \mathbf{Y} be created by a sequence of N i.i.d. realizations of Y . Consider a polar code for source coding [18] with block length $N = 2^n$ and a frozen set defined by (28) (whose rate approaches $I(W)$ asymptotically). Let \mathbf{U} be the random variable denoting the output of the SC encoder. Then for any $0 < \beta < 1/2$, $\epsilon > 0$ and N sufficiently large, $\mathbf{U}, \mathbf{Y} \in A_\epsilon^{*(N)}(U, Y)$ w.p. at least $1 - 2^{-N^\beta}$.

Although not needed in the sequel, Theorem 2 also generalizes to the q -ary case:

Theorem 5: Consider some random variable $Y \in \mathcal{Y}$ and let $\mathcal{X} = \{0, 1, \dots, q-1\}$ where q is prime. Let the source vector random variable \mathbf{Y} be created by a sequence of N i.i.d. realizations of Y . Let $d(x, y)$ be some (finite) distance measure between $x \in \mathcal{X}$ and $y \in \mathcal{Y}$. Let $W(y|x)$ be the test channel that achieves the symmetric rate distortion bound for distance measure $d(\cdot)$ and some distortion level, $D > 0$. Consider a polar code for source coding [18] designed for $W(y|x)$ as described above. Let $\mathbf{X}(\mathbf{Y})$ be the reconstructed source codeword given \mathbf{Y} . Then for any $\delta > 0$, $0 < \beta < 1/2$ and N sufficiently large,

$$Q(d(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N \geq D + \delta) < 2^{-N^\beta} \quad (32)$$

The code rate approaches the symmetric rate distortion function, $R_s(D)$, for N sufficiently large.

Proof: Given some $\delta > 0$, we set $\epsilon > 0$ sufficiently small and N sufficiently large, thus obtaining

$$\begin{aligned} Q(d(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N \geq D + \delta) &\leq Q\left(d(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N \geq D + \delta \cap (\mathbf{X}(\mathbf{Y}), \mathbf{Y}) \in A_\epsilon^{*(N)}\right) \\ &\quad + Q\left((\mathbf{X}(\mathbf{Y}), \mathbf{Y}) \notin A_\epsilon^{*(N)}\right) \\ &< 2^{-N^\beta} \end{aligned}$$

where the last inequality is due to Theorem 4, and the fact that if $(\mathbf{X}(\mathbf{Y}), \mathbf{Y}) \in A_\epsilon^{*(N)}$, for ϵ sufficiently small and N sufficiently large, then $d(\mathbf{X}(\mathbf{Y}), \mathbf{Y})/N < D + \delta$. \square

When q is not prime, the results in this section still apply provided that the polarization transformation is modified as described in [14]. In each step of the transformation, instead of

$$x_1 = u_1 + u_2 \quad , \quad x_2 = u_2$$

we use

$$x_1 = u_1 + u_2 \quad , \quad x_2 = \pi(u_2)$$

where π is a permutation, chosen at random with uniform probability over \mathcal{X} .

B. The generalized WOM problem

Following [19], the generalized WOM is described by a rooted DAG, represented by its set of states (vertices) \mathcal{V} and by its set of edges \mathcal{E} . The set $\mathcal{V} = \{0, 1, \dots, q-1\}$ represents the q possible states of each memory cell. We say that there exists a path from state θ to state θ' in the WOM, and denote it by $\theta \Rightarrow \theta'$, if, for some $k > 0$, there exist vertices $\{\theta = \theta_1, \theta_2, \dots, \theta_{k-1}, \theta_k = \theta'\} \in \mathcal{V}$ such that for $i = 1, 2, \dots, k-1$, θ_i is connected to θ_{i+1} by an

edge in \mathcal{E} (in particular $\theta \Rightarrow \theta'$). The root of the DAG, which represents the initial state of the WOM, is vertex 0. While updating the WOM, only transitions from state θ to state θ' where $\theta \Rightarrow \theta'$ are possible. As an example [19] consider the case where $\mathcal{V} = \{0, 1, 2, 3\}$ and $\mathcal{E} = \{0 \rightarrow 1, 1 \rightarrow 2, 2 \rightarrow 3\}$. In this case, we can update a memory cell from state 0 to any other state. We can update from state 1 to either 1, 2, or 3. We can update from state 2 to either 2 or 3. A memory cell in state 3 will remain in this state forever. For two vectors $\boldsymbol{\theta}, \boldsymbol{\theta}' \in \mathcal{V}^N$, we denote by $\boldsymbol{\theta} \Rightarrow \boldsymbol{\theta}'$ if and only if $\theta_i \Rightarrow \theta'_i$ for $i = 1, 2, \dots, N$. Furthermore, for two random variables X and Y that take values in \mathcal{V} , we denote $X \Rightarrow Y$ if $\Pr(X = x, Y = y) \neq 0$ only if $x \Rightarrow y$.

The capacity region of the WOM is [3], [19],

$$\begin{aligned} C_t = \{ & (R_1, \dots, R_t) \in \mathbb{R}_+^t \mid R_l < H(\Theta_l | \Theta_{l-1}), \\ & l = 1, 2, \dots, t \text{ for some random variables} \\ & 0 = \Theta_0 \Rightarrow \Theta_1 \Rightarrow \Theta_2 \dots \Rightarrow \Theta_t \} \end{aligned} \quad (33)$$

where $H(\cdot | \cdot)$ denotes conditional entropy.

Consider some set of random variables such that

$$0 \equiv \Theta_0 \Rightarrow \Theta_1 \Rightarrow \Theta_2 \dots \Rightarrow \Theta_t \quad (34)$$

Define

$$\epsilon_l(\theta, \theta') \triangleq \Pr(\Theta_l = \theta' \mid \Theta_{l-1} = \theta) \quad (35)$$

and

$$\alpha_l(\theta) \triangleq \Pr(\Theta_l = \theta) \quad (36)$$

It follows that

$$\alpha_l(\theta') = \sum_{\theta=0}^{q-1} \alpha_{l-1}(\theta) \epsilon_l(\theta, \theta') \quad (37)$$

and

$$H(\Theta_l | \Theta_{l-1}) = \sum_{\theta=0}^{q-1} \alpha_{l-1}(\theta) h\left(\{\epsilon_l(\theta, \theta')\}_{\theta'=0}^{q-1}\right) \quad (38)$$

where for a q -dimensional probability vector $\mathbf{x} = (x_0, \dots, x_{q-1})$ (i.e. $x_i \geq 0$ and $\sum_{i=0}^{q-1} x_i = 1$), the entropy function is defined by

$$h(\mathbf{x}) \triangleq - \sum_{i=0}^{q-1} x_i \log_q x_i$$

(in this section the base of all the logarithms is q so that code rate is measured with respect to q -ary information symbols).

C. The proposed nonbinary polar WOM code

Given a set of random variables $\{\Theta_l\}_{l=0}^t$ satisfying (34), with parameters defined in (35)-(36), we wish to show that we can construct a reliable polar WOM coding scheme with WOM rates $(R_1, \dots, R_t) \in \mathbb{R}_+^t$ that satisfy $R_l < H(\Theta_l | \Theta_{l-1})$ for $l = 1, 2, \dots, t$, corresponding to the capacity region (33). For that purpose we consider the following t test channels. The input set of each channel is $\{0, 1, \dots, q-1\}$. The output set is $\{(s, v)\}_{s,v=0}^{q-1}$. Denote the input random variable by X and the output by (S, V) . The probability transition function of the l th channel is defined by,

$$P_l((S, V) = (s, v) | X = x) = \alpha_{l-1}(s)\epsilon_l(s, s + x + v) \quad (39)$$

where the additions are modulo q .

This channel is symmetric in the following sense [20, p. 94]. The set of outputs can be partitioned into subsets (the outputs (s, v) with equal value of s) such that in the matrix of transition probabilities of each subset, each row (column, respectively) is a permutation of any other row (column). Hence, by [20, Theorem 4.5.2], the capacity achieving distribution is the uniform distribution, and the symmetric capacity of this channel is in fact the capacity. For X uniformly distributed over $\{0, 1, \dots, q-1\}$ we obtain (see Appendix A),

$$C_l = 1 - H(\Theta_l | \Theta_{l-1}) \quad (40)$$

For each channel l we design a polar code with blocklength N and frozen set of sub-channels F_l defined by (28). The rate is

$$R'_l = 1 - H(\Theta_l | \Theta_{l-1}) + \delta_l \quad (41)$$

where $\delta_l > 0$ is arbitrarily small for N sufficiently large. This code will be used as a source code.

Denote the information sequence by $\mathbf{a}_1, \dots, \mathbf{a}_t$ and the sequence of WOM states by $\mathbf{s}_0 \equiv 0, \mathbf{s}_1, \dots, \mathbf{s}_t$. Hence $\mathbf{s}_l = \mathbf{E}_l(\mathbf{s}_{l-1}, \mathbf{a}_l)$ and $\hat{\mathbf{a}}_l = \mathbf{D}_l(\mathbf{s}_l)$, where $\mathbf{E}_l(\mathbf{s}, \mathbf{a})$ and $\mathbf{D}_l(\mathbf{s})$ are the l th encoding and decoding functions, respectively, and $\hat{\mathbf{a}}_1, \dots, \hat{\mathbf{a}}_t$ is the retrieved information sequence. We define $\mathbf{E}_l(\mathbf{s}, \mathbf{a})$ and $\mathbf{D}_l(\mathbf{s})$ as follows. All the additions (and subtractions) are performed modulo q .

Encoding function, $\hat{\mathbf{s}} = \mathbf{E}_l(\mathbf{s}, \mathbf{a})$:

- 1) Let $\mathbf{v} = \mathbf{g} - \mathbf{s}$ where \mathbf{g} is a sample from an N dimensional uniformly distributed random q -ary $\{0, 1, \dots, q-1\}$ vector. The vector \mathbf{g} is a common randomness source (dither), known both to the encoder and to the decoder.
- 2) Let $y_j = (s_j, v_j)$ and $\mathbf{y} = (y_1, y_2, \dots, y_N)$. Compress the vector \mathbf{y} using the l th polar code with $\mathbf{u}_{F_l} = \mathbf{a}_l$. This results in a vector \mathbf{u} and a vector $\mathbf{x} = \mathbf{u}G_2^{\otimes n}$.
- 3) Finally $\hat{\mathbf{s}} = \mathbf{x} + \mathbf{g}$.

Decoding function, $\hat{\mathbf{a}} = \mathbf{D}_l(\hat{\mathbf{s}})$:

- 1) Let $\mathbf{x} = \hat{\mathbf{s}} - \mathbf{g}$.
- 2) $\hat{\mathbf{a}} = \left(\mathbf{x} (G_2^{\otimes n})^{-1} \right)_{F_l}$.

As in the binary case, the information is embedded within the set F_l . Hence, when considered as a WOM code, our code has rate $R_l = |F_l|/N = (N - |F_l^c|)/N = 1 - R_l'$, where R_l' is the rate of the source code.

For the sake of the proof we slightly modify the coding scheme as was done above for the binary case (modifications (M1)-(M4)). More precisely,

(M'1) The definition of the l th channel is modified such that in (39) we use $\epsilon'_l(s, s+x+v)$ instead of $\epsilon_l(s, s+x+v)$.

The parameters $\{\epsilon'_l(\theta, \theta')\}_{\theta, \theta'=0}^{q-1}$, $l = 1, 2, \dots, t$, are defined as follows:

$$\epsilon'_l(\theta, \theta') = \begin{cases} \epsilon_l(\theta, \theta'), & \text{if } \theta \neq 0 \\ \epsilon_l(\theta, \theta') + \zeta, & \text{if } \theta = \theta' = 0 \\ \epsilon_l(\theta, \theta') - \zeta/(q-1), & \text{if } \theta = 0 \text{ and } \theta' \neq 0. \end{cases} \quad (42)$$

for some $\zeta > 0$ which will be chosen arbitrarily small. In order to obtain a valid set of parameters, $\{\epsilon'_l(\theta, \theta')\}_{\theta, \theta'=0}^{q-1}$, we first argue that we can assume, without loss of generality, that

$$\epsilon_l(0, \theta') > 0, \quad \forall \theta' \quad (43)$$

Since vertex 0 is the root of our DAG then $0 \Rightarrow \theta', \forall \theta'$. If the required condition (43) is not satisfied then we can slightly shift the probabilities $\epsilon_l(0, \theta')$ such that (43) does hold (all the other transition probabilities, $\epsilon_l(\theta, \theta')$ for $\theta \neq 0$, remain the same). Suppose we can prove the theorem for the shifted parameters. That is, we assume that we can prove the theorem for R_1, \dots, R_t inside the capacity region (33) defined with the shifted parameters. Then, by continuity arguments, if we make the difference between the original and shifted parameters sufficiently small, this will also prove the theorem for rates R_1, \dots, R_t inside the capacity region defined with the original parameters $\{\epsilon_l(\theta, \theta')\}$.

(M'2) The encoder sets $\mathbf{u}_{F_l} = \mathbf{a}_l + \mathbf{g}'_l \pmod{q}$ instead of $\mathbf{u}_{F_l} = \mathbf{a}_l$, where \mathbf{g}'_l is $|F_l|$ dimensional uniformly distributed q -ary (dither) vector known both at the encoder and decoder. In this way, the assumption that \mathbf{u}_{F_l} is uniformly distributed holds. Similarly, the decoder modifies its operation to $\hat{\mathbf{a}} = \left(\mathbf{x} (G_2^{\otimes n})^{-1} \right)_{F_l} - \mathbf{g}'_l \pmod{q}$.

(M'3) This modification is identical to modification (M3) above.

(M'4) Denote by $\gamma_{l,m} = |\{j : s_{l,j} = m\}|$, where $s_{l,j}$ is the j th element of the WOM state after l writes, s_l . Also denote by $\boldsymbol{\gamma}_l = (\gamma_{l,0}, \dots, \gamma_{l,q-1})$. Let the multinomial distribution with N trials and probabilities $\alpha(0), \dots, \alpha(q-1)$, $0 \leq \alpha(s) \leq 1$ and $\sum_{s=0}^{q-1} \alpha(s) = 1$, be denoted by $M(N, \alpha(0), \dots, \alpha(q-1))$. Then $\boldsymbol{\Upsilon} \sim M(N, \alpha(0), \dots, \alpha(q-1))$ if for $k_0, \dots, k_{q-1} \in [0, N]$ such that $k_0 + \dots + k_{q-1} = N$, $\Pr(\boldsymbol{\Upsilon} = (k_0, \dots, k_{q-1})) = \binom{N}{k_0, \dots, k_{q-1}} \prod_{s=0}^{q-1} \alpha(s)^{k_s}$. After the l th write we draw at random a vector $(\eta_0, \dots, \eta_{q-1})$ from the distribution $M(N, \alpha_l(0), \dots, \alpha_l(q-1))$. If $\gamma_{l,m} < \eta_m, \forall m = 1, 2, \dots, q-1$, then, $\forall m = 1, 2, \dots, q-1$, we flip $\eta_m - \gamma_{l,m}$ elements in s_l from 0 to m .

Theorem 6: Consider an arbitrary information sequence $\mathbf{a}_1, \dots, \mathbf{a}_t$ with rates R_1, R_2, \dots, R_t that are inside the capacity region (33) of the q -ary WOM. For any $0 < \beta < 1/2$ and N sufficiently large, the coding scheme described

above can be used to write this sequence reliably over the WOM w.p. at least $1 - 2^{-N^\beta}$ in encoding and decoding complexities $O(N \log N)$.

To prove the theorem we need the following lemma². Consider an i.i.d. source (S, V) with the following probability distribution,

$$P((S, V) = (s, v)) = \frac{1}{q} \alpha_{l-1}(s). \quad (44)$$

Note that this source has the marginal distribution of the output of the l th channel defined by (39) under a symmetric input distribution.

Lemma 2: Consider a q -ary polar code designed for the l th channel defined by (39) as described above. The code has rate R'_l defined in (41), a frozen set of sub-channels, F_l , and some frozen vector \mathbf{U}_{F_l} which is uniformly distributed over all $|F_l|$ dimensional q -ary vectors. The code is used to encode a random vector (\mathbf{S}, \mathbf{V}) drawn by i.i.d. sampling from the distribution (44) using the SC encoder. Denote by \mathbf{X} the encoded codeword. Then for any $\delta > 0$, $0 < \beta < 1/2$ and N sufficiently large, the following holds w.p. at least $1 - 2^{-N^\beta}$ (in the following expressions, additions are modulo q),

$$|\{k : S_k = \xi \text{ and } X_k + V_k = \nu\}| < [\alpha_{l-1}(\xi) \epsilon_l(\xi, \xi + \nu) + \delta] N \quad (45)$$

Furthermore, if $\xi \not\equiv \xi + \nu$ then

$$\{k : S_k = \xi \text{ and } X_k + V_k = \nu\} = \emptyset \quad (46)$$

Proof: According to Theorem 4, for N large enough,

$$(\mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) \in A_{\delta/q}^{*(N)}(X, (S, V))$$

w.p. at least $1 - 2^{-N^\beta}$. Consider all possible triples χ, ξ, ν , where $\chi \in \{0, 1, \dots, q-1\}$, $\xi \in \{0, 1, \dots, q-1\}$ and $\nu \in \{0, 1, \dots, q-1\}$. From the definition of $A_{\delta/q}^{*(N)}$ we have (w.p. at least $1 - 2^{-N^\beta}$),

$$|C(\chi, (\xi, \nu) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) / N - p(\chi, (\xi, \nu))| < \delta/q \quad (47)$$

Furthermore, if $p(\chi, (\xi, \nu)) = 0$ then (47) can be strengthened to

$$C(\chi, (\xi, \nu) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) = 0 \quad (48)$$

In addition, using $P(X = \chi) = 1/q$ and the channel definition (39), we have

$$p(\chi, (\xi, \nu - \chi)) = \frac{1}{q} \alpha_{l-1}(\xi) \epsilon_l(\xi, \xi + \nu)$$

where here, and in the following expressions, $\nu - \chi$ and $\xi + \nu$ are calculated modulo q . Combining this with (47) we obtain

$$C(\chi, (\xi, \nu - \chi) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) < (\alpha_{l-1}(\xi) \epsilon_l(\xi, \xi + \nu) / q + \delta/q) N$$

²This lemma is formulated for the original channel with parameters $\epsilon_l(\theta, \theta')$ (and not for the (M*1) modified channel with parameters $\epsilon'_l(\theta, \theta')$).

Hence,

$$\begin{aligned} |\{k : S_k = \xi \text{ and } X_k + V_k = \nu\}| &= \\ & \sum_{\chi=0}^{q-1} C(\chi, (\xi, \nu - \chi) | \mathbf{X}(\mathbf{U}), (\mathbf{S}, \mathbf{V})) \\ & < (\alpha_{l-1}(\xi)\epsilon_l(\xi, \xi + \nu) + \delta) N \end{aligned}$$

($X_k + V_k$ is also calculated modulo q). This proves (45). Similarly, (46) is due to (48) since $\xi \not\equiv \xi + \nu$ implies $\epsilon_l(\xi, \xi + \nu) = 0$, and therefore, from the definition of the channel, we have $p(\chi, (\xi, \nu - \chi)) = 0$ for all χ . \square

We proceed to the proof of Theorem 6. We denote by $\mathbf{S}_l, \mathbf{S}, \hat{\mathbf{S}}, \mathbf{V}, \mathbf{G}, \mathbf{X}$ and Γ_l the random variables corresponding to s_l, s, \hat{s}, v, g, x and γ_l .

Proof of Theorem 6: Note that we only need to prove successful encoding since the WOM is noiseless.

Recall our definition $\Gamma_{l,m} = |\{j : S_{l,j} = m\}|$. Suppose that $\Gamma_{l-1} \sim M(N, \alpha_{l-1}(0), \dots, \alpha_{l-1}(q-1))$. Our first claim is that under this assumption, for $\rho > 0$ sufficiently small and N sufficiently large, w.p. at least $1 - 2^{-N^\beta}$, the encoding will be successful and $\Gamma_{l,m}/N < \alpha_l(m) - \rho$ for $m = 1, 2, \dots, q-1$. For notational simplicity we use \mathbf{S} instead of \mathbf{S}_{l-1} , and $\hat{\mathbf{S}}$ instead of \mathbf{S}_l . Considering step 1 of the encoding we see that $\mathbf{Y} = (\mathbf{S}, \mathbf{V})$, after the random permutation described in (M'3), can be considered as i.i.d. sampling of the source (S, V) defined in (44). Hence, by Lemma 2 and (M'1), the compression of this vector in step 2 satisfies the following for any $\delta > 0$ and N sufficiently large w.p. at least $1 - 2^{-N^\beta}$.

1) Suppose that $\xi \not\equiv \xi + \nu$. Then $\{k : S_k = \xi \text{ and } X_k + V_k = \nu\} = \emptyset$. In addition, $V_k = G_k - S_k$ and $\hat{S}_k = X_k + G_k = X_k + V_k + S_k$. Hence we conclude, under the above assumption, that if $S_k = \xi$ then $\hat{S}_k \neq \xi + \nu$.

2) For at most $[\alpha_{l-1}(\xi)\epsilon'_l(\xi, \xi + \nu) + \delta] N$ components k we have $S_k = \xi$ and $X_k + V_k = \nu$, i.e., $\hat{S}_k = \xi + \nu$. Hence, the WOM constraints are satisfied, and there are at most $[\alpha_{l-1}(\xi)\epsilon'_l(\xi, \xi + \nu) + \delta] N$ components k for which $S_k = \xi$ and $\hat{S}_k = \xi + \nu$. Therefore, w.p. at least $1 - 2^{-N^\beta}$, the vectors \mathbf{S} and $\hat{\mathbf{S}}$ satisfy the WOM constraints and

$$\Gamma_{l,m} < \sum_{\xi} [\alpha_{l-1}(\xi)\epsilon'_l(\xi, m) + \delta] N$$

Now, recalling (42), we obtain for $m \neq 0$

$$\begin{aligned} \Gamma_{l,m} &< \sum_{\xi \neq 0} [\alpha_{l-1}(\xi) (\epsilon_l(\xi, m)) + \delta] N \\ &+ \left[\alpha_{l-1}(0) \left(\epsilon_l(0, m) - \frac{\zeta}{q-1} \right) + \delta \right] N \\ &= \left[\alpha_l(m) - \frac{\zeta \alpha_{l-1}(0)}{q-1} + q\delta \right] N \end{aligned} \tag{49}$$

where the equality is due to (37). Setting $\rho = \zeta \alpha_{l-1}(0)/(q-1) - q\delta$ (note that $\alpha_l(0) > 0 \forall l$ due to (43)) yields our first claim.

n	M	ΔR_1	ΔR_2	ΔR_3	R_1	R_2	R_3
12	10000	.035	.05	.185	.776	.639	.315
14	10000	.02	.04	.175	.7913	.6487	.325
16	1000	.02	.02	.16	.7913	.6687	.34

TABLE I

THE PERFORMANCE OF $t = 3$ WRITE POLAR WOMS WITH $n = 12, 14, 16$.

From (49) we know that $\eta_1, \dots, \eta_{q-1}$ in (M'4) will indeed satisfy the condition $\eta_m > \Gamma_{l,m} \forall m = 1, \dots, q-1$, w.p. at least $1 - 2^{-N^\beta}$. The proof of the theorem now follows by using induction on l to conclude that (w.p. at least $1 - 2^{-N^\beta}$) the l th encoding is successful and $\Gamma_l \sim M(N, \alpha_l(0), \dots, \alpha_l(q-1))$. \square

VI. SIMULATION RESULTS

To demonstrate the performance of our coding scheme for finite length codes we performed experiments with polar WOM codes with $n = 10, 12, 14, 16$. Each polar code was constructed using the test channel in Figure 1 with the appropriate parameters ϵ_l and α_{l-1} . To learn the frozen set F_l of each code we used the Monte-Carlo approach that was described in [21] (which is a variant of the method proposed by Arikan [11]). Figure 2 describes our experiments with $t = 2$ write WOMs designed to maximize the average rate. Using the results in [3] we set $\epsilon_1 = 1/3$. Hence $\alpha_1 = 2/3$. Each point in each graph was determined by averaging the results of 1000 Monte-Carlo experiments. Figure 2 (left) shows the success rate of the first write as a function of the rate loss ΔR_1 compared to the optimum ($R_1 = h(1/3) = 0.9183$) for each value of n . Here success is defined as $w_H(\mathbf{s}_1)/N \leq \epsilon_1$. Figure 2 (right) shows the success rate of the second write as a function of the rate loss ΔR_2 compared to the optimum ($R_2 = 2/3$). Here we declare a success if the WOM constraints are satisfied. Each experiment in the second write was performed by using a first write with rate loss of $\Delta R_1 = 0.01$. For $n = 10, 12, 14$, ΔR_1 should be higher, but this is compensated by using higher values of ΔR_2 . As an alternative we could have used a higher rate loss ΔR_1 for $n = 10, 12, 14$, in which case ΔR_2 decreases. In terms of total rate loss both options yielded similar results. We see that for $n = 16$ the total rate loss required for successful (with very high probability) first and second write is about 0.08. As was noted earlier, the success rate can be increased if, upon detecting an encoding error, the encoder repeats the encoding with another dither value.

We have also experimented with a $t = 3$ write WOM. We used polar codes with $n = 12, 14, 16$ and set $\epsilon_1 = 1/4$, $\epsilon_2 = 1/3$ and $\epsilon_3 = 1/2$ ($\alpha_1 = 3/4$ and $\alpha_2 = 1/2$) to maximize the average rate in accordance with [3]. To find the frozen set F_l of each code we used density evolution as described in [22] with quantization step $q = 0.25$. The maximum average rate is obtained for $R_1 = .8113$, $R_2 = .6887$ and $R_3 = 1/2$. The actual information rates are presented in Table I, where in M read/write experiments all information triples were encoded (and decoded) successfully.

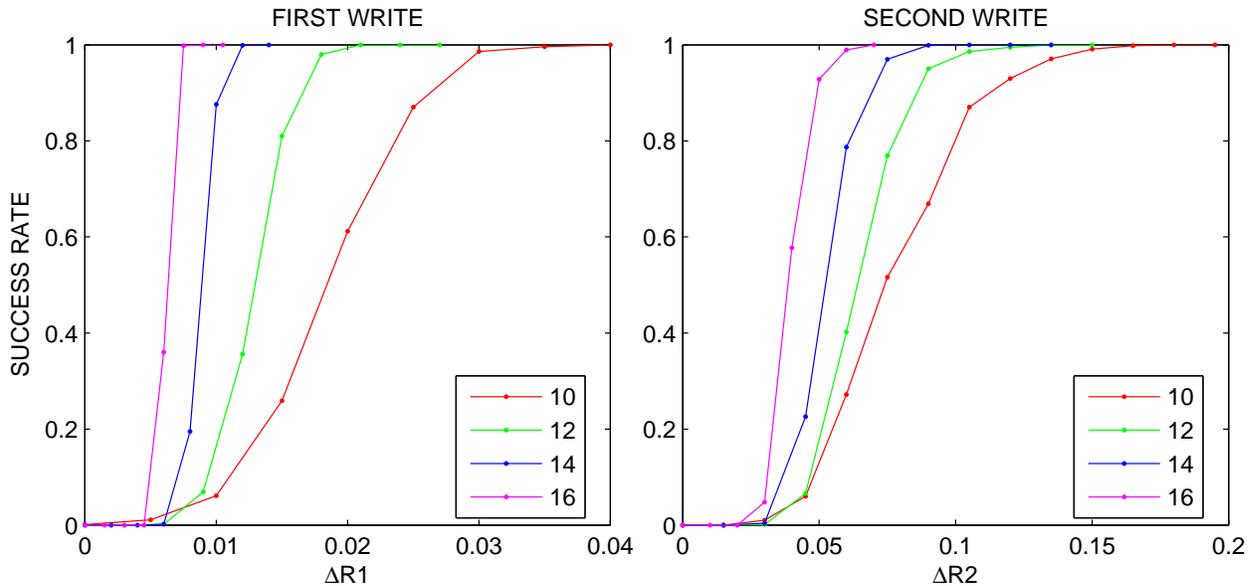

Fig. 2. The success probabilities of the first (left) and second (right) writes to the binary WOM as a function of the rates loss, ΔR_1 and ΔR_2 .

Finally, we performed experiments with generalized WOMs for the case where the DAG representing the WOM is the following. The vertices are $\mathcal{V} = \{0, 1, 2\}$ and the edges are $\mathcal{E} = \{0 \rightarrow 1, 1 \rightarrow 2\}$. We consider the case where there are two writes, i.e., $t = 2$. By [19, Proof of Theorem 3.2] the maximum total number of 3-ary information symbols, $R_1 + R_2$, that can be stored in one storage cell of the WOM is 1.6309. Furthermore, by [19, Proof of Theorem 3.2], the maximum value of $R_1 + R_2$ is achieved for $R_1 = 0.9206$ and $R_2 = 0.7103$, and the following parameters, $\{\alpha_l(\theta)\}_{\theta=0}^2$ and $\{\epsilon_l(\theta, \theta')\}_{\theta, \theta'=0}^2$ for $l = 0, 1$, need to be used in (33).

$$\begin{aligned}
 \alpha_0(0) &= 1, \alpha_0(1) = 0, \alpha_0(2) = 0 \\
 \epsilon_0(0, 0) &= 1/2, \epsilon_0(0, 1) = 1/3, \epsilon_0(0, 2) = 1/6 \\
 \epsilon_0(1, 0) &= 0, \epsilon_0(1, 1) = 2/3, \epsilon_0(1, 2) = 1/3 \\
 \epsilon_0(2, 0) &= 0, \epsilon_0(2, 1) = 0, \epsilon_0(2, 2) = 1 \\
 \alpha_1(0) &= 1/2, \alpha_1(1) = 1/3, \alpha_1(2) = 1/6 \\
 \epsilon_1(0, 0) &= 1/3, \epsilon_1(0, 1) = 1/3, \epsilon_1(0, 2) = 1/3 \\
 \epsilon_1(1, 0) &= 0, \epsilon_1(1, 1) = 1/2, \epsilon_1(1, 2) = 1/2 \\
 \epsilon_1(2, 0) &= 0, \epsilon_1(2, 1) = 0, \epsilon_1(2, 2) = 1
 \end{aligned}$$

Our scheme uses polar codes with $q = 3$ and $n = 10, 12, 14$. Using the above parameters, $\{\alpha_0(\theta)\}_{\theta=0}^2$ and

$\{\epsilon_0(\theta, \theta')\}_{\theta, \theta'=0}^2$, in (39), we obtain the following definition of the first test channel

$$P_1((S, V) = (s, v) | X = 0) = \begin{cases} 1/2 & \text{if } (s, v) = (0, 0) \\ 1/3 & \text{if } (s, v) = (0, 1) \\ 1/6 & \text{if } (s, v) = (0, 2) \end{cases}$$

$$P_1((S, V) = (s, v) | X = 1) = \begin{cases} 1/3 & \text{if } (s, v) = (0, 0) \\ 1/6 & \text{if } (s, v) = (0, 1) \\ 1/2 & \text{if } (s, v) = (0, 2) \end{cases}$$

$$P_1((S, V) = (s, v) | X = 2) = \begin{cases} 1/6 & \text{if } (s, v) = (0, 0) \\ 1/2 & \text{if } (s, v) = (0, 1) \\ 1/3 & \text{if } (s, v) = (0, 2) \end{cases}$$

Similarly, the second test channel is given by

$$P_2((S, V) = (s, v) | X = x) = \begin{cases} 1/6 & \text{if } s = 0 \\ 1/6 & \text{if } s = 1 \text{ and } x + v \pmod{3} \neq 2 \\ 1/6 & \text{if } s = 2 \text{ and } x + v \pmod{3} = 0 \\ 0 & \text{otherwise.} \end{cases}$$

We see that given $S = 0$, V and X are statistically independent. Hence we can simplify this channel by merging the three output symbols, $(0, 0)$, $(0, 1)$ and $(0, 2)$, into one symbol. To learn the frozen set F_l of each code we used the Monte-Carlo approach that was described in [21].

Figure 3 presents the success rate of the first and second writes as a function of the rates loss ΔR_1 and ΔR_2 compared to the optimal rates, $R_1 = 0.9206$ and $R_2 = 0.7103$. This is shown for polar codes with $n = 10$, $n = 12$ and $n = 14$. Each point in the graph was obtained by averaging the results of 10,000 Monte-Carlo experiments. In the first write we declare a success if the fraction of '1' ('2' respectively) in \mathbf{s}_1 is less than or equal to $\alpha_1(1)$ ($\alpha_1(2)$, respectively). In the second write we declare a success if all the WOM constraints are satisfied. Each experiment in the second write was preformed by using $R_1 = 0.9206$ (i.e., $\Delta R_1 = 0$).

VII. CONCLUSION

We have presented a new family of WOM codes based on the recently proposed polar codes. These codes achieve the capacity region of noiseless WOMs when an arbitrary number of multiple writes is permitted. The encoding and decoding complexities scale as $O(N \log N)$ where N is the blocklength. For N sufficiently large the error probability decreases sub-exponentially in N . The results apply both for binary and for generalized WOMs, described by an arbitrary DAG.

There are various directions in which our work can be generalized. The first is the design of codes for noisy WOMs. It should be noted that there are various models for noisy WOMs. The capacity region of the most general model, proposed in [3], is yet unknown. However, for certain special cases [3], [23], the maximum average rate,

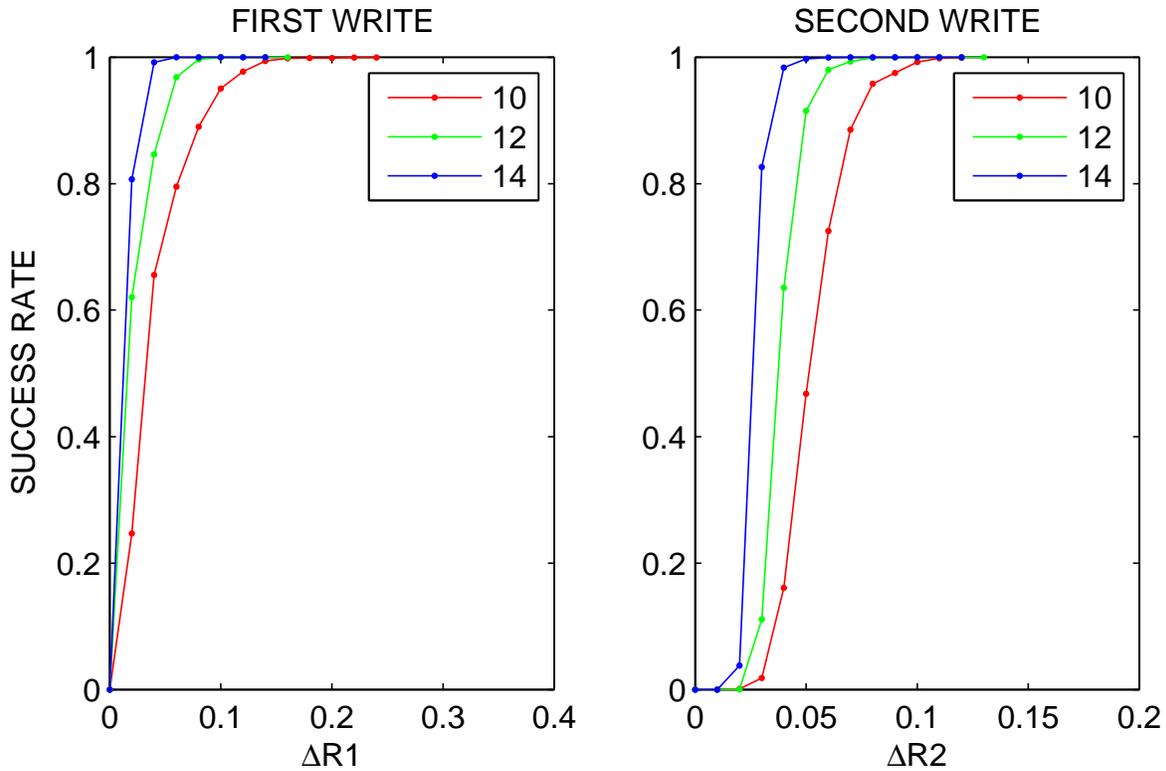

Fig. 3. The success probabilities of the first (left) and second (right) writes to the q -ary WOM for $q = 3$ as a function of the rates loss, ΔR_1 and ΔR_2 .

and in some cases even the capacity region are known. The achievable rate region of some noisy WOM models, presented in [3], [23], are based on coding for Gelfand-Pinsker (GP) side information channels. Hence, in this case one may wish to consider the results in [12] for polar coding over a binary side information channel, and combine them with our method.

Another possibility for further research is the consideration of other codes or decoding methods in our scheme. For example, instead of polar source codes, one may consider low-density generating-matrix (LDGM) codes that were shown in the past to be useful for lossy source coding. Even if polar codes are kept in our scheme, it may be possible to improve performance by using iterative encoding combined with decimation instead of SC encoding. This is due to the fact that iterative decoding usually yields better results compared to SC decoding of polar codes [11], [21]. One may also consider using list decoding of polar codes as proposed in [24].

APPENDIX A
DERIVATION OF (40)

For X uniformly distributed over $\{0, 1, \dots, q - 1\}$ we have $H(X) = \log_q q = 1$. In addition,

$$H(X | (S, V)) = \sum_{s,v} P((S, V) = (s, v)) H(X | (S, V) = (s, v))$$

where

$$H(X | (S, V) = (s, v)) = - \sum_x P(X = x | (S, V) = (s, v)) \log (P(X = x | (S, V) = (s, v)))$$

Now,

$$\begin{aligned} P(X = x | (S, V) = (s, v)) &= \frac{P((S, V) = (s, v) | X = x)P(X = x)}{P((S, V) = (s, v))} \\ &= \frac{\frac{1}{q}\alpha_{l-1}(s)\epsilon_l(s, s + v + x)}{\sum_{x'=0}^{q-1} \frac{1}{q}\alpha_{l-1}(s)\epsilon_l(s, s + v + x')} \\ &= \epsilon_l(s, s + v + x) \end{aligned}$$

Hence,

$$H(X | (S, V) = (s, v)) = h \left(\{ \epsilon_l(s, s') \}_{s'=0}^{q-1} \right)$$

In addition,

$$P((S, V) = (s, v)) = \frac{1}{q}\alpha_{l-1}(s)$$

Hence,

$$\begin{aligned} H(X | (S, V)) &= \sum_{s=0}^{q-1} \sum_{v=0}^{q-1} \frac{1}{q}\alpha_{l-1}(s)H(X | (S, V) = (s, v)) \\ &= \sum_{s=0}^{q-1} \alpha_{l-1}(s)h \left(\{ \epsilon_l(s, s') \}_{s'=0}^{q-1} \right) \\ &= H(\Theta_l | \Theta_{l-1}) \end{aligned}$$

where the last equality is due to (38). Thus we conclude that

$$C_l = H(X) - H(X | (S, V)) = 1 - H(\Theta_l | \Theta_{l-1})$$

and we have obtained (40).
