 $BaRuO₃$ having five different crystal structures has been synthesized by varying the pressure while sintering. Contrary to the other phases being nonmagnetic, the cubic perovskite phase synthesized recently shows an itinerant ferromagnetic character. We investigated this ferromagnetic BaRuO³ using first principles calculations. A few van Hove singularities appear around the Fermi energy, causing unusually high magnetovolume effects of $\Delta M/\Delta a \approx 4.3 \mu_B/\text{\AA}$ as well as a Stoner instability $[IN(0) \approx 1.2]$. At the optimized lattice parameter a, the magnetic moment M is 1.01 μ_B in the local spin density approximation. When spin-orbit coupling is included, the topologies of some Fermi surfaces are altered, and the net moment is reduced by 10% to a value very close to the experimentally observed value of $\sim 0.8 \mu_B$. Our results indicate that this ferromagnetism is induced by the Stoner instability, but the combined effects of the $p - d$ hybridization, the magnetovolume, and the spin-orbit coupling determine the net moment. In addition, we briefly discuss the results of the tight-binding Wannier function technique.

I. INTRODUCTION

Ruthenates, which formally possess tetravalent $4d^4$ Ru ions, show interesting properties: unconventional superconductivity in Sr_2RuO_4 , [\[1\]](#page-3-0) a metal-insulator transition in $La_2Ru_2O_7$ and Li_2RuO_3 , [\[2](#page-3-1), [3](#page-3-2)] metamagnetism in $Sr_3Ru_2O_7$ [\[4](#page-3-3)] and complicated magnetic behaviors in the double pyrochlore $RE_2Ru_2O_7$ ($RE=$ rareearth element)[\[5](#page-3-4)]. In particular, the Ru-based perovskites $ARuO₃$ ($A=alkaline-earth$ elements or Pb) have been studied extensively for several decades due to their atypical and controversial electronic and magnetic behaviors $6-12$. SrRuO₃ is a metallic ferromagnet with $T_C = 160$ K and an experimentally observed moment of $\sim 1.6 \mu_B$, whereas CaRuO₃ is a nonmag-netic metal [\[13](#page-3-7), [14](#page-3-8)]. PbRu O_3 seems to exhibit incipient magnetism, but whether this system is a metal or an insulator at low-T is still under debate[\[15,](#page-3-9) [16](#page-3-10)]. The crystal structure of $BaRuO₃$ depends strongly on the temperature and pressure during synthesis[\[17\]](#page-3-11) whereas the other compounds are orthorhombic. Depending on the amount of corner- and face-sharing $RuO₆$, the structures of $BaRuO₃$ are categorized as the four-, six-, and ten-layered hexagonal phases $(4H, 6H,$ and $10H,$ respectively), in addition to the nine-layered rhombohedral phase $(9R)$ [\[18](#page-3-12)[–22\]](#page-3-13). As discussed both theoretically and experimentally [\[12,](#page-3-6) [18,](#page-3-12) [23\]](#page-3-14), the $10H$ and the 9R phases seem to be semi-metallic whereas the rest are nonmagnetic metals. Early in 2008, Jin et al. synthesized the cubic phase using a high T (\sim 1000 °C) and high P (\sim 18 GPa) technique[\[17](#page-3-11)].

In this research, we will focus on the cubic phase, which shows ferromagnetic behavior with $T_C = 60$ K[\[17\]](#page-3-11). On the basis of resistivity measurements, which show a sharp peak in the T-derivation of the resistivity at T_C , Jin et al. suggested simple metallic characteristics in the high-T region, but a Fermi-liquid behavior in the low-T regime. The effective magnetic moment is 2.6 μ B, close to the value for $S = 1$. However, the saturated moment of 0.8 μ_B is significantly less than the value corresponding to $S = 1$, implying atypical magnetic behaviors. Moreover, when pressure is applied, T_C decreases, reaching 50 K at $P = 3$ GPa.

The elastic properties and the pressure effects have been theoretically investigated to some extent[\[24,](#page-3-15) [25\]](#page-3-16), but no detailed studies of the magnetic and electric properties of this cubic phase have been reported yet. Thus, we will address the magnetic properties of this system through first-principles calculations, including the local spin density approximation (LSDA), the LSDA plus spinorbit coupling (LSDA+SOC), the fixed spin moment (FSM), and a tight-binding Wannier analysis.

II. STRUCTURE AND METHOD OF CALCULATION

First, we optimized the lattice parameter a in the cubic phase. LSDA calculations lead to our optimized $a = 3.938$ Å. This value is about 1.7% smaller than the

FIG. 1: (Color online) Comparison of the nonmagnetic total densities of states (DOSs) per formula unit between cubic and $9R$ BaRuO₃. For the cubic phase, the optimized lattice parameter was used. In the cubic phase, two sharp peaks appear around the Fermi energy E_F , resulting in a strong magnetic instability. The vertical dashed line indicates E_F , which is set to zero.

experimentally-observed value at room temperature[\[17\]](#page-3-11). We used the optimized lattice parameter in our calculations, since the total moment at the optimized a is close to the experimental value, as will be discussed in the next section.

Our calculations were carried out with the LSDA and the LSDA+SOC implemented in the all-electron fullpotential code WIEN2k[\[26\]](#page-3-17). The basis size was determined by using $R_{mt}K_{max} = 7$ and augmented plane wave sphere radii of 2.5 for Ba, 2.0 for Ru, and 1.7 for O. The Brillouin zone was sampled with a $14\times14\times14$ k-mesh. For both the LSDA+SOC and the FSM calculations[\[27\]](#page-3-18), a much denser k-mesh of $20 \times 20 \times 20$ was used. The lattice parameter was relaxed until the forces were smaller than 2 mRy/a.u. Furthermore, the all-electron full-potential local-orbital code FPLO was used for the tight-binding Wannier function analysis[\[28\]](#page-3-19).

III. RESULTS

Figure [1](#page-1-0) shows the overlapped total densities of states (DOSs) between the nonmagnetic $9R$ and cubic phases in the range of –1 to 1 eV. The DOS of the cubic phase is five times larger than that of the 9R phase due to the sharp peaks at E_F and 30 meV, suggesting strong magnetic instability.

Using the LSDA, we calculated the change in the total magnetic moment while varying a from the experimental value to a value slightly smaller than the optimized one. As shown in the inset of Fig. [2,](#page-1-1) the magnetic moment decreases linearly with a slope of $\Delta M/\Delta a \approx 4.3 \mu_B/\text{\AA}$, indicating strong magnetovolume effects. This value is much larger than that of $\sim 1 \mu_B/\text{\AA}$ in the Invar systems

FIG. 2: (Color online) FSM calculations in the cubic phase, while changing the lattice parameter a (in units of \AA). $E(0)$ denotes the energy of the nonmagnetic state for each a. The arrow roughly connects the minimum energy states. Inset: Change in the total magnetic moment M with respect to a in the FM calculations. The arrow indicates the value at the optimized a . A discontinuity occurs at $a \sim 3.91$ Å, because E_F pins a van Hove singularity in the spin-up channel (see text).

FIG. 3: (Color online) Change in the Stoner parameter I (top), the DOS $N(0)$ per single spin at E_F (middle), and $IN(0)$ (bottom) with the lattice parameter in the cubic BaRuO₃. Roughly, $IN(0)$ decreases linearly as the lattice parameter decreases.

 \mathcal{A} Fe₂ (\mathcal{A} =Y, Zr, Hf, and Lu)[\[29\]](#page-4-0).

To clarify these behaviors, FSM calculations were conducted. Plots of energy versus total magnetic moment M for varying values of a are shown in Fig. [2.](#page-1-1) The difference in energy between the $M = 0$ and the ferromagnetic (FM) ground states decreases monotonically from ∼ 32 meV at $a = 4.01$ Å to 17 meV at 3.93 Å. The curves are fitted well by $E(M) - E(0) \approx -\alpha M^2 + \beta M^4$, with constants α and $\beta,$ in the low- M region. For the bare susceptibility $\chi_0 = 2\mu_B^2 N(0)$, the Stoner-enhanced susceptibility is

FIG. 4: (Color online) Total and atom-projected DOSs of the FM cubic $BaRuO₃$ in the full range, including all O 2p and Ru 4d states. In the spin-up channel, peaks appear at -0.2 and –0.1 eV. The DOS $N(0)$ at E_F is 3.34 states per eV for both spins. Upper inset: Expanded view of the total DOSs in LSDA and LSDA+SOC between –0.5 and 0.5 eV. Lower inset: Ru t_{2g} and e_g orbital-projected DOSs.

FIG. 5: (Color online) Blowup of the FM band structure in LSDA (top) and LSDA+SOC (bottom) near E_F in the cubic BaRuO3. In the top panel, the solid and the dashed lines represent the spin-up and -down characters, respectively. Around the X and the M points, the effects of spin-orbit coupling are substantial. The horizontal dashed lines indicate E_F .

given by $\chi = \chi_0/[1 - N(0)I]$, where $N(0)$ is the singlespin DOS at E_F . In the low-M region, $\alpha = \frac{1}{2}\chi^{-1}$. The top panel of Fig. [3](#page-1-2) displays the obtained Stoner parameters $I \approx 0.70(\pm 0.02)$ eV for each a. As a changes, the DOS at E_F fluctuates substantially owing to van Hove singularities (vHSs) near E_F (see below), as given in the middle panel of Fig. [3.](#page-1-2) $IN(0)$ decreases monotonically as a decreases, which is consistent with the substantial magnetovolume effects, but for all the lattice parameters studied here, these values exceed the Stoner instability criterion $IN(0) > 1$.

Like the FSM results, the LSDA results indicate that the FM state is energetically favored over the nonmagnetic state by 16.4 meV for the optimized lattice parameter. For comparison, from a simple Stoner instability, the energy gain of $Im^2/4$ for $I \approx 0.7$ eV is 175 meV, much larger than the calculated value.

Now, we will address the electronic structure of the FM states. Figure [4](#page-2-0) shows the total and the atom-projected DOSs, which can be figured out well using the concept of $RuO₆$ cluster orbitals[\[7](#page-3-20)]. The Ru t_{2g} states, hybridized with the O p_{π} states, produce an antibonding manifold at -2 to 1 eV, a bonding manifold at -6 to -4 eV, and a nonbonding manifold at -4 to -2 eV, as can be seen in the lower inset of Fig. [4.](#page-2-0) The bonding and the antibonding states of the Ru e_q and the O p_σ states lie in the regions of –8 to –6 eV and 0 to 6 eV, respectively. The exchange splitting of the t_{2q} manifold is about 0.5 eV. In the FM state, the total moment of 1.01 μ_B is decomposed into 0.6 μ _B for Ru and 0.28 μ _B for 3O. (The remnant is in the interstitial region.)

The enlarged FM band structure in the LSDA is given in the top panel of Fig. [5.](#page-2-1) In this region, the spin-up and -down structures are nearly identical, except for a difference in the on-site energy of roughly 0.5 eV due to exchange splitting. In the spin-up channel, in addition to a flat band at -0.2 eV along the Γ-X line, which commonly appears in conventional perovskites, two saddle points, one each at the X and the M points, occur, resulting in vHSs just below E_F . These features may cause the unusual electrical properties observed experimentally[\[17](#page-3-11)].

The band structure of the t_{2g} and the p_{π} clusters in the range of –8 eV to 2 eV was reproduced well using the tight-binding Wannier function technique. We obtained two important parameters: $pd\pi$ hopping $t_{\pi} = 1.23$ eV and direct oxygen-oxygen hopping $t'_\pi = 0.17$ eV. Compared with the tight-binding parameters of the nonmag-netic CaRuO₃ obtained by Mazin and Singh[\[7\]](#page-3-20), t_{π} is about 10% smaller, but t'_π is about half as large. This is consistent with the 20% smaller bandwidth of the antibonding t_{2g} manifold in BaRuO₃, implying a stronger magnetic instability.

SOC affects the Fermi surface (FS) topology in isovalent $Sr_3Ru_2O_7[30]$ $Sr_3Ru_2O_7[30]$, though its effects are often negligible in 4d systems. To consider the effects of SOC, we conducted LSDA+SOC calculations. As shown in the upper inset of Fig. [4,](#page-2-0) the changes in the DOS are relatively small, leading to a tiny orbital moment of $-0.013 \mu_B$ on the Ru ion. However, the mixing of states with other spin channel reduces the net moment by 10%, bringing it closer to the experimentally observed value of 0.8 $\mu_B[17]$ $\mu_B[17]$. The net moment is 0.91 μ B, with local moments of 0.55 μ_B for Ru and 0.26 μ_B for 30.

An additional remarkable feature is that vHSs move toward E_F in both spin channels. In the spin-up channel, the vHS at –0.1 eV splits into two peaks whereas two vHSs merge and move to 0.1 eV in the spin down channel. These features reflect changes in the band structure at the X and the M points, as demonstrated in the enlarged band structure in the bottom panel of Fig. [5.](#page-2-1) The strength of the SOC is about 0.1 eV at these points near E_F , but negligible elsewhere. The SOC alters the FS topology at the X -points, in particular, in the intersecting pipe-like and cube-like FSs (not shown here), which are often observed in conventional perovskites[\[31](#page-4-2)]. The open pipe-like surface becomes closed whereas the cubelike closed one becomes open.

IV. DISCUSSION AND SUMMARY

The Fermi-liquid behavior experimentally observed in the low-T region may suggest the presence of correlation effects. Considering that this material is a metallic 4d system, the correlation effects should be weak. In our preliminary calculations using the LDA+U method, applying U to the Ru ion shifts the e_q manifold up and the t_{2q} manifold down, so only the intersecting pipe-like FS disappears. To evaluate the importance of the correlation effects, detailed experimental observations are necessary.

In summary, we investigated the magnetic properties of the ferromagnetic cubic perovskite $BaRuO₃$, using various first principles calculations: FSM, LSDA, LSDA+SOC, and the Wannier function technique. In the nonmagnetic DOS, the cubic phase has a sharp peak pinning at E_F , yielding $IN(0) \approx 1.2$, beyond the Stoner instability. In the LSDA calculations, a few vHSs appear near E_F in both spin channels, resulting in a strong magnetovolume effect of $\Delta M/\Delta a \approx 4.3 \mu_B/\text{\AA}$, significantly higher than that of the Invar system $\mathcal{A}Fe_2$. The effects of the SOC are substantial near E_F around the X and the M points and affect the topology of some of FSs, though the strength of the SOC is negligible in most regions. At the optimized volume, the effects of the SOC reduce the net moment by 10% from the LSDA value, and it becomes very close to the experimentally-observed moment. Our results show that the Stoner instability produces ferromagnetism, and that the combined effects of the hybridization, the magnetovolume, and the SOC determine the magnetic moment. Furthermore, the unusually strong magnetovolume effects may imply atypical transport properties in this $FM BaRuO₃$, suggesting further questions for experimental research.
