Summary: The exclusion of freeriders from common privileges or public acceptance is widely 14 found in the real world. Current models on the evolution of cooperation with incentives mostly 15 assume peer sanctioning, whereby a punisher imposes penalties on freeriders at a cost to itself. 16 It is well known that such costly punishment has two substantial difficulties. First, a rare 17 punishing cooperator barely subverts the asocial society of freeriders, and second, natural 18 selection often eliminates punishing cooperators in the presence of non-punishing cooperators 19 (namely, "second-order" freeriders). We present a game-theoretical model of social exclusion 20 in which a punishing cooperator can exclude freeriders from benefit sharing. We show that 21 such social exclusion can overcome the above-mentioned difficulties even if it is costly and 22 stochastic. The results do not require a genetic relationship, repeated interaction, reputation, or 23 group selection. Instead, only a limited number of freeriders are required to prevent the second-24 order freeriders from eroding the social immune system. 25

Key words: evolution of cooperation; ostracism; costly punishment; second-order freerider;

27 public goods; evolutionary game theory

## 29 **1. Introduction**

We frequently engage in voluntary joint enterprises with nonrelatives, activities that are 30 fundamental to society. The evolution of cooperative behaviors is an important issue because 31 without any supporting mechanism [1], natural selection often favours those that contribute 32 less at the expense of those that contribute more. A minimal situation could easily cause the 33 ruin of a commune of cooperators, namely, the "tragedy of the commons" [2]. Here we 34 consider different types of punishment, such as a monetary fine (e.g., [3–7]) and ostracism (e.g., 35 [8–11]), for the evolution of cooperation. Punishment can reduce the expected payoff for the 36 opponent, and subsequently, change natural selection preferences, to encourage additional 37 contributions to communal efforts [12]. Our model looks at this situation, because "very little 38 work has addressed questions about the form that punishment is likely to take in reality and 39 about the relative efficacy of different types of punishment" [13]. 40

Here, we choose to focus on social exclusion, which is a common and powerful tool to penalise 41 deviators in human societies, and includes behaviors such as eviction, shunning and ignoring 42 [14–16]. For self-sustaining human systems, indeed, the ability to distinguish among 43 individuals and clarify who should participate in the sharing of communal benefits is crucial 44 and expected (of its members) [17]. A specific example is found in the case of traffic violators 45 who are punished, often strictly by suspending or revoking their driver license for public roads. 46 Among non-humans, shunning through partner switching is a common mechanism for inequity 47 aversion and cooperation enforcement [13,18,19]. Experimental studies have shown, for 48 instance, that chimpanzees can use a mechanism to exclude less cooperative partners from 49 potential collaborations [20], or that reef fish will terminate interaction with cleaner fish that 50 cheat by eating the host's mucus rather than parasites [21]. 51

In joint enterprises, by excluding freeriders from benefit sharing, the punishers can naturally benefit, because such exclusion often decreases the number of beneficiaries, with little effect on the total benefit. Consider the example of the division of a pie provided by some volunteers

to a group. If a person is one of the volunteers, it may be justifiable in terms of fairness to 55 suggest or even force freeriders to refrain from sharing in the pie. Although excluding 56 freeriders can be stressful, it increases the share of the pie for the contributors, including the 57 person who performs the actual exclusion. If the situation calls for it, the excluded freerider's 58 share of the group benefits may separately be redistributed among the remaining members in 59 the group [22,23]. Therefore, in either case, the excluded member will obtain nothing from the 60 joint enterprise and the exclusion causes immediate increases in the payoff for the punisher and 61 also the other remaining members in the group. 62

This is a "self-serving" form of punishment [13,18]. It is of importance that if the cost of excluding is smaller than the reallocated benefit, social exclusion can provide immediate net benefits even to the punisher. This can potentially motivate the group members to contribute to the exclusion of freeriders, however, our understanding of how cooperation unfolds through social exclusion is still "uncharted territory" [24].

Most game-theoretical works on cooperation with punishment have focused on other forms of 68 punishment, for example, costly punishment that reduces the payoffs of both the punishers and 69 those who are punished. As is well known, costly punishment poses fundamental puzzles with 70 regard to its emergence and maintenance. First of all, costly punishment is unlikely to emerge 71 in a sea of freeriders, in which almost all freeriders are unaffected, and a rare punisher would 72 have to decrease in its payoff through punishing the left and right [18,25–27]. Moreover, 73 although initially prevalent, punishers can stabilise cooperation, while non-punishing 74 cooperators (so-called "second-order freeriders") can undermine full cooperation once it is 75 established [3,13,17,24,29]. 76

In terms of self-serving punishments, however, we have only started to confront the puzzles that emerge in these scenarios. We ask here, what happens if social exclusion is applied?: that is, do players move toward excluding others?, and can freeriders be eliminated? Or, will others in the group resist? Our main contribution is to provide a detailed comparative analysis for social exclusion and costly punishment, two different types of punishment, from the viewpoint
 of their emergence and maintenance. With the self-serving function, social exclusion is
 predicted to more easily emerge and be maintained than costly punishment.

Few theoretical works have investigated the conditions under which cooperation can evolve by
the exclusion of freeriders. Our model requires no additional modules, such as a genetic
relationship, repeated games, reputation, or group selection. Considering these modules is
imperative for understanding the evolution of cooperation in realistic settings. In fact, these
modules may have already been incorporated in earlier game-theoretical models that included
the exclusion of freeriders [30–32], but we are interested in first looking at the most minimal of
situations to get at the core relative efficacy of costly punishment versus social exclusion.

### 91 2. Game-theoretical model and analysis

To describe these punishment schemes in detail, we begin with standard public good games 92 with a group size of  $n \ge 2$  (e.g., [26,33,34]) in an infinitely large, well-mixed population of 93 players. We specifically apply a replicator system [35] for the dynamic analysis, as based on 94 preferentially imitating strategies of the more successful individuals. In the game, each player 95 has two options. The "cooperator" contributes c > 0 to a common pool, and the "defector" 96 contributes nothing. The total contribution is multiplied by a factor of r > 1 and then shared 97 equally among all (n) group members. A cooperator will thus pay a net cost  $\sigma = c(1 - r/n)$ 98 through its own contribution. If all cooperate, the group yields the optimal benefit c(r-1) for 99 each; if all defect, the group does nothing. To adhere to the spirit of the tragedy of the 100 commons, we hereafter assume that r < n holds, in which case a defecting player can improve 101 its payoff by  $\sigma > 0$ , whatever the coplayers do, and the defectors dominate the cooperators. To 102 observe the robustness for stochastic effects, we also consider an individual-based simulation 103 with a pairwise comparison process [36,37]. See the electronic supplementary material (ESM) 104 for these details. 105

# 106 (a) Costly punishment

We then introduce a third strategy, "punisher", which contributes *c*, and moreover, punishes the defectors. Punishing incurs a cost  $\gamma > 0$  per defector to the punisher and imposes a fine  $\beta > 0$  per punisher on the defector. We denote by *x*, *y*, and *z* the frequencies of the cooperator (C), defector (D), and punisher (P), respectively. Thus, *x*, *y*,  $z \ge 0$  and x + y + z = 1. Given the

- expected payoffs  $P_S$  for the three strategies (S = C, D, and P), the replicator system is written
- 112 by

113 
$$\dot{x} = x(P_{\rm C} - \overline{P}), \quad \dot{y} = y(P_{\rm D} - \overline{P}), \quad \dot{z} = z(P_{\rm P} - \overline{P}), \quad (2.1)$$

- where  $\overline{P} := xP_{\rm C} + yP_{\rm D} + zP_{\rm P}$  describes the average payoff in the entire population. Three
- homogeneous states (x = 1, y = 1, and z = 1) are equilibria. Indeed,

116 
$$P_{\rm C} = \frac{r_{\rm C}}{n} (n-1)(x+z) - \sigma$$
, (2.2a)

117 
$$P_{\rm D} = \frac{rc}{n} (n-1)(x+z) - \beta(n-1)z, \qquad (2.2b)$$

118 
$$P_{\rm p} = \frac{rc}{n}(n-1)(x+z) - \sigma - \gamma(n-1)y.$$
 (2.2c)

Here the common first term denotes the benefit that resulted from the expected (n-1)(x+z)contributors among the (n-1) coplayers, and  $\beta(n-1)z$  and  $\gamma(n-1)y$  give the expected fine on a defector and expected cost to a punisher, respectively.

First, consider only the defectors and punishers (figure 1). Thus, y + z = 1, and the replicator system reduces to  $\dot{z} = z(1-z)(P_{\rm P} - P_{\rm D})$ . Solving  $P_{\rm P} = P_{\rm D}$  results in that, if the interior equilibrium R between the two strategies exists, it is uniquely determined by

125  $z = 1 - \frac{(n-1)\beta - \sigma}{(n-1)(\beta + \gamma)}.$  (2.3)

The point R is unstable. If the fine is much smaller:  $\beta < \sigma/(n-1) =: \beta_0$ , punishment has no effect on defection dominance, or otherwise, R appears and the dynamics turns into bistable [33,34]: R separates the state space into basins of attraction of the different homogeneous states for both the defector and excluder. The smaller  $\gamma$  or larger  $\beta$ , the more the coordinate of R shifts to the defector end: the more relaxed the initial condition required to establish a punisher population (figure 1*a*). Note that a rare punisher is incapable of invading a defector population because the resident defectors, almost all unpunished, earn 0 on average, and the rare punisher does  $-\sigma - \gamma (n-1) < 0$ .

Next, consider all of the cooperators, defectors, and punishers (figure 1b). Without defectors, 134 no punishing cost arises. Thus, no natural selection occurs between the cooperators and 135 punishers, and the edge between the cooperators and punishers (x + z = 1) consists of fixed 136 points. A segment consisting of these fixed points with  $z > \beta_0 / \beta$  is stable against the invasion 137 of rare defectors, and the other segment not so [33,34]. Therefore, this stable segment appears 138 on the edge PC if and only if the edge PD is bistable. We denote by K<sub>0</sub> the boundary point with 139  $z = \beta_0 / \beta$ . There can thus be two attractors: the vertex D and segment PK<sub>0</sub>. The smaller  $\gamma$  or 140 larger  $\beta$ , the broader the basin of attraction for the mixture states of the contributors. That is, 141 the higher the punishment efficiency, the more relaxed the initial condition required to 142 establish a cooperative state. This may collaborate with evidence from recent public-good 143 experiments [38–40], which suggest the positive effects of increasing the punishment 144 efficiency on average cooperation. 145

However, the stability of PK<sub>0</sub> is not robust for small perturbations of the population. Since 146  $P_{\rm P} < P_{\rm C}$  holds in the interior space, an interior trajectory eventually converges to the boundary, 147 and  $d(z/x)/dt = (z/x)(P_{\rm P} - P_{\rm C}) < 0$ : the frequency ratio of the punishers to cooperators 148 decreases over time. Thus, if rare defectors are introduced, for example by mutation or 149 immigration, into a stable population of the two types of contributors, the punishers will 150 gradually decline for each elimination of the defectors. Such small perturbations push the 151 population into an unstable regime around K<sub>0</sub>C, where the defectors can invade the population 152 and then take it over. See figure S1 of ESM and also [26] for individual-based simulations. 153

### 154 (b) Social exclusion

We turn next to social exclusion. The third strategy is now replaced with the excluder (E) that contributes *c* and also tries to exclude defectors from sharing benefits at a cost to itself of  $\overline{\gamma} > 0$  per defector. The multiplied contribution is shared equally among the remaining members in the group. We assume that an excluder succeeds in excluding a defector with the probability  $\overline{\beta}$  and that the excluded defector earns nothing. For simplicity, we conservatively assume that the total sanctioning cost for an excluder is given by  $\overline{\gamma}$  times the number of defectors in a group, whatever others do.

We focus on perfect exclusion with  $\overline{\beta} = 1$ : exclusion never fails. Under this condition, however, we can analyse the nature of social exclusion considered for cooperation. Indeed, we formalise the expected payoffs, as follows:

165 
$$P_{\rm C} = c(r-1) - (1-z)^{n-1} \frac{rc}{n} (n-1) \frac{y}{1-z},$$
 (2.4a)

166 
$$P_{\rm D} = (1-z)^{n-1} \frac{rc}{n} (n-1) \frac{x}{1-z},$$
 (2.4b)

167 
$$P_{\rm E} = c(r-1) - \overline{\gamma}(n-1)y$$
. (2.4c)

- Equation (2.4c) describes that the excluder can constantly receive the group optimum c(r-1)168 at the exclusion cost expected as  $\overline{\gamma}(n-1)y$ . In equations (2.4a) and (2.4b),  $(1-z)^{n-1}$  denotes the 169 probability that we find no excluder in the (n-1) coplayers, and if so, (n-1)y/(1-z) and 170 (n-1)x/(1-z) give the expected numbers of the defectors and cooperators, respectively, 171 among the coplayers. Hence, the second term of equations (2.4a) specifies an expected benefit 172 that could have occurred without freeriding, and equation (2.4b) describes an expected amount 173 that a defector has nibbled from the group benefit, in the group with no excluder. The expected 174 payoffs for any  $\overline{\beta}$  are formalised in ESM. 175
- First, the dynamics between the excluders and defectors can only exhibit bi-stability or excluder dominance for  $\overline{\beta} = 1$  (figure 2*a*). Considering that  $P_{\rm D} = 0$  holds for whatever the fraction of excluders, solving  $P_{\rm E} = 0$  gives that, if the interior equilibrium R exists, it is uniquely determined by

180 
$$z = 1 - \frac{(r-1)c}{(n-1)\overline{\gamma}}.$$
 (2.5)

The point R is unstable. As before, for larger values of  $\overline{\gamma}$ , the dynamics between the two strategies have been bistable. The smaller the value of  $\overline{\gamma}$ , the larger the basin of attraction to the vertex E. In contrast to costly punishment, an excluder population can evolve, irrespective of the initial condition, for sufficiently small values of  $\overline{\gamma}$ . When decreasing  $\overline{\gamma}$  beyond a

of the initial condition, for sufficiently small values of  $\gamma$ . When decreasing  $\gamma$  beyond a

threshold value, R exits at the vertex D, and thus, the current dynamics of bi-stability turns into

excluder dominance. From substituting z = 0 into equation (2.5), the threshold value is

calculated as  $\overline{\gamma}_0 = (r-1)c/(n-1)$ . We note that the dynamics exhibit defector dominance no

matter what  $\overline{\gamma}$ , if  $\overline{\beta}$  is smaller than  $z_0$ , which is from solving  $(1-\overline{\beta})^{n-1} rc(n-1)/n > c(r-1)$ :

the unexcluded rare defector is better off than the resident excluders.

Next, consider all three strategies (figure 2*b*). Solving  $P_{\rm C} = P_{\rm D}$  results in

191 
$$z = 1 - \left(\frac{n(r-1)}{r(n-1)}\right)^{\frac{1}{n-1}} =: z_0.$$
 (2.6)

By the assumption r < n, we have  $0 < z_0 < 1$ . Let us denote by K<sub>0</sub> a point at which this line connects to the edge EC (x + y = 1). This edge consists of fixed points, each of which corresponds to a mixed state of the excluders and cooperators. These fixed points on the segment EK<sub>0</sub> ( $z > z_0$ ) are stable, and those on the segment K<sub>0</sub>C are unstable. Similarly, solving  $P_{\rm E} = P_{\rm C}$  gives

197 
$$z = 1 - \left(\frac{n\gamma}{rc}\right)^{\frac{1}{n-2}} =: z_1.$$
 (2.7)

We denote by  $K_1$  a point at which the line  $z = z_1$  connects to EC. These two lines are parallel, and thus, there is no generic interior equilibrium.

Importantly, the time derivative of z/x is positive in the interior region with  $z < z_1$ . Therefore, the dynamics around the segment  $K_1K_0$  are found to be the opposite of costly punishment, if  $z_1 > z_0$  (or otherwise,  $K_1K_0$  has been unstable against rare defectors). In this case, introducing rare defectors results in that, for each elimination of the defectors, the excluders will gradually rise along  $K_1K_0$  yet fall along the segment  $EK_1$ . Consequently, with such small perturbations, the population can remain attracted to the vicinity of  $K_1$ , not converging to D. Moreover, if  $\overline{\gamma} < \overline{\gamma}_0$ , the excluders dominate the defectors, and thus, all interior trajectories converge to the segment  $EK_0$ , which appears globally stable (figure 2*b*). This result remains robust for the intermediate exclusion probability (figure 3). See figures S2 and S3 of ESM for individualbased simulations.

# 210 **3. Discussion**

Our results regarding social exclusion show that it can be a powerful incentive and appears in 211 stark contrast to costly punishment. What is the logic behind this outcome? First, it is a fact 212 that the exclusion of defectors can decrease the number of beneficiaries, especially when it 213 does not affect the contributions, thereby increasing the share of the group benefit. Therefore, 214 in a mixed group of excluders and defectors, the excluder's net payoff can become higher than 215 the excluded defector's payoff, which is nothing, especially if the cost to exclude is sufficiently 216 low. If social exclusion is capable of 100% rejection at a cheap cost, it can thus emerge in a sea 217 of defectors and dominate them. In our model, self-serving punishment can emerge even when 218 freeriding is initially prevalent by allowing high net benefits from the self-serving action. 219

Moreover, we find that an increase in the fraction of excluders produces a higher probability of 220 an additional increase in the excluder's payoff. This effect can yield the well-known Simpson's 221 paradox (e.g., [41]): the excluders can obtain a higher average payoff than the cooperators, 222 despite the fact that the cooperators always do better than the excluders for any mixed group of 223 the cooperators, defectors, and excluders. Hence, in the presence of defectors, the replicator 224 dynamics often favour the excluders at the expense of the cooperators. Significantly, if a player 225 may occasionally mutate to a defector, social exclusion is more likely than costly punishment 226 to sustain a cooperative state in which all contribute. In our model, a globally stable, 227 cooperative regime can be sustained when solving the second-order freerider problem by 228 allowing mutation to freeriders. 229

230 Sanctioning the second-order freeriders has also often been considered for preventing their

proliferation [3,29,34,36], although such second-order sanction appears rare in experimental

settings [42]. And, allowing for our simple model, it is obvious that in the presence of

defectors and cooperators, a second-order punisher that also punishes the cooperators is worse 233 off than the existing punisher, and thus, does not affect defector dominance as in our main 234 model. However, given that excluding more coplayers can cause an additional increase in the 235 share of the group benefit, it is worth exploring whether the second-order excluder that also 236 excludes the cooperators is more powerful than the excluder. Interestingly, our preliminary 237 individual-based investigation often finds that second-order excluders are undermined by the 238 excluders and cooperators, which forms a stable coexistence (figures S4 of EMS): second-239 order exclusion can be redundant. 240

A fundamental assumption of the model is that defection can be detected with no or little cost. 241 This assumption appears most applicable to local public goods and team production settings in 242 which the coworker's contribution can be easily monitored. However, if the monitoring of co-243 players for defection imposes a certain cost on the excluders, the cooperators dominate the 244 excluders, and the exclusion-based full cooperation is no longer stable. A typical example is 245 found in a potluck party that will often rotate so that every member takes charge of the party by 246 rotation. This rotation system can promote the equal sharing of the hosting cost; or otherwise, 247 no one would take turn playing host. 248

We assessed by extensive numerical investigations the robustness of our results with respect to 249 the following variants (figures S5 and S6 of EMS). First, we considered a different group size 250 n [3,43], In costly punishment, the stable segment PK<sub>0</sub> expands with n, yet our main results 251 were unaffected: with small perturbations, the population eventually converges to a non-252 cooperative state in which all freeride. In social exclusion, our results remain qualitatively 253 robust with smaller and larger sizes (n = 4 and n = 10), but the limit exclusion cost  $\overline{\gamma}$  becomes 254 more restricted as *n* increases. Next, we considered a situation in which a punisher or excluder 255 can choose the number of defectors they sanction. For simplicity, here we assume that each of 256 them sanctions only one [22,44], who is selected randomly from all defectors in the group. Our 257 results remain unaffected, except that social exclusion becomes incapable of emerging in a 258 defector population, in which the payoff of a rare excluder is only given by 259

 $rc/(n-1) - c - \overline{\gamma} < 0$ . To bring forth the possibility of an emergence, a rare excluder is required to exclude more than  $n - rc/(c + \overline{\gamma})$  defectors.

Our results spur new questions about earlier studies on the evolution of cooperation with 262 punishment. A fascinating extension is to the social structures through which individuals 263 interact. To date, a large body of work on cooperation has looked at how costly punishment 264 can propagate throughout a social network [45–47]: for example, the interplay of costly 265 punishment and reputation can promote cooperation [48]; strict-and-severe punishment and 266 cooperation can jointly evolve with continuously varying strategies [49]; and evolution can 267 favour anti-social punishment that targets cooperators [50]. Our results show that social 268 exclusion as considered is so simple, yet extremely powerful. That is, even intuitively applying 269 it to previous studies can help us much in understanding how humans and non-humans have 270 been incentivized to exclude freeriders. 271

To resist the exclusion, it is likely that conditional cooperators capable of detecting ostracism (e.g., [8]) evolve. This would then raise the comprehensive cost of exclusion to the excluders because of more difficulties of finding and less opportunities of excluding freeriders. This situation can then result in driving an arms race of the exclusion technique and exclusion detection system. An extensive investigation for understanding joint evolution of these systems is for future work.

### 409 **Figure captions**

Figure 1. Effects of punishing freeriders. (a) Between the punishers and freeriders. I, If  $\beta$  is 411 smaller than a threshold value  $\beta_0 = \sigma/(n-1)$ , where  $\sigma = c(1-r/n)$  describes a net cost for the 412 single contributor, the defectors dominate. II, If  $\beta$  is greater than  $\beta_0$ , punishing leads to 413 bistable competition between the two strategies. With increasing  $\beta$  or decreasing  $\gamma$ , the 414 minimal frequency of the punishers outcompeting the defectors decreases. However, the 415 excluders cannot dominate the defectors for finitely large values of  $\beta$ . Parameters: group size 416 n = 5, multiplication factor r = 3, and contribution cost c = 1. (b) In the presence of second-417 order freeriders. The triangle represents the state space,  $\Delta = \{(x, y, z) : x, y, z \ge 0, x + y + z = 1\}$ , 418 where x, y, and z are the frequencies of the cooperators, defectors, and punishers, respectively. 419 The vertices, C, D, and P, correspond to the three homogeneous states in which all are the 420 cooperators (x = 1), defectors (y = 1), or punishers (z = 1). The edge PC consists of a 421 continuum of equilibria. The defectors dominate the cooperators. Here we specifically assume 422  $\beta = 0.5$  and  $\gamma = 0.03$ , which result in an unstable equilibrium R within PD and the 423 segmentation of PC into stable part PK<sub>0</sub> and unstable part K<sub>0</sub>C. The interior of  $\Delta$  is separated 424 into the basins of attraction of D and PK<sub>0</sub>. In fact, given the occasional mutation to a defector, 425 the population's state must leave PK<sub>0</sub> and then enter the neighborhood of the unstable segment 426  $K_0C$  because  $P_P > P_C$  holds over the interior space. The population eventually converges to D. 427 428

Figure 2. Effects of excluding freeriders. (a) Between the excluders and freeriders. I, If  $\overline{\beta}$  is 430 smaller than a threshold value  $z_0$ , the defectors dominate. II, If  $\overline{\beta}$  is greater than  $z_0$ , 431 exclusion leads to bistable competition between the two strategies. With increasing  $\overline{\beta}$  or 432 decreasing  $\overline{\gamma}$ , the minimal frequency of the excluders outcompeting the defectors decreases. 433 III, If  $\overline{\beta}$  and  $\overline{\gamma}$  are sufficiently high and low, the excluders dominate. The parameters are as 434 in figure 1a. (b) In the presence of second-order freeriders. The triangle  $\Delta$  is as in figure 1b, 435 except that z denotes the excluder frequency and the vertex E corresponds to its homogeneous 436 state. Similarly, the edge EC consists of a continuum of equilibria. Here we specifically 437 assume  $\overline{\beta} = 1$  and  $\overline{\gamma} = 0.03$ . EC is separated into stable and unstable segments. The coloured 438 area in the interior of  $\Delta$  is the region in which  $P_{\rm E} > P_{\rm C}$  holds. In fact, given the occasional 439 mutation to a defector, the population's state must converge to the vicinity of the point K<sub>1</sub>, 440 because the advantage of the excluders over the cooperators becomes broken when the 441 population's state goes up beyond K<sub>1</sub>. 442

Figure 3. Effects of intermediate social exclusion in the presence of second-order freeriders. 445 The parameters and triangles are as in figure 1, except that  $\overline{\beta} = 0.5$  and  $\overline{\gamma} = 0.03$  (a), 0.13 (b), 446 0.18 (c), or 0.28 (d). EC is separated into stable and unstable segments. The coloured area is 447 the interior region in which  $P_{\rm E} > P_{\rm C}$  holds. (a) The dynamics of ED are unidirectional to E. All 448 interior trajectories converge onto the stable segment EK<sub>0</sub>. Moreover, occasionally mutating to 449 a defector leads to upgrading E to a global attractor. (b-d) An unstable equilibrium R appears 450 on ED. The interior space is separated into the basins of attraction of D and EK<sub>0</sub>. R is a saddle 451 (b) or source (c and d). In (c) especially, the interior space has a saddle point Q. Given the 452 mutant defectors, the population's state around  $EK_0$  will gradually move to  $K_1$  (b and c), or to 453 the unstable segment  $K_0C(d)$ . The last case is followed by a convergence toward D. 454

### 3 Materials and methods

4 We first determine the strategy's payoffs in public good games with social exclusion, then

5 show details of individual-based simulations for assessing the robustness with respect to

6 stochastic evolutionary game dynamics.

7 **Payoffs for social exclusion:** We consider the replicator dynamics for the cooperator (C),

8 defector (D), and excluder (E), with frequencies of x, y, and z, respectively. Thus, x, y,  $z \ge 0$ 

9 and x + y + z = 1. We denote the expected payoff values for the three strategies by  $P_S$ , with S =

10 C, D, and E, respectively. The replicator system is given by

11 
$$\dot{x} = x(P_{\rm C} - P), \ \dot{y} = y(P_{\rm D} - P), \ \dot{z} = z(P_{\rm E} - P)$$

where  $\overline{P} := xP_{\rm C} + yP_{\rm D} + zP_{\rm E}$  describes the average payoff in the entire population. We denote by X, Y, and Z the number of the cooperators, defectors, and excluders, respectively, among the (*n*-1) coplayers around a focal player. Then, if W of the Y defectors have not been excluded by every excluder, the expected payoff for each strategy is given by

16 
$$P_S = \sum_{X=0}^{n-1} \sum_{Y=0}^{n-1-X} \sum_{W=0}^{Y} \pi_S p_S.$$
 (S1)

In equation (S1),  $p_s$  denotes the payoff for the focal player who follows the strategy *S* among the (n-1) coplayers with a configuration of  $\{X, Y, Z, W\}$ , and  $\pi_s$  denotes the probability to find the specified coplayers. Using a function  $\alpha(Z)$  that denotes the probability that all of the

Z excluders fail to exclude a targeted defector, we have

21 
$$p_{\rm C} = \frac{rc(X+Z+1)}{X+W+Z+1} - c$$
, (S2)

22 
$$p_{\rm D} = \alpha(Z) \frac{rc(X+Z)}{X+W+Z+1},$$
 (S3)

$$23 p_{\rm E} = p_{\rm C} - \overline{\gamma} Y \,, (S4)$$

24 
$$\pi_{\rm C} = \pi_{\rm D} = {n-1 \choose X, Y, Z} x^X y^Y z^Z {Y \choose W} \alpha(Z)^W [1-\alpha(Z)]^{Y-W}, \qquad (S5)$$

25 
$$\pi_{\rm E} = {n-1 \choose X, Y, Z} x^X y^Y z^Z {Y \choose W} \alpha (Z+1)^W [1-\alpha(Z+1)]^{Y-W}.$$
 (S6)

26 In equations (S5) and (S6),  $\binom{n-1}{X,Y,Z}$  and  $\binom{Y}{W}$  represent the multinomial and binomial

27 coefficients. Thus,  $\binom{n-1}{X,Y,Z} x^X y^Y z^Z$  describes the probability of finding the (n-1) coplayers

28 with *X* cooperators, *Y* defectors, and *Z* excluders, and  $\begin{pmatrix} Y \\ W \end{pmatrix} \alpha(Z)^{W} [1 - \alpha(Z)]^{Y-W}$  describes the

29 probability that *W* of the *Y* defectors have not been excluded. In the paper, we assume

30  $\alpha(Z) = (1 - \overline{\beta})^Z$ , where  $\overline{\beta}$  is the exclusion probability: an excluder succeeds in excluding a 31 defector.

Individual-based simulation: Here, we consider a finitely large, well-mixed population with 32 *M* interacting individuals. For the dynamic analysis, instead of the replicator system [35], we 33 implement a pairwise comparison process among finite individuals [36,37], which is based on 34 preferentially imitating strategies of more successful individuals. We assume that the 35 individual strategies are updated asynchronously as follows. First, an individual *i* is selected at 36 random and then earns its "average" payoff  $p_i$  after engaging in T games with coplayers 37 38 randomly selected in each case. Second, the focal individual *i* faces a model individual *j* who is 39 drawn at random, with its average payoff  $p_i$  that is calculated throughout independent T games. If  $p_i \ge p_j$ , no update occurs; or otherwise, *i* will adopt *j*'s strategy, with the probability 40 given by 41

42 
$$\theta_{i \to j} = \frac{1}{1 + \exp(-K(p_j - p_i))},$$

43 where *K* denotes the selection strength. Finally, the focal individual *i* can mutate and turn into a 44 cooperator, defector, or punisher (or excluder) with probabilities  $\mu_{\rm C}$ ,  $\mu_{\rm D}$ ,  $\mu_{\rm P}$  (or  $\mu_{\rm E}$ ). Our 45 numerical results demonstrated in figures S1–S6 are robust with respect to changes in the 46 parameter values of *M*,  $\mu_{\rm C}$ ,  $\mu_{\rm D}$ ,  $\mu_{\rm P}$ ,  $\mu_{\rm E}$ , and *K*.

## 47 Supplementary figures

#### 48

Figure S1. Individual-based simulation for public good games with costly punishment. We 49 50 began with a 100%-punisher population to observe its stability. First, because the punishing of 51 mutant defectors is costly, the former major punishers (blue) will gradually be replaced by the initially minor cooperators (namely, second-order freeriders, black). Next, when a critical 52 fraction of punishers is lost, the mutant defectors (red) succeed in invading the population and 53 then quickly prevail. The parameters are as in figure 1*b*: group size n = 5, multiplication factor 54 r = 3, contribution cost c = 1, punishment cost  $\beta = 0.5$ , and punishment fine  $\gamma = 0.03$ . The 55 defectors dominate the cooperators, and the excluders and defectors are under bistable 56 competition. Other parameters are as the population size  $M = 10^4$ , sample game count T = 50, 57 selection strength K = 200, mutation rate to D  $\mu_{\rm D} = 5 \times 10^{-3}$ , mutation rates to C and P 58  $\mu_{\rm C} = \mu_{\rm P} = 10^{-5}$  (low mutation rate) or  $\mu_{\rm C} = \mu_{\rm P} = 10^{-3}$  (high mutation rate), and the unit of 59

60 evolutionary time t describes  $10^4$  times the iteration of the update sequence.

Figure S2. Individual-based simulation for public good games with perfect social exclusion. 62 The parameters are as in figure 2b: n=5, r=3, c=1, exclusion probability  $\overline{\beta} = 1$ , and 63 exclusion cost  $\overline{\gamma} = 0.03$ . We began with a 100%-punisher population to observe the 64 establishment of a cooperative state. Whether the minimal mutation rate is high  $(10^{-3})$  or low 65  $(10^{-5})$ , the former major defectors (red) will soon be replaced by the initially minor excluders 66 (blue), whose part will then be gradually replaced by the cooperators (black). The population 67 eventually converges to a certain mixture state of the contributors without a second-order 68 freerider problem. The final state has been indicated by point  $K_1$  in figures 2b. The simulation 69 parameters are as in figure S1. 70

Figure S3. Individual-based simulation for public good games with intermediate social 72 exclusion. The parameters are as in figure 3: n = 5, r = 3, c = 1, and  $\overline{\beta} = 0.5$ . We began with 73 different initial conditions, depending on the value of  $\overline{\gamma}$ : 90% cooperators and 10% excluders 74 for  $\overline{\gamma} = 0.03$  (a) and 100% excluders for  $\overline{\gamma} = 0.13$  (b), 0.18 (c), or 0.28 (d). (a) The former 75 major cooperators (black) will gradually be replaced by the initially minor excluders (blue), 76 which then stably occupy the entire population (b and c). The initially minor cooperators will 77 first replace part of the excluders, and the population will then converge to a certain mixture 78 state, which has been indicated by the point  $K_1$  in figures 3b and 3c, respectively (d). As in (b 79 and c), the cooperators will gradually expand. When a critical fraction of the excluders is lost 80 (the point  $K_0$ ), the mutant defectors (black) succeed in invading the population and will then 81 quickly prevail to 100%. The simulation parameters are as in figure S1 with the low mutation 82 83 rate.

Evolutionary time, t

Figure S4. Individual-based simulation for public good games with second-order social 85 exclusion. The parameters are as in figure 2b, except that  $\overline{\gamma} = 0.03$  (low exclusion cost) or 86  $\overline{\gamma} = 0.28$  (high exclusion cost). We began with the initial condition: 100% second-order 87 excluders (green) who in the presence of the defectors, also exclude the cooperators, as well as 88 the defectors (with the same cost and probability). The initial residents will first be replaced 89 with the excluders (blue), and then are partially invaded by the cooperators (black): the 90 population will converge to a certain mixture state of the contributors, whether with a high or 91 low exclusion cost. The simulation parameters are as in figure S1. 92

Figure S5. Effect of different group sizes. The parameters are as in figure 2*b*, for perfect exclusion (*a*) and (*b*), and in figure 3, for intermediate exclusion (*c*–*h*). The initial conditions are 100% second-order excluders in (*a*) and (*b*) and 100% excluders in (*c*–*h*).

97

Figure S6. Effect of options to choose the number of sanctioned defectors. The model and simulation parameters, and initial conditions are as in figure S1, for costly punishment (top), and in figure S3, for intermediate exclusion (middle and bottom, a-d). Here we assume that a punisher or excluder is willing to sanction only one defector selected at random from all defectors in the group. The results are almost same as in figures S1 and S3.
