Motivated by the increasing interest in the properties of multimode optomechanical devices, here we study a system in which a driven mode of a large-area optical cavity is despersively coupled to a deformable mechanical element. Two different models naturally appear in such scenario, for which we predict the formation of periodic patterns, localized structures (cavity solitons), and domain walls, among other complex nonlinear phenomena. Further, we propose a realistic design based on intracavity membranes where our models can be studied experimentally. Apart from its relevance to the field of nonlinear optics, the results put forward here are a necessary step towards understanding the quantum properties of optomechanical systems in the multimode regime of both the optical and mechanical degrees of freedom.

Introduction. Since the eighties of the past century, the advent and rapid growing of quantum information have boosted the research on quantum technologies that try to develop microdevices allowing for robust implementations of controllable quantum interactions for long coherence times. By today the state of the art permits the fabrication of devices functioning in such strong coupling regime with unprecedented control and accuracy in a rapidly growing field. These new quantum devices are very diverse including cavity—QED [1], optical lattices [2], trapped ions [3], superconducting circuits [4], quantum dots [5], atomic ensembles [6], etc.

In typical optomechanical cavities [7] the interaction occurs between a light field and a mechanical oscillator via radiation pressure. This type of system has been known for a long time in classical optics [8], and to some extent resembles a nonlinear Kerr cavity [9] as the cavity length (and consequently the cavity resonance) depends on the intracavity field intensity. At present, the stress is made on their capability to show quantum coherent phenomena such as cooling and amplification [10], strong (linear) coupling effects like optomechanically induced transparency [11], or to prepare squeezed states of light dissipatively [12-15]. Attention has also been recently paid to the nonlinear dynamics of optomechanical arrays [16], cavities in which radiation pressure competes with the photothermal effect [17], planar dual-nanoweb waveguides subject to radiation pressure [18], and optomechanical cavities containing atomic ensembles [19].

Except for some of these recent works, up to now most studies deal with a small number of modes either in the optical or the mechanical degrees of freedom, while the nonlinear interplay between many optical and mechanical modes entails the existence of correlations among them that can provide optomechanical systems with new capabilities. At the quantum level, these correlations may lead to multipartite entanglement [20–22]; at the classical level, they help for the spontaneous appearance of

dissipative structures that are long range ordered configurations, including periodic, quasiperiodic and aperiodic patterns, as well as localized structures, which may also exhibit nontrivial temporal behavior [23].

The interplay between the quantum and classical perspectives in multimode systems has received theoretical attention mainly in the context of optical parametric oscillators for which some exciting phenomena were predicted [24]. No such studies exist concerning optomechanical systems, and here we make a step towards this goal by proposing a multimode optomechanical cavity configuration in which dissipative structures are predicted to appear. We keep our study at the classical level by concentrating on the analysis of the general conditions under which such patterns can appear and how they are, leaving the study of their quantum properties for a future publication. As we show below, periodic patterns, localized structures (cavity solitons), and domain walls are predicted to occur in a wide region of the two models that naturally follow from the proposed configuration.

Model. Consider an optical cavity with large-area mirrors containing a dispersive element which can be thought of as a thin tense membrane that can be deformed locally, but is also allowed to oscillate as a whole (Fig. 1). Energy is fed in the cavity from the outside by injecting a coherent laser field through the partially transmitting mirror, modelled as a paraxial beam

$$E_{\rm inj}(z, \mathbf{r}, t) = i \mathcal{V} A_{\rm inj}(z, \mathbf{r}, t) e^{i(k_{\rm L}z - \omega_{\rm L}t)} + \text{c.c.}, \qquad (1)$$

where  $\mathbf{r} = (x, y)$  denotes the position in the plane transverse to the cavity axis (z-axis), and  $\mathcal{V}$  is a constant having the dimensions of voltage, which we choose as  $\mathcal{V} = \sqrt{\hbar \omega_c/4\varepsilon_0 L}$  in order to make contact with quantum optics (see [24, 25]),  $\omega_c$  being the frequency of the longitudinal cavity mode closest to the injected frequency  $\omega_L$  (with corresponding wave vectors  $k_j = \omega_j/c$  and wavelengths  $\lambda_j = 2\pi/k_j$ ). The intracavity field  $E(z, \mathbf{r}, t)$  can

FIG. 1: Cartoon of the system.

be written generically as

$$E(z, \mathbf{r}, t) = i\mathcal{V} \left( A_{+} e^{ik_{L}z} + A_{-} e^{-ik_{L}z} \right) e^{-i\omega_{L}t} + \text{c.c.}, (2)$$

which is the superposition of two waves with slowly varying complex amplitudes  $A_{\pm}(z, \mathbf{r}, t)$ , propagating along the positive  $(A_{+})$  and negative  $(A_{-})$  z direction. We first derive an evolution equation for the amplitude  $A_{+}(z=L,\mathbf{r},t)$  at the end mirror's surface, which we will denote by  $A(\mathbf{r},t)$ . The procedure consists in propagating the field along a full cavity roundtrip [25, 26], which, in the paraxial approximation, and assuming that the fields change very little after one roundtrip (with associated time  $t_{c}=2L/c$ ), as well as a small reflectance  $\varrho^{2}$  of the membrane, leads to [25–28]

$$\partial_t A = \gamma_c \mathcal{E} + \gamma_c \left( -1 + i\Delta + il_c^2 \nabla_\perp^2 \right) A$$

$$-i \frac{4\gamma_c \varrho}{T} \cos \left[ 2k_L \left( z_0 + Q \right) \right] A$$
(3)

where  $T = T_1 + T_2$  is the sum of the mirrors' transmittances,  $\gamma_c = cT/4L$  is the cavity damping rate,  $\Delta = (\omega_L - \omega_c)/\gamma_c$  is the dimensionless detuning parameter,  $l_c^2 = 2L/k_LT$  is the diffraction length (squared),  $\nabla_{\perp}^2 = \partial_x^2 + \partial_y^2$  is the transverse Laplacian, and  $\mathcal{E} = 2\sqrt{T_1/T^2}A_{\rm inj}$  is a scaled version of the injection field amplitude. The local displacement of the membrane perpendicular to its rest position at  $z = z_0$  is measured by the field  $Q(\mathbf{r}, t)$ , so Q = 0 in the absence of illumination.

The equation for the light field must be complemented with an equation for the displacement field  $Q(\mathbf{r},t)$ . In the absence of forcing and dissipation Q obeys a wave equation  $\partial_t^2 Q + \mathbb{L} Q = 0$ , where  $\mathbb{L}$  is a suitable differential operator whose form depends on the specific implementation. Including damping, assumed homogeneous for simplicity, and coupling of the membrane to the light field, we get [25]

$$\partial_t^2 Q + \gamma_{\rm m} \partial_t Q + \mathbb{L} Q = \frac{4 \varrho \hbar k_{\rm L}}{\sigma t_{\rm c}} \sin \left[ 2 k_{\rm L} \left( z_0 + Q \right) \right] \left| A \right|^2, \ (4)$$

where  $\sigma$  is the membrane's surface mass density.

For the sake of simplicity and analyticity, we choose  $\mathbb{L} = \Omega_{\rm m}^2 - v^2 \nabla_{\perp}^2$ , which models a membrane (characterized by its sound speed v) that can oscillate as a whole

at frequency  $\Omega_{\rm m}$ . This choice ensures that the model will possess spatially homogeneous solutions (invariant under translations across the transverse plane), which can become unstable in favor of patterns that break such symmetry, as usual in spontaneous pattern forming scenarios [29]. As we show below through numerical simulations, the existence of such sufficiently homogeneous solutions turns out to be essential for pattern formation, and later we propose a specific experimental implementation leading to this particular choice of  $\mathbb{L}$ .

Eqs. (3) and (4) constitute the basic model for our optomechanical setup, which coincides with previous singlemode models [30, 31] in the limit of small reflectance  $\varrho^2$  and ignoring transverse spatial effects. The type of model that appears depends strongly on the location  $z_0$ of the membrane. In this work we consider two typical situations leading to significantly different scenarios [30, 31]: either the membrane is located at a node of the driven mode's standing wave  $(z_0/\lambda_L = 0, 1/2, 1, ...)$ or half-way between a node and an antinode  $(z_0/\lambda_L)$ 1/8, 3/8, 5/8, ...). We will refer to the corresponding models as the *quadratic* and *linear* models, respectively, because this is the dependence that the light's frequency shift has on the mechanical field on each case, see Eq. (5a) below. We simplify the model equations in these two configurations by following the usual procedure in which, taking into account that the membrane's displacement Q is small compared with the laser's wavelength, the coupling terms in Eqs. (3) and (4) can be expanded around Q = 0 to the first nontrivial order in Q. The two resulting models can be written in a compact and clean form by introducing an index  $\mu$  which equals 1 or 2 for the linear or quadratic models, respectively, as well as normalized variables and parameters. Defining the dimensionless time  $\tau = \gamma_{\rm c} t$ , spatial coordinates  $\bar{\bf r} = {\bf r}/l_{\rm c}$ , plus parameters  $\gamma = \gamma_{\rm m}/\gamma_{\rm c}$  and  $\Omega = \Omega_{\rm m}/\gamma_{\rm c}$ , we get [25]

$$\partial_{\tau} F = \left[ -1 + i \left( \Delta_{\mu} + \nabla^2 + Z^{\mu} \right) \right] F + E, \quad (5a)$$

$$\partial_{\tau}^{2}Z + \gamma \partial_{\tau}Z + \Omega^{2} \left(1 - \rho^{2} \nabla^{2}\right) Z = \Omega^{2} Z^{\mu - 1} \left|F\right|^{2}, \quad (5b)$$

where F, Z, and E are normalized dimensionless versions of the optical field A, the mechanical field Q, and the pump  $\mathcal{E}$ , respectively [25],  $\nabla^2 = \left(\partial_{\bar{x}}^2 + \partial_{\bar{y}}^2\right)$ ,  $\Delta_{\mu} = \Delta - 4(\mu - 1)\varrho/T$ , and we have defined the 'effective rigidity' parameter  $\rho = v/\Omega_{\rm m}l_{\rm c}$ , so that the larger  $\rho$  the more rigidly the membrane behaves. Alternatively,  $\rho$  is a measure of how local the response of the membrane is to a stress: when  $\rho \to 0$  the response is local, while for  $\rho \to \infty$  it is completely integrated, that is, only the homogeneous mode is excited.

Let us remark that we have also considered the situation in which the end mirror is the deformable mechanical element, optomechanical coupling arising from the radiation pressure force [7] in such case. The resulting normalized model coincides with the linear model introduced above, Eq. (5) with  $\mu=1$ . Also, note that we have

FIG. 2: (a-d) Cartoon of the generic steady-states and instabilities of the linear (LM) and quadratic (QM) models introduced in the text. We plot the mechanical displacement  $\bar{Z}$  of the homogeneous steady-state solution as a function of the injection  $E^2$ , with the stable (unstable) regions denoted by solid (dashed) lines. We mark the Pitchfork bifurcation leading to pattern formation (red squares), as well as the Hopf instability (blue squares) leading to oscillatory solutions, the arrows indicating the portion of the curve which they make unstable. The insets shown in (a) and (d) show the type of patterns expected for injections marked by the thin grey line, corresponding to solitons in the linear model and domain walls in the quadratic one. (e,f) Localized structures found by numerically solving the equations modelling a realistic implementation based on framed membranes, expected to lead to an effective 1D model with homogeneous mode and patterns occurring along the x axis, as long as only one or few modes of the membrane are excited in the y direction; in (e) we show a soliton parameter in the region marked with a vertical dashed line in (a), while in (f) we show a domain wall appearing in the region marked in (d). The specific parameters of the simulation can be checked in [25].

not included the case of the membrane being in an antinode  $(z_0/\lambda_{\rm L}=1/4,3/4,5/4,...)$ , what results in a model like the one above with  $\mu=2$  but with an extra negative sign in front of the terms  $Z^{\mu}$  and  $Z^{\mu-1}$ , because we haven't found any pattern forming instabilities in such configuration [25].

Homogeneous solutions, their stability, and pattern formation. When the injected field is a plane wave propagating along z, the amplitude E is a constant that we take real and positive without loss of generality. In such a case Eqs. (5) admit spatially homogeneous solutions which coincide with the well-known ones of the single-mode models [7], Eqs. (5) with  $\nabla \to 0$ .

For the linear model (LM),  $\mu = 1$ , the stationary homogeneous solutions verify  $\bar{Z}_{\rm LM} = |\bar{F}_{\rm LM}|^2$  with

$$E^{2} = \left[1 + \left(\Delta + \bar{Z}_{\rm LM}\right)^{2}\right] \bar{Z}_{\rm LM}.\tag{6}$$

(Overbars denote steady homogenous solutions.) This is the usual state equation of the single-mode optomechanical cavity (or of a Kerr cavity), which shows a bistable region whenever  $\Delta < -\sqrt{3}$ , see Figs. 2(a) and 2(b).

Differently, in the case of the quadratic model (QM),  $\mu=2$ , there are two homogeneous steady states that

bifurcate one into the other: the trivial state, for which  $\bar{Z}_{\mathrm{QM}}=0$  and  $\bar{F}_{\mathrm{QM}}=E/\left(1-\mathrm{i}\Delta\right)$ , and the nontrivial one

$$\bar{Z}_{\text{QM}}^2 = \sqrt{E^2 - 1} - \Delta, \ |\bar{F}_{\text{QM}}|^2 = 1,$$
 (7)

which exists only for  $E^2 > (1 + \Delta^2)$ . Note that for  $\Delta < 0$  there is a region where the trivial and nontrivial solutions coexist, see Figs. 2(c) and 2(d).

These spatially homogeneous steady states can suffer different instabilities leading to the appearance of new solutions, such as self-pulsing or space-dependent solutions (through Hopf or pattern-forming bifurcations, respectively). Standard linear stability analysis techniques [32] allow us to derive the location of these bifurcations in the parameter space [25]. However the general analysis is quite involved as up to five parameters enter the models, and hence we will give the details elsewhere, commenting here only on some general trends and focusing on examples which show that pattern formation is possible.

Both models show a static pattern forming instability, as well as a Hopf instability. The latter leads either to a pulsing homogeneous state (homogeneous Hopf) or to a pulsing structure (pattern forming Hopf) depending on the system parameters. Together with the homogeneous

stationary solutions  $\bar{Z}$ , in Fig. 2 we have marked the typical location of these instabilities, as well as the regions of  $\bar{Z}$  that become unstable. In very general terms, we can say that the existence of pattern forming instabilities requires a rigidity  $\rho$  below some maximum value which, e.g., for the linear model is unity for most detuning values, and can be even larger for large negative detunings. As for the Hopf instability, we can also say that the smaller  $\gamma$  or the larger  $\Omega$  are, the closer it is to the limit of existence of the nonzero solutions, in particular tending to invade the whole domain of existence of the nontrivial solution for small  $\gamma$  in the quadratic model.

In order to study the type of patterns appearing in the unstable regions, we have performed a numerical analysis of the model equations in both one (1D) and two (2D) transverse dimensions using periodic boundary conditions, check [25] for details. Our analysis has revealed periodic patterns (hexagonal in 2D) and localized structures, as well as more complex spatio-temporal phenomena. Remarkably, stable localized structures appear in the regions where there is coexistence between the stable lower branch and the unstable upper branch solutions in the linear model (see the inset of Fig. 2a), or between the stable trivial and unstable nontrivial solutions in the quadratic one. We have checked that these localized structures can be written, erased, and moved individually, so that they behave as true cavity solitons [33]. An important difference between the two models is that the quadratic one has intrinsic phase bistability, since  $Z(\bar{\mathbf{r}},\tau) \to -Z(\bar{\mathbf{r}},\tau)$  leaves the equations invariant, which leads to the existence of domain walls that appear between two adjacent regions occupied by solutions differing only in their sign (see the inset of Fig. 2d).

Physical implementation. State-of-the-art optomechanical setups allow for the use of silicon nitride membranes both as intracavity elements dispersively coupled to the light contained in the resonator [30, 31, 34–39] or directly as end mirrors, hence sensitive to radiation pressure [40–42]. In all these experiments the membrane is held by a fixed frame, so that the membrane cannot be displaced as a whole in the axial direction. Such systems are then described by our 2D model equations (3) and (4) with  $\mathbb{L} = -v^2 \nabla^2$  and fixed boundary conditions. We have performed extensive numerical simulations of this scenario obtaining no stable 2D patterns. This has lead us to the conclusion that  $\Omega_{\rm m} \neq 0$  is a necessary condition for spatial instabilities to occur, since otherwise it is not possible to have a sufficiently homogeneous mechanical background to sustain such structures, in agreement with the intuition we provided when first introducing the differential operator as  $\mathbb{L} = \Omega_{\rm m}^2 - v^2 \nabla_{\perp}^2$ . While it is true that this condition excludes the possibility of studying the phenomena predicted by our 2D models with the membrane-based setups mentioned above, in the following we show that under conditions leading to the excitation of one or few mechanical modes in one transverse

direction, an effective homogeneous mode appears in the orthogonal direction, allowing for the observation of the patterns predicted by our models in 1D.

In order to see this, let us consider a mechanical field of the form  $Q(\mathbf{r},t) = \cos(\pi y/L_y)Q_{1D}(x,t)$ , where  $L_y$  is the length of the membrane in the y direction, in which only the fundamental mode is assumed to be excited for simplicity. The application of the differential operator  $\mathbb{L} = -v^2 \nabla^2$  onto it leads to  $\mathbb{L}Q \equiv \Omega_{\mathrm{m,eff}}^2 (1 - \rho_{\mathrm{eff}}^2 \partial_{\bar{x}}^2) Q$ , with  $\Omega_{\mathrm{m,eff}} = \pi v / L_y$  and  $\rho_{\mathrm{eff}} = v / \Omega_{\mathrm{m,eff}} l_{\mathrm{c}} = L_y / \pi l_{\mathrm{c}}$ , which is the 1D version of the analogous term in Eq. (5b), allowing for homogeneous excitations along the xaxis. Thus, we obtain an effective 1D rigidity parameter which is solely controlled by the length of the membrane in the y direction (normalized to  $l_c$ ). A relevant question is whether current setups can reach the condition  $\rho_{\rm eff} \lesssim 1$  which typically leads to pattern formation for a wide range of the rest of parameters, as explained above. Taking as in [39] a laser at  $\lambda_{\rm L} = 1064 {\rm nm}$  and a cavity of L=10cm but smaller finesse  $\mathcal{F}=500$  (it is 50,000 in [39]), we get a diffraction length  $l_c = \sqrt{\lambda_L L \mathcal{F}}/2\pi \approx$ 1mm. Since commercial membranes have typical sizes on the millimeter scale, this shows that current experiments have indeed access to the desired regime.

We have performed numerical simulations that confirm this simple picture, using a quasi-planar injection of finite width (supergaussian) [25]. The conditions for exciting just one or few mechanical modes are naturally accomplished by choosing a membrane short enough along the y axis for the frequencies of the normal modes to be well spaced, but long enough along the x axis for the desired spatial structures to exist. In Figs. 2(e) and 2(f) we show results for both the linear and quadratic models, in particular showing a cavity soliton from the linear model and a domain wall from the quadratic one. The particular parameters used in the simulations can be checked in [25], but they are not of real relevance since the structures are robust and easily found within the region of the parameter space where they are expected to appear according to the effective 1D model.

Conclusions. We have proposed an optomechanical system in which pattern formation can be observed. In our proposal, the mechanical degrees of freedom come from a membrane which can be locally deformed by its interaction with light. Two different models appear in this scenario, for which we have been able to locate their pattern forming instabilities. An important conclusion of our numerical investigations is that the existence of such structures requires the presence of a sufficiently homogeneous mechanical mode, and we have proposed realistic implementations of the 1D models based on currently available membranes, proving how patterns (solitons and domain walls) indeed appear in such systems. Future venues will include the study of the quantum spatial correlations present on (and between) the optical and mechanical fields, which may lead to noncritical squeezing and multipartite entanglement, similarly to what has been found in optical parametric oscillators [24, 43].

## Supplemental material

In this supplemental material we offer a detailed derivation of the model equations, and give more details about the linear stability analysis performed onto the homogeneous stationary solutions present in the system, as well as about the numerical simulations performed both for the model and the proposed implementation.

**Derivation of the light field equation.** In this section we offer a detailed derivation of Eq. (2) of the main text, which describes the evolution of the optical field at the plane of the end mirror.

We will denote by  $r_1$  ( $r_2$ ) the reflection coefficients of the left (right) cavity mirrors,  $1 - |r_j|^2 = T_j$  being the corresponding transmittances, which are assumed very close to zero: good cavity limit. The left (right) mirror is located at z = 0 (L), and we assume for definiteness that light is injected through the left mirror.

In the absbence of illumination the membrane has an equilibrium position at  $z=z_0$ , while in the presence of optical fields any point  $\mathbf{r}$  of the membrane will be displaced along the cavity axis by  $Q(\mathbf{r},t)$  from equilibrium, which defines the mechanical field introduced in the main text. We treat this deformable membrane as a thin, lossless symmetric beam splitter, with (complex) transmission and reflection coefficients denoted by  $\tau_{\pm}$  and  $\varrho_{\pm}$ , where the subscript refers to the side of the membrane from which the beam emerges after transmission or reflection (+ for right and – for left). As in any lossless beam splitter [27], the phases of these coefficients satisfy

$$\arg(\rho_{+}) + \arg(\rho_{-}) - \arg(\tau_{+}) - \arg(\tau_{-}) = \pi,$$
 (8)

while further for a symmetric one,

$$|\tau_{\pm}| = \tau, \quad |\varrho_{\pm}| = \varrho, \tag{9}$$

with the relation  $\tau^2 + \rho^2 = 1$ .

At any point in space and time, we write the optical field as  $E(z, \mathbf{r}, t) = E_{+}(z, \mathbf{r}, t) + E_{-}(z, \mathbf{r}, t)$ , which is a sum of two waves traveling to the right (+) and to the left (-). We choose arbitrarily to derive the evolution equation for the field  $E_{+}(L, \mathbf{r}, t)$  impinging the right cavity mirror. Such an equation is derived by following the usual approach of propagating the field along the resonator (see e.g. [26]), assuming that any modification of the field along a cavity roundtrip (due to diffraction and to transmission and reflection on the membrane or on the cavity mirrors) is small. This means that we are considering (i) short enough propagation distances (either geometrically small, or optically small, as in quasi selfimaging resonators [28]), and (ii) membranes with very small reflectivities,  $\rho \ll 1$ . The presence of the intracavity membrane makes the derivation a bit complicated because, at any instant,  $E_{+}(L, \mathbf{r}, t)$  is the superposition of infinitely many contributions, corresponding to waves that have travelled in the cavity through paths with different combinations of transmissions and reflections in

the membrane and the mirrors, and meet at the right mirror. However, as the membrane reflectivities  $\varrho_{\pm}$  are assumed small,  $E_{+}(L, \mathbf{r}, t)$  can be approximated at any instant as the sum of just four partial waves, as sketched in Figure 3: (I) the injected field transmitted through the input mirror and the membrane (call it  $E_{\rm I}$ ), (II) the field that, after reflection on the right cavity mirror, has performed a full cavity roundtrip just by transmitting through the membrane (call it  $E_{\rm II}$ ); (III) the field that, after reflection on the right cavity mirror, relfects back from the right face of the membrane (call it  $E_{\rm III}$ ); and (IV), the field that, after transmission through the membrane and reflection on the left cavity mirror, has reflected from the left side of the membrane, reflected again from the left mirror, and finally transmitted through the membrane (call it  $E_{\text{IV}}$ ). Any other partial wave has an amplitude on the order of  $\rho^2$  or smaller, which we neglect. Hence we write

$$E_{+}(L, \mathbf{r}, t) = E_{\mathrm{I}}(\mathbf{r}, t) + E_{\mathrm{II}}(\mathbf{r}, t) + E_{\mathrm{III}}(\mathbf{r}, t) + E_{\mathrm{IV}}(\mathbf{r}, t),$$
(10)

where the four partial waves can be written as

$$E_{\rm I}(\mathbf{r},t) = K_{\rm I} \mathcal{U}_L E_{\rm inj}(0,\mathbf{r},t-t_{\rm c}/2),$$
 (11a)

$$E_{\mathrm{II}}(\mathbf{r},t) = K_{\mathrm{II}}\mathcal{U}_{2L}E_{+}(L,\mathbf{r},t-t_{\mathrm{c}}), \qquad (11b)$$

$$E_{\text{III}}(\mathbf{r}, t) = K_{\text{III}} \mathcal{U}_{L_2} e^{-2ik_{\text{L}}Q(\mathbf{r}, t - t_2)}$$

$$\times \mathcal{U}_{L_2} E_+ (L, \mathbf{r}, t - 2t_2),$$

$$(11c)$$

$$E_{\text{IV}}(\mathbf{r},t) = K_{\text{IV}} \mathcal{U}_{L+L_1} e^{2ik_{\text{L}}Q(\mathbf{r},t-t_{\text{c}}/2-t_1)}$$

$$\times \mathcal{U}_{L+L_1} E_{+}(L,\mathbf{r},t-t_{\text{c}}-2t_1),$$
(11d)

with

$$K_{\rm I} = \sqrt{T_1} \tau_+, \tag{12}$$

$$K_{\rm II} = r_2 r_1 \tau_+ \tau_-,$$
 (13)

$$K_{\rm III} = r_2 \rho_+, \tag{14}$$

$$K_{\rm IV} = r_1^2 r_2 \tau_+ \tau_- \varrho_-.$$
 (15)

The operator  $\mathcal{U}_d = \exp\left[\mathrm{i}(d/2k_\mathrm{L})\nabla_\perp^2\right]$  accounts for diffraction in the paraxial approximation, corresponding to a propagation distance equal to d. Here  $L_1 = z_0$  and  $L_2 = L - z_0$ ,  $t_{1,2} = L_{1,2}/c$ , and  $t_c = 2 (t_1 + t_2) = 2L/c$  is the cavity roundtrip time. The factors  $e^{\pm 2ik_\mathrm{L}Q(\mathbf{r},t)}$  model the phase front modification produced by the reflection on the membrane in the paraxial approximation.

Before continuing it proves useful to express the coefficients  $K_{\rm II}$ ,  $K_{\rm III}$  and  $K_{\rm IV}$  in terms of the modulus and argument of  $K_{\rm II}$ . Let us then write

$$K_{\rm II} = r \exp\left(\mathrm{i}\theta\right),$$
 (16a)

$$K_{\text{III}} = K_{+} r \exp\left(i\theta\right),$$
 (16b)

$$K_{\rm IV} = K_- r \exp\left(i\theta\right),\tag{16c}$$

FIG. 3: Sketch of the paths travelled by the main waves superposing at the right cavity mirror at a given instant.

with

$$r = |r_1 r_2 \tau_+ \tau_-| \,, \tag{17a}$$

$$\theta = \arg(r_1) + \arg(r_2) + \arg(\tau_+) + \arg(\tau_-), \quad (17b)$$

$$K_{+} = \frac{\varrho_{+}}{r_{1}\tau_{+}\tau_{-}},\tag{17c}$$

$$K_{-} = r_1 \varrho_{-}. \tag{17d}$$

Remembering that the mirrors' transmittances are small, so we assume in particular  $T_j = O(\varrho)$ , we have  $r = |r_1r_2|\tau^2 = |r_1r_2| + O(\varrho^2)$ . Expressing  $|r_j| = \sqrt{1 - T_j}$ , we get then

$$r = 1 - \frac{1}{2} (T_1 + T_2) + O(\varrho^2).$$
 (18)

Further, taking into account that  $\arg(K_+) + \arg(K_-) = \pi$ , see (17c), (17d), and (8), we note that

$$K_{+} = \mp \rho \exp\left(\mp i\beta\right) + O(\rho^{2}),\tag{19}$$

where we have defined  $\beta = \arg(r_1) + \arg(\rho_-)$ .

We will denote the slowly varying complex amplitude of  $E_+(L, \mathbf{r}, t)$  by  $A(\mathbf{r}, t)$ , so that  $E_+(L, \mathbf{r}, t) = i\mathcal{V}A(\mathbf{r}, t)\,e^{ik_LL-i\omega_Lt}$ , where  $\mathcal{V} = \sqrt{\hbar\omega_c/4\varepsilon_0L}$  is a suitable factor with dimensions of voltage, chosen in such a way that  $|A(\mathbf{r}, t)|^2$  can be interpreted as the number of photons per unit area which arrive at point  $\mathbf{r}$  of the mirror during a roundtrip, what is convenient to make contact with quantum theory, see the next section. When the expressions (11) of the partial waves are introduced into (10) and all the fields are expressed in terms of the complex amplitude A, we get, shifting time for convenience as  $t \to t + t_c$ ,

$$A(\mathbf{r}, t + t_{c}) - A(\mathbf{r}, t) = \sqrt{T_{1}} \tau_{-} \mathcal{U}_{L} A_{\text{inj}} (0, \mathbf{r}, t + t_{c}/2)$$

$$+ (re^{i\Psi} \mathcal{U}_{2L} - 1) A(\mathbf{r}, t) \qquad (20)$$

$$- \varrho e^{i\Psi} r \mathcal{U}_{L_{2}} e^{-2ik_{L} [\tilde{z}_{0} + Q(\mathbf{r}, t + t_{c} - t_{2})]} \mathcal{U}_{L_{2}} A(\mathbf{r}, t + 2t_{1})$$

$$+ \varrho e^{i\Psi} r \mathcal{U}_{L+L_{1}} e^{2ik_{L} [\tilde{z}_{0} + Q(\mathbf{r}, t + t_{c} + t_{2})]} \mathcal{U}_{L+L_{1}} A(\mathbf{r}, t - 2t_{1}),$$

where we have subtracted  $A(\mathbf{r},t)$  from both sides for convenience, and we have defined

$$\Psi = 2k_{\rm L}L + \theta, \tag{21a}$$

$$\tilde{z}_0 = z_0 + \beta/2k_{\rm L}. \tag{21b}$$

Note that the left hand side of Eq. (20) can be approximated by  $t_c \partial_t A(\mathbf{r}, t)$ , whenever its right hand side is small; more rigorously if it is of the form  $\mathcal{L}A(\mathbf{r},t)$ , with  $\mathcal{L}$  a small operator. Inspection of the equation shows that this is satisfied provided that  $\rho \ll 1$ , as already assumed, and  $e^{i\Psi}r\mathcal{U}_{2L}-1=O\left(\varrho\right)$ . This second condition requires (i)  $\Psi = 2m\pi + \delta$ , with  $m \in \mathbb{Z}$  and  $\delta$  an  $O(\rho)$  normalized detuning whose value is controlled by the injection frequency, see Eq. (21a), and (ii)  $\mathcal{U}_{2L}$  can be approximated as  $1 + i(L/k_L) \nabla_{\perp}^2$ , with the effect of the last term on the order of  $\varrho$ , which is effected by the choice of a sufficiently small value of L (small diffraction). Under these conditions,  $e^{i\Psi}$ , r,  $\mathcal{U}_{L_2}$ , and  $\mathcal{U}_{L+L_1}$  in the last two terms can be approximated by 1 (note that these terms already contain  $\varrho$  as a factor), while  $A(\mathbf{r}, t \pm 2t_1)$  can be set to  $A(\mathbf{r},t)$ , since  $A(\mathbf{r},t\pm 2t_1)\simeq A(\mathbf{r},t)\pm 2t_1\partial_t A(\mathbf{r},t)$ , but  $2t_1 \partial_t A(\mathbf{r},t) < t_c \partial_t A(\mathbf{r},t) = O(\rho)$ . Accordingly Eq. (20) can be approximated as

$$t_{c}\partial_{t}A\left(\mathbf{r},t\right) = A_{0}\left(\mathbf{r},t\right) - \frac{T}{2}A + i\left(\delta + \frac{L}{k_{L}}\nabla_{\perp}^{2}\right)A \quad (22)$$
$$+ \varrho\left[e^{2ik_{L}\left[\tilde{z}_{0} + Q\left(\mathbf{r},t + t_{c} + t_{2}\right)\right]} - e^{-2ik_{L}\left[\tilde{z}_{0} + Q\left(\mathbf{r},t + t_{c} - t_{2}\right)\right]}\right]A,$$

where  $A_0\left(\mathbf{r},t\right) = \tau_-\sqrt{T_1}\mathcal{U}_LA_{\rm inj}\left(0,\mathbf{r},t+t_c/2\right)$  is the injected field at the plane of the right mirror. Note that  $A_0\left(\mathbf{r},t\right) \approx \sqrt{T_1}e^{\mathrm{i}\arg(\tau_-)}A_{\rm inj}\left(0,\mathbf{r},t+t_c/2\right)$ . There remains making a last simplification, consisting in approximating  $Q\left(\mathbf{r},t+t_c\pm t_2\right)$  by  $Q\left(\mathbf{r},t\right)$ . Note that  $Q\left(\mathbf{r},t+t_c\pm t_2\right)\approx Q\left(\mathbf{r},t\right)+(t_c\pm t_2)\,\partial_tQ\left(\mathbf{r},t\right)$ , and we have checked self-consistently that the last term is on the order of  $\varrho$  or smaller in our simulations. This last approximation leads us then to

$$\partial_{t} A\left(\mathbf{r}, t\right) = \frac{1}{t_{c}} A_{0}\left(\mathbf{r}, t\right) - \frac{T}{2t_{c}} A + i\left(\frac{\delta}{t_{c}} + \frac{L}{k_{L}t_{c}} \nabla_{\perp}^{2}\right) A$$
$$+ i\frac{2\varrho}{t_{c}} \sin\left[2k_{L}\left(\tilde{z}_{0} + Q\right)\right] A, \tag{23}$$

which coincides with Eq. (3) of the main text once we introduced the parameters defined there, and the normalized detuning apearing on it is identified with  $2\delta/T$ . In addition, note that in the main text we have chosen  $\beta = -\pi/2$  and  $\arg(\tau_-) = 0$  to simplify the notation and make connection with previous works.

Derivation of the coupling in the mechanical equation. In this section we derive the optomechanical coupling term appearing on the right hand side of the mechanical equation of motion, Eq. (4) in the main text. We show in the following that this is easily done from the coupling term derived for the optical field in the previous section, together with a (momentary) quantum description of the system. In such description, the fields A and Q are replaced by two operators  $\hat{A}$  and  $\hat{Q}$ , obeying standard equal-time commutation relations  $\left[\hat{A}\left(\mathbf{r},t\right),\hat{A}^{\dagger}\left(\mathbf{r}',t\right)\right]=\delta^{2}\left(\mathbf{r}-\mathbf{r}'\right)$  [24]

and  $\left[\hat{Q}\left(\mathbf{r},t\right),\hat{P}\left(\mathbf{r}',t\right)\right]=\mathrm{i}\hbar\delta^{2}\left(\mathbf{r}-\mathbf{r}'\right)$ , with  $\hat{P}=\sigma\partial_{t}\hat{Q}$  the momentum density field of the membrane ( $\sigma$  is its mass surface density). The coupling between the optical and mechanical fields is described in the quantum theory through an interaction Hamiltonian  $\hat{H}_{\mathrm{int}}$ , which contributes to the equation of motion of any operator  $\hat{O}$  according to Heisenberg's equation

$$\partial_t \hat{O}|_{\text{int}} = \frac{\mathrm{i}}{\hbar} \left[ \hat{H}_{\text{int}}, \hat{O} \right].$$
 (24)

Now, from the optical equation that we derived in the previous section, we know that when Eq. (24) is applied to the field  $\hat{A}(\mathbf{r},t)$ , we should get

$$\partial_t \hat{A}(\mathbf{r}, t) \Big|_{\text{int}} = i \frac{2\varrho}{t_c} \sin \left\{ 2k_L \left[ \tilde{z}_0 + \hat{Q}(\mathbf{r}, t) \right] \right\} \hat{A}, \quad (25)$$

and hence the interaction Hamiltonian must have the form

$$\hat{H}_{\text{int}} = -\hbar \int d^2 \mathbf{r} \frac{2\varrho}{t_{\text{c}}} \sin \left\{ 2k_{\text{L}} \left[ \tilde{z}_0 + \hat{Q}(\mathbf{r}, t) \right] \right\}$$
 (26) 
$$\times \hat{A}^{\dagger}(\mathbf{r}, t) \hat{A}(\mathbf{r}, t) .$$

On the other hand, once we know the interaction Hamiltonian, we can particularize the Heisenberg equation (24) to the mechanical momentum density field, obtaining

$$\partial_{t} \hat{P}(\mathbf{r}, t) \Big|_{\text{int}} = \frac{4k_{\text{L}} \varrho}{t_{\text{c}}} \cos \left\{ 2k_{\text{L}} \left[ \tilde{z}_{0} + \hat{Q}(\mathbf{r}, t) \right] \right\} (27)$$
$$\times \hat{A}^{\dagger}(\mathbf{r}, t) \hat{A}(\mathbf{r}, t) ,$$

where we have used the property

$$\left[ F\left(\hat{Q}\left(\mathbf{r}',t\right)\right),\hat{P}\left(\mathbf{r},t\right) \right] = i\hbar \left(\partial F/\partial \hat{Q}\right) \delta^{2}\left(\mathbf{r}-\mathbf{r}'\right), (28)$$

valid for any function F; the classical limit of this expression,  $\{\hat{Q}, \hat{P}, \hat{A}, \hat{A}^{\dagger}\} \rightarrow \{Q, \sigma \partial_t Q, A, A^*\}$ , provides the coupling appearing in Eq. (4) of the main text,

$$\partial_t^2 Q(\mathbf{r}, t) \mid_{\text{int}} = \frac{4\hbar k_{\text{L}} \rho}{\sigma t_{\text{c}}} \cos \left\{ 2k_{\text{L}} \left[ \tilde{z}_0 + Q(\mathbf{r}, t) \right] \right\} |A(\mathbf{r}, t)|^2,$$
(29)

where note that in main text we have taken  $\beta = -\pi/2$  and hence  $2k_{\rm L}\tilde{z}_0 = 2k_{\rm L}z_0 - \pi/2$  for simplicity and definitiness.

Linear and quadratic models and their normalization. Starting from the general model equations (3) and (4) of the main text, in this section we provide a detailed derivation of the quadratic and linear models introduced in Eqs. (5). Consider the interaction terms of Eqs. (3) and (4), which can be written as

$$\partial_t A|_{\text{int}} = -i \frac{4\gamma_c \varrho}{T} \cos\left[2k_{\text{L}} (z_0 + Q)\right] A,$$
 (30a)

$$\partial_t^2 Q|_{\text{int}} = \frac{4\varrho\hbar k_{\text{L}}}{\sigma t_{\text{c}}} \sin\left[2k_{\text{L}}\left(z_0 + Q\right)\right] \left|A\right|^2.$$
 (30b)

Taking into account that the mechanical displacement is typically much smaller than the optical wavelength, we can expand the trigonometric functions around Q=0, obtaining

$$\cos [2k_{\rm L} (z_0 + Q)] \approx \cos(2k_{\rm L} z_0)(1 - k_{\rm L}^2 Q^2)$$
 (31a)  
-  $2k_{\rm L} \sin(2k_{\rm L} z_0) Q$ ,

$$\sin [2k_{\rm L} (z_0 + Q)] \approx \sin (2k_{\rm L} z_0) (1 - k_{\rm L}^2 Q^2)$$
 (31b)  
  $+ 2k_{\rm L} \cos (2k_{\rm L} z_0) Q.$ 

The interaction terms admit then different approximations depending on where the membrane is located. In particular, when  $\cos(2k_{\rm L}z_0)=\pm 1$  and  $\sin(2k_{\rm L}z_0)=0$ , that is,  $z_0/\lambda_{\rm L}=n/4$  with n=0,1,2,..., the sign of the cosine being positive (negative) for even (odd) n, we get

$$\partial_t A|_{\text{int}} \approx \pm i \frac{4\gamma_c \varrho}{T} (k_L^2 Q^2 - 1) A,$$
 (32a)

$$\partial_t^2 Q|_{\text{int}} \approx \pm \frac{8\varrho\hbar k_{\text{L}}^2}{\sigma t_c} Q|A|^2,$$
 (32b)

leading to the model equations

$$\partial_t A = \gamma_c \mathcal{E} + \gamma_c \left( -1 + i\Delta_{\pm} + il_c^2 \nabla_{\perp}^2 \right) A \tag{33a}$$

$$\pm i \frac{4\gamma_{c}k_{L}^{2}\varrho}{T}Q^{2}A,$$

$$\partial_{t}^{2}Q + \gamma_{m}\partial_{t}Q + (\Omega_{m}^{2} - v^{2}\nabla_{\perp}^{2})Q \qquad (33b)$$

$$= \pm \frac{8\varrho\hbar k_{L}^{2}}{\sigma t_{c}}Q|A|^{2},$$

where  $\Delta_{\pm} = \Delta \mp 4\varrho/T$  is a shifted detuning. It is convenient both for the numerical and analytical analysis to introduce the nomalized time  $\tau = \gamma_{\rm c}t$  and spatial coordinates  $\bar{\bf r} = {\bf r}/l_{\rm c}$ , plus variables and parameters

$$\begin{split} Z \; &=\; \sqrt{\frac{8\varrho}{T}} k_{\rm L} Q, \quad F = \sqrt{\frac{8\varrho\hbar k_{\rm L}^2}{\sigma t_{\rm c}\Omega_{\rm m}^2}} A, \\ \gamma \; &=\; \frac{\gamma_{\rm m}}{\gamma_{\rm c}}, \;\; \Omega = \frac{\Omega_{\rm m}}{\gamma_{\rm c}}, \;\; E = \sqrt{\frac{8\varrho\hbar k_{\rm L}^2}{\sigma t_{\rm c}\Omega_{\rm m}^2}} \mathcal{E}, \end{split}$$

which transform the previous equations into

$$\partial_{\tau} F = \left[ -1 + i \left( \Delta + \nabla^2 \pm Z^2 \right) \right] F + E, \tag{34a}$$

$$\partial_{\tau}^{2} Z + \gamma \partial_{\tau} Z + \Omega^{2} \left( 1 - \rho^{2} \nabla^{2} \right) Z = \pm \Omega^{2} Z \left| F \right|^{2}, \quad (34b)$$

where  $\nabla^2 = l_{\rm c}^2 \left(\partial_x^2 + \partial_y^2\right) = \left(\partial_x^2 + \partial_y^2\right)$ , and  $\rho = v/\Omega_{\rm m} l_{\rm c}$  is the 'effective rigidity parameter' defined in the main text. In the case of the positive sign, this is the equation that we introduced in the main text defining the quadratic model, Eqs. (5) with  $\mu = 2$ . The negative sign case is not interesting because no pattern forming instabilities are found, and hence we have not introduced it in the main text.

Let us consider now the case  $\cos(2k_{\rm L}z_0)=0$  and  $\sin(2k_{\rm L}z_0)=\pm 1$ , that is,  $z_0/\lambda_{\rm L}=(2n+1)/8$  with

n=0,1,2,..., the sign of the sine function being positive (negative) for even (odd) n. This choice leads to

$$\partial_t A|_{\text{int}} \approx \pm i \frac{8\gamma_c k_{\text{L}} \varrho}{T} Q A,$$
 (35a)

$$\partial_t^2 Q|_{\text{int}} \approx \pm \frac{4\varrho\hbar k_{\text{L}}}{\sigma t_{\text{c}}} |A|^2,$$
 (35b)

and hence to the model equations

$$\partial_t A = \gamma_c \mathcal{E} + \gamma_c \left( -1 + i\Delta + il_c^2 \nabla_\perp^2 \right) A$$
 (36a)

$$\pm i \frac{8\gamma_{\rm c}k_{\rm L}\varrho}{T}QA,$$

$$\partial_t^2 Q + \gamma_{\rm m} \partial_t Q + (\Omega_{\rm m}^2 - v^2 \nabla_{\perp}^2) Q$$

$$= \pm \frac{4 \varrho \hbar k_{\rm L}}{\sigma t_{\rm c}} |A|^2.$$
(36b)

In this case, the most convenient normalization is the same as before, except for the fields and pump parameter, which are normalized as

$$Z = \pm \frac{8k_{\rm L}\varrho}{T}Q, \quad F = \sqrt{\frac{32\varrho^2\hbar k_{\rm L}^2}{\sigma t_{\rm c}\Omega_{\rm m}^2}}A, \tag{37}$$

$$E = \sqrt{\frac{32\varrho^2\hbar k_{\rm L}^2}{\sigma t_{\rm c}\Omega_{\rm m}^2}}\mathcal{E}.$$

These normalizations transform the previous equations into

$$\partial_{\tau} F = \left[ -1 + i \left( \Delta + \nabla^2 + Z \right) \right] F + E, \tag{38a}$$

$$\partial_{\tau}^{2} Z + \gamma \partial_{\tau} Z + \Omega^{2} \left( 1 - \rho^{2} \nabla^{2} \right) Z = \Omega^{2} \left| F \right|^{2}, \quad (38b)$$

precisely the equation that we introduced in the main text defining the linear model, Eqs. (5) with  $\mu = 1$ .

Details of the linear stability analysis. In the following we explain how we have performed the stability analysis of the homogeneous, stationary solutions associated to the model equations (5), which we gave in the main text. We have followed the standard linear stability analysis, by studying the evolution of small perturbations  $(\delta F, \delta Z)$  added to the steady solution  $(\bar{F}, \bar{Z})$ . Upon linearizing the model equations (5) with respect to  $(\delta F, \delta Z)$ , expressing them in terms of the normal mode basis of the uncoupled mechanical and optical systems (plane waves) as  $\delta F(\mathbf{\bar{r}}, \tau) = \sum_{\mathbf{k}} \phi_{\mathbf{k}}(\tau) e^{i\mathbf{k}\cdot\mathbf{\bar{r}}}$  and  $\delta Z(\mathbf{\bar{r}}, \tau) = \sum_{\mathbf{k}} \zeta_{\mathbf{k}}(\tau) e^{i\mathbf{k}\cdot\mathbf{\bar{r}}}$  (note that  $\zeta_{-\mathbf{k}}^* = \zeta_{\mathbf{k}}$  because  $\delta Z$  is a real field), and equating coefficients of like exponentials, we get, for each  $\mathbf{k}$ , a linear system of differential equations for the modal perturbations  $\mathbf{v} \equiv (\phi_{\mathbf{k}}, \phi_{-\mathbf{k}}^*, \zeta_{\mathbf{k}}).$ Owed to this linearity and the time invariance of the system, its solutions have the form  $\mathbf{v}(\tau) = \mathbf{v}(0) e^{\lambda \tau}$ . Upon making such substitution, a homogeneous linear system of algebraic equations in  $\mathbf{v}(0)$  is got, whose condition for existence of nontrivial solutions can be written as  $C(k^2; \lambda) \equiv \sum_{n=0}^{4} c_n(k^2) \lambda^n = 0$ , where  $k = |\mathbf{k}|$ .

In the case of the linear model and after simple algebra, we get

$$c_4 = 1, \quad c_3 = 2 + \gamma,$$
 (39a)

$$c_2 = 1 + 2\gamma + \Omega_k^2 + \Delta_k^2,$$
 (39b)

$$c_1 = \gamma (1 + \Delta_k^2) + 2\Omega_k^2, \tag{39c}$$

$$c_0 = 2\bar{Z}_{LM}\Delta_k\Omega^2 + (1 + \Delta_k^2)\Omega_k^2, \tag{39d}$$

where  $\Omega_k^2 \equiv \Omega^2 (1 + \rho^2 k^2)$  and  $\Delta_k \equiv \Delta - k^2 + \bar{Z}_{LM}$ . On the other hand, the quadratic model leads to

$$c_4 = c_3 = 0, \quad c_2 = 1, \quad c_1 = \gamma,$$
 (40a)

$$c_0 = \Omega^2 [1 + \rho^2 k^2 - E^2/(1 + \Delta^2)],$$
 (40b)

for the trivial solution ( $\bar{Z}_{QM} = 0$ ), and

$$c_4 = 1, \quad c_3 = 2 + \gamma,$$
 (41a)

$$c_2 = 1 + 2\gamma + \mu_k^2 + \Omega^2 \rho^2 k^2,$$
 (41b)

$$c_1 = \gamma (1 + \mu_k^2) + 2\Omega^2 \rho^2 k^2,$$
 (41c)

$$c_0 = [\rho^2 k^2 (1 + \mu_k^2) + 4\mu_k (\bar{Z}_{OM}^2 - \Delta)]\Omega^2,$$
 (41d)

for the nontrivial solution  $\bar{Z}_{\rm QM}^2 = \sqrt{E^2 - 1}$ , with  $\mu_k = \bar{Z}_{\rm QM}^2 - k^2$ .

We observe that the growth exponents  $\lambda(k^2)$ , solutions to  $C(k^2; \lambda) = 0$ , depend on k and not on k because of the rotational invariance of both the steady state and the model equations. Whenever  $Re\{\lambda\} < 0$  for all k the steady state is stable, while if  $Re\{\lambda\} > 0$  for some k it is unstable. The condition  $Re\{\lambda\} = 0$  thus defines a possible instability, or bifurcation, which is met either when  $\lambda = 0$  (static or pitchfork instability:  $c_0 = 0$ ) or when  $\lambda = i\sqrt{c_1/c_3}$  (self-pulsing or Hopf instability:  $c_1c_2c_3 = c_4c_1^2 + c_3^2c_0$ ). On the other hand, when the bifurcation is associated with k=0 the new state is spatially uniform (homogeneous instability), while if  $k \neq 0$ the instability is pattern forming. In both the linear and quadratic models the expressions for the  $c_n(k^2)$  coefficients are simple enough as to allow us to locate all the static instabilities analytically, while the Hopf instabilities can be efficiently and systematically found numerically, and even analytically in the experimentally relevant limits  $\gamma \ll 1$  and  $\Omega \gg 1$ . We will give further details in future works.

Details of the numerical simulation of the model equations. As explained in the text, we have performed an extensive numerical analysis of the patterns appearing in the model equations (5) of the main Letter, and here we want to say a few words about the method we have used, as well as show some examples of the transverse structures which we have found.

We have performed the numerical simulation of the evolution equations by using a symmetrized split-step Fourier method, whose name comes from the fact that it treats the linear and non-linear terms of the evolution equations separately, alternating them in short time

FIG. 4: Numerical simulation of the linear model equations. In (a) we show the bifurcation diagram for  $\Delta=-2.2, \gamma=0.1,$   $\Omega=10,$  and  $\rho=1.13,$  parameters which we use in this example. The intensity  $\bar{I}$  of the homogeneous steady-state solution is plotted as a function of the injection  $E^2$ , denoting by solid (dashed) lines the stable (unstable) regions. We mark with a yellow square the static pattern-forming instability at  $\bar{I}=\bar{I}_{\rm PB}$ , as well as the rest of instabilities mentioned in the text. Patterns are expected to appear for injections within the unstable domain of the upper branch occurring for  $\bar{I}_+ < \bar{I} < \bar{I}_{\rm PB}$ . We have found two types of patterms: periodic (hexagonal in 2D) patterns (b), whose maximum (as obtained from a 1D simulation) is represented as a yellow dashed-dotted line in their domain of existence; and localized structures (c), represented as a green, dotted line, which can be "written" and "erased" individually at any desired position in the transverse plane by injecting an pulse of Gaussian transverse profile with the proper width and centered at the corresponding point. At  $\bar{I}=\bar{I}_{\rm HB}$  the steady state undergoes a Hopf bifurcation leading to time-dependent long-time term solutions (limit cycles) not shown in the figure.

steps. The linear evolution is computed in the spatial frequency domain by using the fast Fourier transform; as for the evolution coming from the non-linear terms, it turns out that we can solve it exactly at every step for these model equations. The method is exact up to second order in the (normalized) time step, and given that we move to Fourier domain in the spatial variables, it naturally requires periodic boundary conditions in the chosen spatial window (although fixed boundary conditions can be simulated as well, simply by forcing the fields to have the desired values, typically zero, at the boundaries, as we do in the last section).

We have carried simulations of the model equations both in 1D and 2D, finding periodic patterns (which turn out to be hexagons in 2D) and localized structures which satisfy all the properties of cavity solitons (e.g., they can be written and erased individially). In Fig. 4 we show examples of such structures as obtained from the linear model, Eqs. (5) with  $\mu=1$  in the main text. From a numerical point of view, in order to find periodic patterns, the reciprocal spatial lattice which we choose has to contain the wave vectors which form such pattern. In the case of the localized structures, the spatial window has to be large enough to hold the number of solitons which we want to write, as well as allow for their mobility if thats the case.

Details about the numerical simulation of the proposed implementation. In the main text we showed two examples of structures appearing when numerically simulating the quasi-1D implementation explained in the last section, what indeed proves that patterns can be observed with it; let us here give details about the actual parameters used for such simulations, although, as explained in the text, patterns can be easily found wherever they are expected to appear in the

bifurcation diagram.

Let us first remark that in this case we have not assumed the existence of a prior homogeneous mode, that is, we have numerically simulated Eq. (5), but setting to zero the term  $\Omega^2 Z$  in (5b), leading to the equations

$$\partial_{\tau}F = \left[-1 + i\left(\Delta + \nabla^2 + Z^{\mu}\right)\right]F + E,$$
 (42a)

$$\partial_{\tau}^{2}Z + \gamma \partial_{\tau}Z - \Omega^{2}\rho^{2}\nabla^{2}Z = \Omega^{2}Z^{\mu-1} |F|^{2}, \qquad (42b)$$

with  $\mu=1$  or 2 for the linear or quadratic models, respectively. Note that in both sets of equations  $\Omega$  can be eliminated with the change  $\Omega\rho\to\rho,\,\Omega F\to F,\,$  and  $\Omega E\to E,\,$  but we have decided to keep it just so the definition of normalized fields and parameters is the same as in the main text. This equation is supplemented with fixed boundary conditions at the rectangular frame of the membrane, that is,  $Z(\pm \bar{L}_x/2,\bar{y})=0=Z(\bar{x},\pm \bar{L}_y/2),$  which we directly impose in the split-step method. Of course,  $\bar{L}_x$  and  $\bar{L}_y$  are the dimensions of the membrane along the x and y directions, respectively, normalized to the diffraction length  $l_c$ .

In Fig. 2(e) of the main text we show a soliton obtained from the linear model ( $\mu=1$ ), expected to appear wherever bistability is present and the upper branch is unstable because of the static pattern forming bifurcation, see Fig. 2(a). In order to be in this region, we have chosen the following parameters in (42):  $\Omega=10, \ \gamma=0.1, \ \rho=1, \ \Delta=-2.2$ . In addition we have chosen widths  $\bar{L}_y=3.125$  and  $\bar{L}_x=40$  for the membrane, and a quasi-plane injection of finite width given by the supergaussian profile  $E(\bar{\bf r})=E_0\exp[-(\bar{x}^{20}/2\sigma_x^{20})-(\bar{y}^{20}/2\sigma_y^{20})]$ , with  $\sigma_x=7, \ \sigma_y=3$ , and  $E_0=1.45$ . Note that for these choices, the effective 1D parameters become  $\rho_{\rm eff}=3.125/\pi\approx0.995$  and  $\Omega_{\rm m,eff}/\gamma_c=\Omega/\rho_{\rm eff}\approx10.05$ , according to the simple analysis when only the fundamental mode is assumed to

be excited in the y axis.

On the other hand, in Fig. 2(f) of the main text we show a domain wall expected to appear in the quadratic model ( $\mu=2$ ) when the nontrivial homogeneous stationary solutions with opposite signs coexist, see Fig. 2(d). In this case we have simulated equations (42), choosing  $\Omega=\sqrt{0.1}, \gamma=0.1, \rho=1, \Delta=5, \bar{L}_y=6.25$  and  $\bar{L}_x=80$ , and the same kind of supergaussian illumination as be-

fore, but with  $\sigma_x = 7.5$ ,  $\sigma_y = 3$ , and  $E_0 = 6.8$ . These parameters lead to effective 1D ones  $\rho_{\rm eff} = 6.25/\pi \approx 2$  and  $\Omega_{\rm m,eff}/\gamma_{\rm c} = \Omega/\rho_{\rm eff} \approx 0.16$ . Let us remark that we haven't chosen a larger value of  $\Omega$  because otherwise the Hopf bifurcation tends to the point where the trivial and nontrivial solutions connect, making it impossible to find stationary solutions above that point (although it is possible to find dynamic ones, such as pulsing domain walls).
