(Dated: September 18, 2018)

We study continuum percolation problem of overlapping discs with a distribution of radii having a power-law tail; the probability that a given disc has a radius between R and $R + dR$ is proportional to $R^{-(a+1)}$, where $a > 2$. We show that in the low-density non-percolating phase, the two-point function shows a power law decay with distance, even at arbitrarily low densities of the discs, unlike the exponential decay in the usual percolation problem. As in the problem of fluids with long-range interaction, we argue that in our problem, the critical exponents take their short range values for $a > 3 - \eta_{sr}$ whereas they depend on a for $a < 3 - \eta_{sr}$ where η_{sr} is the anomalous dimension for the usual percolation problem. The mean-field regime obtained in the fluid problem corresponds to the fully covered regime, $a \leq 2$, in the percolation problem. We propose an approximate renormalization scheme to determine the correlation length exponent ν and the percolation threshold. We carry out Monte-Carlo simulations and determine the exponent ν as a function of a. The determined values of v show that it is independent of the parameter a for $a > 3 - \eta_{sr}$ and is equal to that for the lattice percolation problem, whereas ν varies with a for $2 < a < 3 - \eta_{sr}$. We also determine the percolation threshold of the system as a function of the parameter a.

I. INTRODUCTION

In problems like effective modeling of random media, the continuum models of percolation are more realistic than their lattice counterparts. So, much effort has been put into the study of such systems in the recent past. In two dimensions, the model systems studied involve discs, squares etc. of the same size or of different sizes [\[1](#page-7-0)[–6](#page-7-1)] and in three dimensions spheres, cubes etc., distributed randomly in space [\[7](#page-7-2)[–11\]](#page-7-3). An interesting sub-class of problems is where the basic percolating units have an unbounded size distribution. These are comparatively less studied, though a few formal results are available [\[12\]](#page-7-4). The problem of disc percolation where discs have bounded sizes has been studied a lot, mainly by simulation [\[2,](#page-7-5) [13,](#page-7-6) [14\]](#page-7-7). For the single sized disc percolation, threshold is known to a very high degree of accuracy [\[13\]](#page-7-6). Also simulation studies have shown that the disc percolation in 2D with discs of bounded size falls in the same universality class as that of lattice percolation in 2D [\[15\]](#page-7-8). For a review of continuum percolation see [\[16\]](#page-7-9).

In this paper we consider continuum percolation model of overlapping discs in 2D where distribution of the radii of the discs has a power-law tail. We address questions like whether the power-law tail in the distribution of radii changes the critical behavior of the system, and how does the percolation threshold depend on the power of the power-law tail. From an application point of view, a power-law polydispersity for an extended range of object sizes is quite common in nature especially for fractal systems [\[17](#page-7-10)]. Disordered systems like carbonate rocks

often contain pores of widely varied sizes covering many decades in length scales [\[18,](#page-7-11) [19](#page-7-12)], whose geometry may be well modeled by a power-law distribution of pore sizes. The power-law distribution of the radii makes our system similar to the Ising or fluid system with long-range interactions. For the latter case, it is known that the long-range nature of the interaction does affect the critical behavior of the system for slow enough decay of the interaction [\[20\]](#page-7-13). For similar results in the context of longrange epidemic processes, see [\[21](#page-7-14)].

The behavior of our model differs from that of the standard continuum percolation model in two aspects. Firstly the entire low density regime in our model shows a power-law decay of the two-point function in contrast to the exponential decay in the standard continuum percolation. Thus the whole low density regime is 'critical'. However, there is a non-zero percolation threshold below which there is no infinite cluster exist in the system. Secondly the critical exponents are functions of the power a of the power-law distribution for low enough a. So while the system belong to the same universality class as the standard continuum percolation for high enough a, the critical behavior is quite different for low values of a.

The plan of this paper is as follows: In section [II,](#page-1-0) we define the model of disc percolation precisely. In section [III,](#page-1-1) using a rigorous lower bound on the two-point correlation function, we show it decays only as a powerlaw with distance for arbitrarily low coverage densities. We discuss the two-point function and critical exponents. In section [IV,](#page-2-0) we propose an approximate renormalization scheme to calculate the correlation length exponent ν and the percolation threshold in such models. In section [V,](#page-4-0) we discuss results from simulation and section [VI](#page-6-0) contains some concluding remarks.

II. DEFINITION OF THE MODEL

We consider a continuum percolation model of overlapping discs in two dimensions. The number density of discs is n , and the probability that any small area element dA has the center of a disc in it is ndA , independent of all other area elements. For each disc, we assign a radius, independently of other discs, from a probability distribution $Prob(R)$. We consider the case when $Prob(R)$ has a power-law tail; the probability of radius being greater than R varies as R^{-a} for large R. For simplicity, we consider the case when radii take only discrete values $R_0 \Lambda^j$ where $j = 0, 1, 2, \dots$, with probabilities $(1 - p)p^j$ where $p = \Lambda^{-a}$. Here R_0 is the size of smallest disc, and Λ is a constant > 1. We call the disc of size $R_0 \Lambda^j$ as the disc of type j.

The fraction of the entire plane which is covered by at least one disc, called the covered area fraction $f_{covered}$, is given by

$$
f_{covered} = 1 - \exp(-A)
$$
 (1)

where A is the areal density - mean area of the discs per unit area of the plane - of the discs, which is finite only for $a > 2$. For $a \leq 2$, in the thermodynamic limit all points of the plane are eventually covered, and $f_{covered} = 1$. If $a > 2$, we have areal density,

$$
A = n\pi R_0^2 (1 - p)/(1 - p\Lambda^2)
$$
 (2)

We define the percolation probability P_{∞} as the probability that a randomly chosen disc belongs to an infinite cluster of overlapping discs. One expects that there is a critical number density n^* such that for $n < n^*$, P_∞ is exactly zero, but $P_{\infty} > 0$, for $n > n^*$. We shall call the phase $n < n^*$ the non-percolating phase, and the phase $n > n^*$ as the percolating phase.

It is easy to show that $n^* < \infty$. We note that for percolation of discs where all discs have the same size R_0 , there is a finite critical number density n_1^* , such that for $n > n_1^*$, $P_\infty > 0$. Then, for the polydisperse case, where all discs have radii R_0 or larger, the percolation probability can only increase, and hence $n^* \leq n_1^*$. Also it has been proved that when ever we have a bounded distribution of radii of the discs, the critical areal density is greater than that for a system with single sized discs [\[22\]](#page-7-15). Our simulation results show that this remains valid for unbounded distribution of radii of the discs.

III. THE NON-PERCOLATING PHASE

We define two point function $Prob(1 \rightsquigarrow 2)$ as the probability that points P_1 and P_2 in the plane are connected by overlapping discs. Then, by rotational invariance of the problem, Prob(1 \rightsquigarrow 2) is only a function of the euclidean distance r_{12} between the two points. Let Prob⁽¹⁾(1 \rightsquigarrow 2) denote the probability that there is at

Figure 1: Points 1 and 2 in the plane at a distance r from each other will be covered by a single disc of radius R , if the center of such a disc falls in the area of intersection of two circles with radius R and centers at 1 and 2.

least one disc that covers both P_1 and P_2 . Then, clearly,

$$
Prob(1 \rightsquigarrow 2) \ge Prob^{(1)}(1 \rightsquigarrow 2). \tag{3}
$$

It is straightforward to estimate $Prob⁽¹⁾(1 \rightsquigarrow 2)$ for our model. Let j be the minimum number such that radius of disc of type j is greater than or equal to r_{12} , i.e. $R_0 \Lambda^j \geq$ r_{12} . Let S be the region of plane such that the distance of any point in S from P_1 or P_2 is less than or equal to $R_0 \Lambda^j$. This region S is greater than or equal to the region where each point is within a distance r_{12} from both P_1 and P_2 . Using elementary geometry, the area of region S is greater than or equal to $(2\pi/3 - \sqrt{3}/4)r_{12}^2$ (See Fig. [1\)](#page-1-2). The number density of discs with radius greater than or equal to $R_0 \Lambda^j$ is $n\Lambda^{-aj}$. Therefore, the probability that there is at least one such disc in the region S is $\frac{1-\exp(-n|S|\Lambda^{-a_j})}{\Gamma}$, where |S| is the area of region S. Thus we get,

$$
\text{Prob}^{(1)}(1 \rightsquigarrow 2) \ge 1 - \exp\left[-nK\Lambda^{-aj}r_{12}^2\right] \tag{4}
$$

where $K = 2\pi/3 - \sqrt{3}/4$.

Now, clearly, $R_0 \Lambda^j \leq r_{12} \Lambda$. Hence we have $\Lambda^{-aj} >$ $r_{12}^{-a}\Lambda^{-a}/R_0^{-a}$. Putting this in Eq. [4,](#page-1-3) we get

$$
Prob^{(1)}(1 \rightsquigarrow 2) \ge 1 - \exp[-nK\Lambda^{-a}r_{12}^{-a+2}] \qquad (5)
$$

where some constant factors have been absorbed into K. For large r_{12} , it is easy to see that this varies as r_{12}^{2-a} . Hence the two-point correlation function is bounded from below by a power-law.

We can extend this calculation, and write the twopoint correlation function as an expansion

$$
Prob(1 \rightsquigarrow 2) = \sum_{n=1}^{\infty} Prob^{(n)}(1 \rightsquigarrow 2)
$$
 (6)

where $\text{Prob}^{(n)}(1 \rightarrow 2)$ is the probability that the path of overlapping discs connecting points P_1 and P_2 requires n discs. The term $n = 2$ corresponds to a more complicated integral over two overlapping discs. But it easy to see that for large r_{12} , this also decays as r_{12}^{-a+2} . Assuming that similar behavior holds for higher order terms as well, we expect that for all non-zero densities n , the twopoint correlation function decays as a power law even for arbitrarily low densities of discs.

We note that this is consistent with the result that for continuum percolation in d dimensions, the diameter of the connected component containing the origin say $\langle D \rangle$ is divergent even for arbitrarily small number densities when $\langle R^{d+1} \rangle$ is divergent [\[12\]](#page-7-4). Here R denote the radii variable. In our case $\langle D \rangle = \int r_{12} \frac{dProb(r_{12})}{dr_{12}}$ $\frac{d\sigma(\frac{r}{12})}{dr_{12}}dr_{12} \sim$ $\int r_{12}^{2-a} dr_{12}$ (where P_1 is the origin) is divergent when $a \leq 3$, consistent with the above.

The power-law decay of the two-point function is the result of the fact that for any distance r , we have discs of radii of the order of r . However for large values of r , we can imagine that there would also be a contribution from a large number of overlapping discs of radii much smaller than r connecting the two points separated by the distance r , which as in the usual percolation problem decays exponentially with distance. Therefore it is reasonable to write the two point function in our problem as a sum of two parts; the first part say $G_{sr}(r)$ due to the 'short range' connections which has an exponential decay with distance for large r and the second one say $G_{lr}(r)$ due to the 'long range' connections which has a power law decay with distance. Therefore,

$$
G(r) = G_{sr}(r) + G_{lr}(r)
$$
\n⁽⁷⁾

where

$$
G_{lr}(r) \sim D(A)/r^{a-2} + higher\ order\ terms
$$
 (8)

where $D(A)$ is assumed to go to a non-zero constant as A goes to its critical value and its dependence on A is a slowly varying one.

The power-law distribution of the radii, makes this system similar to a long range interaction problem in statistical physics in the sense that given two points in the plane, a direct connection by a single disc overlapping both the points is possible. In fact similar behavior for the two-point function exists whenever we have long range interactions in a system, such as in Ising model with long range potentials or fluid with long range interactions [\[23,](#page-7-16) [24\]](#page-7-17). In such systems, the two-point function shows a power-law decay just as in our problem [\[25](#page-7-18)]. The effect of such long range potentials on the critical exponents have been studied earlier [\[20,](#page-7-13) [23](#page-7-16), [26–](#page-7-19)[29\]](#page-7-20) with the general conclusion that the long range part of the interaction do influence the critical behavior of the system [\[30\]](#page-7-21). More precisely, if we have an attractive pair potential in d dimensions of the form $-\phi(r) \sim \frac{1}{r^{d+1}}$ $\frac{1}{r^{d+\sigma}}$ where

 $\sigma > 0$, then critical exponents take their short-range values for all $\sigma \geq 2 - \eta_{sr}$ where η_{sr} is the anomalous dimension (For the 'short range' problem in 2D, at criticality, the two point function decays with distance as $1/r^{\eta_{sr}}$). For $\sigma < 2 - \eta_{sr}$, two kinds of behavior exist. For $0 < \sigma \leq d/2$, the exponents take their mean-field values and for $d/2 < \sigma < 2 - \eta_{sr}$, the exponents depend on the value of σ (See [\[20\]](#page-7-13) and references therein). So $\sigma = 2 - \eta_{sr}$ is the dividing line between the region dominated by short range interactions and the region dominated by long-range interactions.

Though there is a well established connection between the lattice percolation problem and the Ising model [\[31\]](#page-7-22), there is no similar result connecting the continuum percolation problem to any simple Hamiltonian system. However, the following simple argument provide us with a prediction about the values of the parameter a for which the power-law nature of the distribution is irrelevant and the system is similar to a continuum percolation system with a bounded size distribution for the percolating units. Assuming that the strength of the long range interaction from a given point in the Ising/fluid system (which decays like $\sim \frac{1}{r^{2+}}$ $\frac{1}{r^{2+\sigma}}$ in 2D) is like the strength of the connectivity from the center of a given disc which is given by the distribution of the radii; in our problem, we expect the dividing line between the region dominated by short-range connectivity and the region dominated by long-range connectivity to be the same as that for an Ising system with long range potential of the form $-\phi(r) \sim \frac{1}{r^{a+1}}$ $\frac{1}{r^{a+1}}$ where $a > 2$. Then the results for the long-range Ising system discussed in the last paragraph should carry over with $\sigma = a-1$. So for our problem, a deviation from the standard critical behavior is expected when $a < 3 - \eta_{sr}$ and the critical exponents will take their short-range values for $a > 3-\eta_{sr}$. For 2D percolation, $\eta_{sr} = 5/24$ [\[32](#page-7-23)]. Also mean-field behavior is expected when $a \leq 2$. However for this range of a, the entire plane is covered for all non-zero number densities and hence there is no phase transition.

In the next two sections, we investigate for the dependence of exponents on the power-law tail of the distribution of the radii of the discs. First we develop an approximate RG method. Then we carry out simulation studies which show that the correlation length exponent ν takes its short range value for $a > 3 - \eta_{sr}$, while it depends upon a for $a < 3 - \eta_{sr}$.

IV. CRITICAL BEHAVIOR NEAR THE PERCOLATION THRESHOLD

In this section, we propose an approximate RG method to analyze the behavior of continuum percolation models near the percolation threshold, when the percolating units have a distribution of sizes. We assume that we can replace discs of one size having a number density n with discs of another size and number density n' , provided the correlation length remains the same. Application of a similar idea in disc percolation problem with only two sizes of discs may be found in [\[5\]](#page-7-24).

We will illustrate the method by considering a problem in which the radii of discs take only two possible values, say R_1 and R_2 . Let their areal densities be A_1 and A_2 respectively, and assume that both A_1 and A_2 are below A[∗] , the critical threshold for the percolation problem with only single sized discs present ($A^* \approx 1.128085$ [\[13\]](#page-7-6)). Also let ξ_1 represent the correlation length when only discs of size R_1 are present in the system and ξ_2 represent that when only discs of size R_2 are present. Invariance of the two point function under length rescaling requires that the expression for the correlation length ξ is of the form $\xi = Rg(A)$, where the function $g(A)$ determines how the correlation length depends on the areal density A and is independent of the radius R. Let \tilde{A}_2 is the areal density of the discs of size R_2 which will give the same correlation length as the discs of size R_1 . i.e,

$$
\xi_1(A_1) = \xi_2\left(\tilde{A}_2\right) \tag{9}
$$

or

$$
R_1 g\left(A_1\right) = R_2 g\left(\tilde{A}_2\right) \tag{10}
$$

Given the form of the function $g(A)$, we can invert the above equation to find \tilde{A}_2 . Formally,

$$
\tilde{A}_2 = g^{-1} \left(\frac{R_1}{R_2} g(A_1) \right) \tag{11}
$$

So the problem is reduced to one in which only discs of size R_2 are present, whose net areal density is now given by,

$$
A_2' = \tilde{A}_2 + A_2 \tag{12}
$$

System percolates when $A'_2 = A^*$. Now, when areal density A is close to A^* , we have

$$
g(A) = C (A^* - A)^{-\nu}
$$
 (13)

where C is some constant independent of A and ν is the correlation-length exponent in the usual percolation problem. Using this in Eq. [11,](#page-3-0) we get

$$
\tilde{A}_2 = A^* - (A^* - A_1) (R_2/R_1)^{1/\nu}
$$
 (14)

Therefore, for a given value of $A_1 < A^*$, the areal density of discs of radius R_2 , so that the system becomes critical is given by,

$$
A_2 = A^* - \tilde{A}_2
$$

= $(A^* - A_1) (R_2/R_1)^{1/\nu}$ (15)

So the total areal density at the percolation threshold is,

$$
A_1 + A_2 = A_1 + (A^* - A_1) (R_2/R_1)^{1/\nu}
$$

= $A_1(1-x) + A^*x$

Figure 2: Variation of ε_m with m for different values of ρ_0 showing sub critical and supercritical regimes. We have used $a = 3$ and $\Lambda = 2$.

where $x = (R_2/R_1)^{1/\nu}$. Without loss of generality we may assume $R_2 > R_1$. Then $x > 1$ and we can see from the above expression that the percolation threshold $A_1 + A_2 > A^*$, a result well known from both theoretical studies [\[22](#page-7-15)] and simulation studies [\[13\]](#page-7-6).

Now in our problem assume that areal density of discs of type 0 do not exceed A^* . Renormalizing discs up to type m in our problem gives the equation for the effective areal density of the m -th type discs A'_m as

$$
A'_{m} = A^{*} - (A^{*} - A'_{m-1}) \Lambda^{1/\nu} + \rho_{m}
$$
 (16)

where $m \geq 1$, $A'_0 = \rho_0$ and $\rho_m = n_0 \pi \Lambda^{(2-a)m}$ denote the areal density of discs of radius Λ^m . Here n_0 is the number density of discs of radius R_0 (or of type 0), which for convenience we have set equal to unity. If we denote $A^* - A'_m$ by ε_m which is the distance from the criticality after m-th step of the renormalization, then the above expression becomes

$$
\varepsilon_m = \varepsilon_{m-1} \Lambda^{1/\nu} - \rho_m \tag{17}
$$

The equation describes the flow near the critical point when we start with a value of ρ_0 , the areal density of the first type of discs. Here ε_m gives the effective distance from criticality of the m-th order discs in the system, in which now only m-th and higher order discs are present. Now for given values of the parameters a and Λ , we can evaluate ε_m in Eq. [17](#page-3-1) using a computer program and plot ε_m verses m. Depending upon the value of ρ_0 , we get three different behaviors. For value of ρ_0 below the critical value denoted by ρ_0^* , ε_m will go to A^* asymptotically (System is sub critical) and when it is above ρ_0^* , ε_m will go to $-\infty$ asymptotically (System is super critical). As $\rho_0 \to \rho_0^*$, we get the critical behavior characterized by ε_m tending to the RG fixed point 0 asymptotically. Typ-ical result using Eq [17](#page-3-1) with $\Lambda = 2$ and $a = 3$ is shown

in Fig [2.](#page-3-2) We can see that as we tune ρ_0 , the system approaches criticality, staying closer to the $\varepsilon_m = 0$ line longer and longer. Critical behavior here can be characterized by the value of m at which the curve deviates from the approach to $\varepsilon_m = 0$ line. To understand how the correlation length diverges as we approach criticality, we assume that we can replace the sub critical system with a system where only discs of type m' is present and has a fixed areal density below A^* , where m' is the value of m at which ε_m shows a substantial increase - say ε_m becomes $A^*/2$. For continuum percolation problem with single sized discs, the correlation length $\xi = Rg(A)$, where $g(A)$ is a function with no explicit dependence on radius R. Therefore, correlation length in our problem,

$$
\xi \propto \Lambda^{m'} \tag{18}
$$

We can write the recurrence relation $Eq.(17)$ $Eq.(17)$ in terms of the areal density ρ_n as

$$
\varepsilon_m = A^* \Lambda^{\frac{m}{\nu}} - \sum_{n=0}^m \rho_n \Lambda^{\left[\frac{m-n}{\nu}\right]}
$$
 (19)

But $\rho_n = \rho_0 \Lambda^{n(2-a)}$. Therefore,

$$
\varepsilon_m = A^* \Lambda^{\left[\frac{m}{\nu}\right]} - \frac{\rho_0 \Lambda^{\left[\frac{m}{\nu}\right]} \left[1 - \Lambda^{m(2-a-1/\nu)}\right]}{\left[1 - \Lambda^{(2-a-1/\nu)}\right]} \tag{20}
$$

For large values of m , the last term in the above equation involving $\Lambda^{m(2-a-1/\nu)}$ can be neglected. Then,

$$
\varepsilon_m = \Lambda^{\left[\frac{m}{\nu}\right]} \left[A^* - \frac{\rho_0}{1 - \Lambda^{(2 - a - 1/\nu)}} \right] \tag{21}
$$

Therefore,

$$
\Lambda^{\left[\frac{m}{\nu}\right]} = \frac{\varepsilon_m}{\left[A^* - \frac{\rho_0}{1 - \Lambda^{(2 - a - 1/\nu)}}\right]}
$$
(22)

For a given value of $\rho_0 \leq A^*$, the order m' at which ε_m is increased substantially, say to a value $A^*/2$ is given by

$$
m' = \left[\log_{\Lambda} (A^*/2) - \log_{\Lambda} (\rho_0^* - \rho_0) \right]
$$

$$
+ \log_{\Lambda} \left(1 - \Lambda^{(2-a-1/\nu)}\right) \nu
$$
(23)

So for ρ_0 close to ρ_0^* and large values of a,

$$
m' \sim \log_{\Lambda} (\rho_0^* - \rho_0)^{-\nu} . \tag{24}
$$

so that

$$
\xi \propto \left(\rho_0^* - \rho_0\right)^{-\nu} \tag{25}
$$

Thus we find that the correlation length exponent ν is independent of the parameters α and Λ of the distribution. From Eq. [22,](#page-4-1) we can also obtain the percolation threshold $ρ_0^*$ as a function of the parameters a and Λ. In Eq. [22](#page-4-1) left hand side is positive definite. So for values

of ρ_0 for which $\frac{\rho_0}{1-\Lambda(2-a-1/\nu)} < A^*$, we will have $\varepsilon_m > 0$ for large values of m. Similarly for values of ρ_0 for which $\frac{\rho_0}{1-\Lambda^{(2-a-1/\nu)}} > A^*$, we will have $\varepsilon_m < 0$ for large values of m. Hence the critical areal density ρ_0^* must be given by

$$
\rho_0^* = A^* \left[1 - \Lambda^{(2-a-1/\nu)} \right] \tag{26}
$$

Or in terms of the total number density, the percolation threshold n^* is given by,

$$
n^* = n_c \left(1 - \Lambda^{(2-a-1/\nu)} \right) / \left(1 - \Lambda^{-a} \right) \tag{27}
$$

where $n_c = A^*/\pi$, the critical number density for percolation with single sized discs of unit radius. Note that this approximate result does not give the correct limit, $n^* \to 0$ as $a \to 2$. The RG scheme depends on the approximation that the effect of size R_1 of areal density A_1 is the same as that of discs of radius R_2 of density A_2 , as in Eq. [9.](#page-3-3) This is apparently good only for $a > 3 - \eta_{sr}$. Fig. [3](#page-5-0) shows the variation of the critical threshold with a for two different values of Λ using Eq. [27](#page-4-2) along with simulation results (See section [V](#page-4-0) for details of simulation studies). We see that a reasonable agreement is obtained between the two for higher values of a. Also, as one would expect, for large values of a, n^* tends to n_c .

From Eq. [27,](#page-4-2) we can obtain the asymptotic behavior of the critical number density n^* as $\Lambda \rightarrow 1$. This is useful since it corresponds to the threshold for a continuous distribution of radii with a power-law tail and we no more have to consider the additional discretization parameter Λ. It is easy to see that in the limit $Λ \rightarrow 1$, Eq. [27](#page-4-2) becomes

$$
n_{\Lambda \to 1}^* = n_c \left(1 - \frac{5}{4a} \right) \tag{28}
$$

where we have used the value $\nu = 4/3$. Thus we expect that a log-log plot of $(n_c - n_{\Lambda \to 1}^*)$ against a will be a straight line with slope -1 and y-intercept $\log(5n_c/4) \approx$ -0.35 for large values of a. A comparison with the thresholds obtained from simulation studies show that Eq. [28](#page-4-3) indeed predicts the asymptotic behavior correctly (See Fig. [7\)](#page-6-1).

V. SIMULATION RESULTS

We determine the exponent ν and the percolation threshold n^* by simulating the continuum percolation system in 2D, with discs having a power law distribution for their radii. We consider two cases for the distribution of the radii variable. To explicitly compare the prediction of the approximate RG scheme for the percolation threshold given in section [IV,](#page-2-0) we use a discrete distribution for the radii variable, with discretization factor Λ as in section [II.](#page-1-0) The results for the thresholds thus obtained

Figure 3: Variation of n^* with a for two different values of Λ. Dashed curves correspond to values given by Eq. [27](#page-4-2) and continuous ones correspond to those from simulation studies. The horizontal line corresponds to the threshold for the single sized discs case.

is shown in Fig. [3.](#page-5-0) To determine the correlation length exponent ν , we consider the radii distribution in the limiting case $\Lambda \to 1$, so that we do not have to consider the additional parameter Λ . In this case, given a disc, the probability that it has a radius between R and $R + dR$ is equal to $aR^{-(a+1)}$ where $a > 2$. We also obtain the percolation threshold with this continuous distribution for the radii and compare it with the predicted asymptotic behavior in Eq. [28.](#page-4-3) The minimum radius is assumed to be unity.

For $a \leq 2$ the entire plane is covered for arbitrarily low densities of the discs. We use cyclic boundary conditions and consider the system as percolating whenever it has a path through the discs from the left to the right boundary. We drop discs one at a time on to a region of a plane of size $L \times L$, each time checking whether the system has formed a spanning cluster or not. Thus number density is increased in steps of $1/L^2$. So after dropping the $n-th$ disc, the number density is n/L^2 . Now associated with each number density we have a counter say f_n which is initialized to 0 in the beginning. If the system is found to span after dropping the n' -th disc, then all counters for $n \geq n'$ is incremented by one. After a spanning cluster is formed, we stop. By this way we can determine the spanning probability $\Pi(n,L) = f_n/N$ where N is the number of realizations sampled. The number of realizations sampled varies from a maximum of 2.75×10^7 for $a = 2.05$ and $L = 90$ to a minimum of 4000 for $a = 10.0$ and $L = 1020$ [For obtaining the results for the threshold in Fig. [3,](#page-5-0) the number of realizations sampled is 20000 for all values of a and Λ . This method of dropping basic percolating units one by one until the spanning cluster is formed has been used before [\[33\]](#page-7-25) in the context of stick percolation which was based on the algorithm developed in [\[34\]](#page-7-26), and allows us to study relatively large system sizes with large number of realizations within reasonable time.

The probability that there is at least a single disc which span the system of size L at number density n is $1 \exp^{(-n2^a/L^{a-2})}$. It is easy to see that to leading order in n , this 'long range' part of the spanning probability $\Pi(n,L)_{lr}$ is $\frac{n2^a}{L}$ $\frac{1}{L^{a-2}}$. So one can write a scaling form for the spanning probability,

$$
\Pi(n, L) = \Pi(n, L)_{lr} + (1 - \Pi(n, L)_{lr})\phi((n^* - n)L^{1/\nu})
$$
\n(29)

Therefore we can define the 'short range' part of the spanning probability $\Pi'(n,L) = (H(n,L) \Pi(n,L)_{lr}/(1-\Pi(n,L)_{lr})$ where the leading long range part is subtracted out. Therefore, we have

$$
\Pi'(n, L) = \phi((n^* - n)L^{1/\nu})
$$
\n(30)

and the scaling relations, (See for eg. [\[35\]](#page-7-27))

$$
\Delta(L) \propto L^{-1/\nu} \tag{31}
$$

$$
n_{eff}^*(L) - n^* \propto \Delta \tag{32}
$$

where $n_{eff}^*(L)$ is a suitable defined effective percolation threshold for the system of size L, and Δ is the width of the percolation transition obtained from the spanning probability curves $\Pi'(n,L)$. Note that Eqs. [31](#page-5-1) and [32](#page-5-2) are applicable with any consistent definition of the effective percolation threshold and width Δ [\[35](#page-7-27)]. A good way to obtain n_{eff}^* and Δ is to fit the sigmoidal shaped curves of the spanning probability $\Pi'(n,L)$ with the function $1/2[1+erf[(n-n[*]_{eff}(L))/\Delta(L)]]$ (see [\[14\]](#page-7-7)), which defines the effective percolation threshold n_{eff}^* as the number density at which the spanning probability is $1/2$. We determined n_{eff}^* and Δ for each value of a and L and determined $1/\nu$ and n^* for different values of a using Eqs. [31](#page-5-1) and [32](#page-5-2) respectively. Typical examples are shown in fig. [4](#page-6-2) and Fig. [5.](#page-6-3)

At first, we determined the percolation threshold and the exponent for a system of single sized discs of unit radius. We obtained $n^* = .3589(\pm .0001)$ (or areal density ≈ 1.12752) and $1/\nu = .758(\pm .018)$ in very good agreement with the known value for the threshold [\[13\]](#page-7-6) and the conjectured value of $1/\nu = 3/4$ for the exponent. Values of $1/\nu$ obtained for various values of a are shown in fig[.6.](#page-6-4) We scan the low a regime more closely for any variation from the standard answer. We can see that the estimates for $1/\nu$ are very much in line with the standard percolation value for $a > 3 - \eta_{sr}$ while it varies with a for $a < 3-\eta_{sr}$. Fig. [7](#page-6-1) shows the variation of the percolation threshold n^* with a. As expected, with increasing a, the percolation threshold increases and tends to the single sized disc value as $a \to \infty$, and as $a \to 2$, the threshold tends to zero. The data also shows that n^* converges to the threshold for the single sized disc value as $1/a$ as predicted by Eq. [28.](#page-4-3) Values of the threshold for some values of a are given in Table [I.](#page-6-5)

Figure 4: Plot of effective percolation threshold n_{eff}^* against Δ for $a = 2.25$ and $a = 3.25$. The best straight line fit is obtained with the last four data points.

Figure 5: Log-Log plot of Δ Vs L for $a = 2.25$ and $a = 4.0$ along with lines of slope −.47 and −.75.

Figure 6: Variation of $1/\nu$ with a. The horizontal line corresponds to the standard 2D percolation value $1/\nu = 3/4$.

Figure 7: Variation of percolation threshold n^* with a. The horizontal line corresponds to the threshold for the single sized discs case. (Inset) Asymptotic approach of n^* to the single sized discs value $n_c = .3591$ along with a straight line of slope −1 and y-intercept −0.35 (See Eq. [28\)](#page-4-3).

Table I: Percolation threshold n^* for a few values of a along with corresponding critical areal density η^* and the critical covered area fraction ϕ^* .

Finally as a check, we plot the spanning probability $\Pi'(n,L)$ (see Eq. [30\)](#page-5-3) against $(n-n^*)L^{1/\nu}$ to be sure that a good scaling collapse is obtained. We show two such plots for $a = 2.50$ and $a = 4$ in fig. [8.](#page-7-28) We can see that a very good collapse is obtained. Similar good collapse is obtained for other values of a as well.

VI. CONCLUDING REMARKS

In this paper, we discuss the effect of a power-law distribution of the radii on the critical behavior of a disc percolation system. If the distribution of radii is bounded, then one would expect the critical exponents to be unchanged and would be the same as that for standard percolation. However, if the distribution of radii has a power-law tail, we show that this strongly influence the nature of the phase transition. The whole of the lowdensity non-percolating phase has power-law decay of correlations in contrast to the exponential decay for the

Figure 8: Variation of $\Pi(n,L)$ with n (top row) and the scaling collapse (bottom row) for $a = 2.50$ (on left) and $a = 4.00$ (on right).

standard percolation and this occurs for any value of the power a, howsoever large. The critical exponents depend on the value of a for $a < 3-\eta_{sr}$ and take their short-range

values for $a > 3 - \eta_{sr}$. We also propose an approximate RG scheme to analyse such systems. Using this, we compute the correlation-length exponent and the percolation threshold. The approximate RG scheme is good only for $a > 3 - \eta_{sr}$. Monte-Carlo simulation results for the percolation thresholds and the correlation-length exponent are presented.

We can easily extend the discussion to higher dimensions, or other shapes of objects. It is easy to see that the power law correlations will exist in corresponding problems in higher dimensions as well.
