22 Abstract:

Extracting the sequence information of DNA from the blocked ionic current is the 23 crucial step of the ionic current-based nanopore sequencing approaches. The thinnest 24 25 graphene nanopore, which contained only one layer of carbon atoms, potentially has ultra-high DNA sequencing sensitivity. However, the dynamical translocation 26 information of DNA contained in the blocked ionic current has not been well 27 understood to date. In this letter, an assessment to the sensitivity of ionic 28 current-based graphene nanopore DNA sensing approach was carried out using 29 molecular dynamics simulations. By filtering the molecular thermal motion induced 30 noise of ionic current, we found that the instantaneous conformational variations of 31 DNA in graphene nanopore could be revealed from the fluctuations of the denoised 32 ionic current. However, the blockage of ionic current which induced by the proximity 33 of the DNA base-pairs to the nanopore (within 1.5 nm) was also observed. Although 34 the expected single-base resolution of graphene nanopore should be enhanced by 35 further studies, our findings indicated that the ionic current-based graphene nanopore 36 sensing approach has high sensitivity to the instantaneous translocation status of 37 38 DNA. 39 40 41 42 43 44 45 Keywords: graphene nanopore, molecular dynamics simulation, biosensors, DNA 46

- 47 sequencing, noise of ionic current, translocation status of DNA
 - 48

Nanopore sequencing is a new technology promising to directly read out the gene 49 information of DNA at single-molecule level.^{1, 2} The center stage of nanopore 50 sequencing is to distinguish the signals of different kinds of bases of DNA through a 51 nanopore.³⁻⁹ The subnanometer thickness (0.34 nm) of graphene sheet comparable to 52 the spatial interval of DNA nucleotide suggests that the nanopore sequencing at 53 single-base level could be realized utilizing a graphene nanopore.^{4, 10} Based on 54 graphene nanopores created experimentally,¹¹ the translocation of double-stranded 55 DNA (dsDNA) through monolayer and/or multilayer graphene nanopores has been 56 recently demonstrated.⁵⁻⁷ In these experiments, the fluctuation of blocked ionic 57 current was observed, explained as the difference induced by folded/unfolded DNA or 58 the unzipping of DNA chains.⁵⁻⁷ Thanks to the atomic level molecular dynamics (MD) 59 simulation technology, the subtle structural features of DNA and the graphene-DNA 60 interactions during translocation could be further revealed. In 2011, Schulten et al. 61 observed the difference of ionic current blockages which induced by the 62 folded/unfolded DNA, and suggested that under suitable bias conditions A-T and G-C 63 base-pairs can be discriminated using graphene nanopores.¹² Recently, Aksimentiev et 64 al. reported that the translocation of single-stranded DNA (ssDNA) through graphene 65 nanopores might occur in single nucleotide steps,¹³ similar with the biologic 66 nanopores. However, the sensitivity of ionic current blockades to the orientations of 67 nucleotides in graphene nanopore has also been observed.^{13, 14} 68

Actually, ionic current-based nanopore sensing relies on ions through a nanopore 69 which contribute to both the signal and the noise.¹⁵⁻¹⁹ In particular, the membrane 70 capacitance produces noise fluctuations that increase with the bandwidths of 71 measurement,³ and the noise of ionic current in membrane-like graphene nanopore 72 was distinctly huger than that in the channel-like synthetic nanopore.^{12, 20} To reduce 73 the electrical noise of graphene nanopore, a stacked graphene-Al₂O₃ nanopore was 74 constructed and the temporal resolution of DNA and/or DNA-protein complexes 75 detection was significantly improved recently.²¹ Based on the differences of ionic 76 current, researchers found that the translocation of DNA in nanopores usually 77 accompanied with the deformation of DNA.^{12, 20, 22-24} Due to the atomic thickness of 78

79 graphene, the graphene nanopore sensors might have ultra-high sensitivity to the 80 instantaneous translocation statues of DNA. However, the translocation information 81 of DNA contained in the fluctuation of blocked ionic current has not been well 82 understood to date.

Therefore, a systematic MD simulation study was presented in this letter, to explore 83 84 the sensitivity of ionic current to the instantaneous translocation statuses of DNA within graphene nanopore. Before we extract the translocation information of DNA 85 from ionic current, the ionic current measurement itself $(I(t) = \{\sum_{i=1}^{N} q_i | z_i(t + t)\}$ 86 Δt) – $z_i(t)$]/ ΔtLz) was assessed by investigating the fluctuation (root-mean-square, 87 RMS) dependencies of ionic current to the measure interval $(\Delta t)^{16, 20}$, simulation 88 temperature and bias voltage. By monitoring the variations of local conformation, 89 in-pore translocation velocity and graphene-DNA interaction of DNA within graphene 90 nanopore, how the conformational, dynamical and interactional information of in-pore 91 DNA revealed from the fluctuation of ionic current signal were presented. We found 92 that 1) the synchronous change of the number of atoms of DNA accumulated in 93 94 graphene nanopore and the blockage of ionic current was directly showed after the thermal noise of ionic current has been filtered; 2) the blockage of ionic current could 95 also be induced by the proximity of DNA base-pairs to the nanopore. To the best of 96 our knowledge, it should be the first reported result dynamically shows the high 97 sensitivity of graphene nanopore to the instantaneous translocation statuses of in-pore 98 99 DNA.

As shown in Figure 1a, the interactions among ions, water molecules and graphene 100 directly impact the motion of the charge carriers (ions) in NaCl solution.²⁵ Therefore 101 the impact of measurement frequency $(1/\Delta t)$ to the fluctuation of open-pore ionic 102 current was investigated with different temperatures (280K, 300K and 320K), bias 103 voltages (0V and 1V), graphene models (flexible and rigid) and cell dimensions (10 104 nm and 20 nm in z-direction). The obtained average (AVG) and fluctuation 105 (root-mean-square, RMS) of ionic currents were plotted as function of the measure 106 frequency $(1/\Delta t)$ in Figure 1b-d. If no external bias voltage was applied (0V, 300K), 107 the average ionic current was maintained in zero because no directional movement of 108

ions was occurred in the system. While the fluctuation of ionic current was increased 109 with the rise of measure frequency linearly, indicating that the molecular thermal 110 motion (no bias voltage) induced Johnson-Nyquist (thermal) noise of ionic current 111 was sensitive to the choice of measure frequency. After the bias voltage (1V, 300K) 112 was applied, the fluctuation of the ionic current was even higher than the average 113 ionic current (8 nA) when Δt was shorter than 4 ps (250 GHz), and it was 114 undistinguishable with net thermal noise (0V, 300K). With the decrease of measure 115 116 frequency, the fluctuation of ionic current was reduced, but it still obviously greater than net thermal noise, suggesting that the bias voltage could also induce the 117 enhancement of the noise of ionic current.¹⁵ Comparing the results of different 118 simulation temperatures (280K, 300K and 320K), the temperature sensitivity of both 119 average and fluctuation of ionic current were distinctly presented (Figure 1b), 120 suggesting that in a certain bias voltage the temperature determined molecular thermal 121 motion contributes significantly to the ionic current. Although the ions would also 122 accumulate on the surface of graphene nanopore for the oppression of applied electric 123 field,^{12, 25} but the impact of the shaking of carbon atoms at graphene nanopore edge 124 (Figure S2) to the fluctuation of ionic current (Figure 1c) was not as obvious as the 125 influence of temperature (Figure 1b). By the way, similar with the reported study for 126 biologic nanopore (α -Hemolysin),²⁶ the average ionic current could maintain steady 127 only if the time interval of measurements were shorter than 50 ps (> 20 GHz). The 128 abnormal drop of average ionic current might result from the periodic boundary 129 condition (PBC) employed in MD simulations, because it has been effectively 130 alleviated (Figure 1d) by using a bigger simulation cell (20 nm in z-direction). These 131 findings suggest that the "signal-to-noise" ratio could be improved by modulating the 132 measure frequency, analogous to the experimental and theoretical results that the 133 thermal noise of ionic current increases with the bandwidth of a detector. ^{16, 18, 24-26} 134

Based on above discussions, the measure interval of ionic current in the following studies was chose as 50 ps to ensure the "signal-to-noise" ratio > 5 (Figure 1d). The microscopic kinetics of a dsDNA chain (d-poly(CAGT)₄₈) electrophoretically passing through a 2.4 nm monolayer graphene nanopore were investigated based on 6 sections

of MD simulations (indexes 10-15 in Table S1). As shown in Figure 2a, the original 139 ionic current signals (grey lines) were further denoised with a FFT filter (cutoff 140 frequency was 10GHz) to remove the impact of the thermal noise (red lines). 141 Therefore, the presentation ability of ionic current to the instantaneous translocation 142 statues of DNA in graphene nanopore was improved (blue lines). The profiles of the 143 denoised ionic current (blue lines) were extremely different in the repeat MD 144 simulations (R1, R2 and R3), suggesting that the translation statuses of DNA in 145 146 graphene nanopore might be different in these simulations. To capture the instantaneous dynamical information of DNA in graphene nanopore, the in-pore 147 translocation velocity of DNA was monitored: 148

149
$$V(t) = \frac{1}{N(t)\Delta t} \sum_{i=1}^{N(t)} [z_i(t + \Delta t) - z_i(t)]$$
(1)

Namely, the in-pore velocity of DNA was defined as that within time interval of Δt the 150 displacement of the part of DNA located in graphene nanopore with a length of ΔZ ; 151 N(t) represents the number of atoms of in-pore DNA at time point of t. The ΔZ was 152 chose as 1 nm in calculation. As shown in panels of [1V, R1], [1V, R2], [2V, R1] and 153 154 [2V, R2] in Figure 2b, although the bias voltage used in the calculations were 10 times higher than that in experiments,^{1, 5, 6, 12} the translocation velocities of in-pore DNA 155 were fluctuated around 2 mm/ms (5.5 kbp/ms) and around 3 mm/ms (8.5 kbp/ms) in 156 most of the translocation time for 1 V and 2 V bias voltages, respectively. The 157 translocation velocities of DNA in these simulations seem to be comparable with that 158 of DNA which obtained experimentally using solid-state nanopores.²⁷⁻³⁰ While there 159 also were some unpredictable quick translocation events presented in these results, 160 suggesting that the translocations of DNA in graphene nanopore were unstable. 161 Especially, similar with the translocation of ssDNA in graphene nanopores,¹³ the 162 unceasing velocities fluctuations of DNA in simulations of [1V, R3] and [2V, R3] 163 showed that the translocation of dsDNA could also be stagnated in graphene nanopore. 164 The corresponding ionic current signals were fluctuated around 3 nA and 3.5 nA, 165 respectively. While for the other four results in Figure 2a, the magnitude of ionic 166 current signals were rose to the level of open-pore ionic current after about 12 ns ([1V, 167

168 R1]), 10 ns ([1V, R2]), 6 ns ([2V, R1]) and 5 ns ([2V, R2]), respectively. These results 169 indicated that not only the initial conformations of DNA (folded/unfolded), the 170 instantaneous translocation statues of DNA could also impact the blockaded ionic 171 current significantly.

Therefore, the undulates of the denoised ionic current (Figure 2a) were further 172 investigated to explore more detailed instantaneous translocation information of DNA. 173 As an example, the peaks and troughs of the denoised ionic current of [2V, R1] in 174 175 Figure 2a were marked with arrows a-g in Figure 3. Results show that the peaks and troughs of blocked ionic current were corresponding to different local conformations 176 of DNA in graphene nanopore one by one (insets a-e of Figure 3). Meanwhile, the 177 trajectory of MD simulation (Movie S1) also dynamically shows that the 178 instantaneous conformational variations (such as yawing and upright) of in-pore DNA 179 did accompanied with the fluctuations of blocked ionic current. Different with the 180 stacking interaction-induced stepwise translocation of ssDNA in graphene nanopore,¹³ 181 the instantaneous conformational variations induced velocity fluctuations of dsDNA 182 183 (Figure 2b) were more like a DNA deformation-induced translocation jam. The comparison between the number of atoms of DNA accumulated in graphene nanopore, 184 N(t), violet region of DNA in Figure 4a, and the ionic current signals (Figure 4b and 185 Figure S3) directly show that the fluctuations of blocked ionic current were reciprocal 186 to N(t) elaborately for all the non-stagnant translocation events ([1V, R1], [1V, R2], 187 [2V, R1], [2V, R2]). However, a plane parameter "effective unoccupied area", which 188 was proposed in a recent publication, could only basically reveal the spatial blockage 189 effect of DNA to the fluctuation of ionic current, because the spatial blockage effect 190 of DNA towards ionic current was reduced into a 2-dimensional (2D) parameter in 191 their model.³¹ These results indicate that not only the occupied area of nanopore, the 192 instantaneous conformational variations of the in-pore DNA was also a key factor of 193 the fluctuation of ionic current blockages. 194

The unstable translocations of DNA which revealed from the ionic current suggest that the interactions between DNA and graphene were varied with the translocation. As shown in Figure 4c, the DNA-graphene interaction was fluctuated in range of -25

 \sim -150 kJ/mol in the first 3 ns. Compared with the average interaction energy (-27.08 198 ± 6.32 kJ/mol) between a short in-pore DNA fragment composed of only two 199 base-pairs(ApT and GpC) and the same graphene nanopore (aperture 2.4 nm, 200 monolayer) in previous research,²⁴ the enhanced DNA-graphene interaction imply that 201 the nucleobases were exposed toward graphene surface (π - π stacking interaction was 202 much greater than edge-edge interaction between nucleobases and graphene^{32, 33}), 203 and/or the neighbor DNA base-pairs contributes to the DNA-graphene interaction also. 204 205 The MD trajectories (Movie S1-S2) showed that the exposed nucleobases did adhered on the bottom of graphene nanopore steadily after 3 ns, according with the 206 dramatically enhancement of DNA-graphene interaction after 3 ns (inset of Figure 3c). 207 By the way, due to the strong π - π stacking interaction, the in-pore translocation 208 velocity of DNA was also reduced after 3ns, and the DNA translocation was almost 209 stagnated around 4 ns ([2V, R1] in Figure 2b). While, the energy barrier of the 210 bending of DNA and the strong electrostatic force applied on DNA which near to 211 graphene nanopore^{12, 24} induced the remaining DNA crosswise lying down and 212 213 blocked graphene nanopore closely (insets e-f of Figure 3 and Movies S1-S2). Thus the adherence of DNA on graphene could also induce the unexpected fluctuations of 214 ionic current (marked with arrows e-f in Figure 3). After DNA passed through the 215 graphene nanopore (6~8 ns), the magnitude of ionic current (Figure 3) was rose to the 216 level of open-pore ionic current (> 10 nA), and the structural fluctuation of graphene 217 nanopore (highlighted with yellow band in Figure 4d) was also decreased to the level 218 of no DNA system (Figure S2). Thus the fluctuations of the blocked ionic current 219 might also be influenced by the DNA-graphene interaction induced structural 220 221 fluctuations of graphene nanopore.

As we suggested above, the translocation statues of DNA base-pairs near to graphene nanopore could also influence the fluctuation of ionic current. Thus a DNA fragment composed of only two base-pairs $(d-(AG)_2)$ was employed as a stopper to probe the blockage effect of the neighbor base-pairs of DNA at pore entrance. A set of MD simulations (indexes 16-59 in Table S1) were performed to get the ionic blockage effect of the stopper at different positions and orientations. The shift range of the

stopper (probe DNA) to the center of graphene nanopore was $-2 \text{ nm} \sim 2 \text{ nm}$ (see insets 228 of Figure 5a). The schematic diagrams of the orientation altering of probe DNA were 229 shown as insets of Figure 5b. The obtained ionic blockages which induced by the 230 probe DNA with two orientations were shown in Figure 5a. We found that the blocked 231 ionic current (I) induced by DNA within graphene nanopore (distance was 0 nm) was 232 only about half of the open-pore current (I_o) , it accords with the reported result.¹⁴ The 233 interesting result was that the DNA near to graphene nanopore could also induce the 234 235 ionic current blockages. For instance, when the probe DNA was positioned within 0.4 nm to graphene nanopore in z-direction, the blocked ionic currents were almost equal 236 to a half of the open-pore current (I_{a}) , suggesting that the blockage effect of DNA 237 which near to the entrance of graphene nanopore towards ionic current (I/I_o) was 238 similar to that of DNA within nanopore (Figure 5b). Additionally, the ionic current 239 blockages were enhanced with the decrease of the DNA-graphene interval (Figure 5a) 240 when the probe DNA was positioned within 1.5 nm of graphene nanopore. The 241 neighborhood effect of DNA to ionic current blockage indicated that the 242 243 conformational variation of the neighbor base-pairs of DNA around graphene nanopore entrance could also induce the fluctuation of ionic current. 244

In summary, a series of MD simulations were carried out to assess the ionic current 245 measurement and to extract the instantaneous translocation information of DNA in 246 graphene nanopore from the fluctuations of blocked ionic current. A key result of our 247 study was that the instantaneous conformational variations of in-pore DNA were 248 synchronously revealed from the undulations of denoised ionic current because the 249 fluctuation of the number of atoms of DNA accumulated in graphene nanopore. 250 251 However, we also found that both the DNA base-pairs within and near to the entrance of graphene nanopore have similar blockage effect to ionic current. Compared with 252 other sensing approaches based on graphene (i.e. the transverse conductance 253 measurement of graphene nanopore,³⁴ nanoelectrode³⁵ and nanoribbon³⁶ etc.), the 254 DNA base-specific resolution of the ionic current-based graphene nanopore sensing 255 should be further improved. Modifying the graphene nanopore with functionalized 256 groups,³⁵ might be a potential strategy to enhance the DNA base distinguish ability of 257

258 ionic current based on graphene nanopore sequencing system.

Figure 1. (a) The schematic diagram of open-pore ionic current simulation. The Na⁺, 335 Cl and graphene nanopore were colored with yellow, blue and cyan in "VDW 336 model". For representation convenience, here only 10% of the water molecules in 337 simulation system were showed in "CPK model". (b-d) The average (AVG) and the 338 fluctuation (root-mean-square, RMS) of open-pore ionic current for the simulations 339 of (b) different temperature and bias voltage, of (c) flexible and rigid graphene 340 nanopores and of (d) the big simulation box $(6.3 \times 6.3 \times 20 \text{ nm}^3)$ were plotted as 341 function of the measure frequency $(1/\Delta t)$. Data were obtained from the last 3-ns of 342 the 4-ns MD trajectories. 343

Figure 2. (a) The ionic current signals (grey lines) which obtained from the MD simulations of 10-15 in Table S1 were plotted as function of simulation time. The denoised ionic current signals (blue lines) were smoothed by a FFT filter with cutoff frequency of 10GHz. The filtered noises were also presented (red lines). (b) The instantaneous translocation velocity of DNA in graphene nanopore was plotted as function of simulation time. In all the legends, the 1V and 2V were the applied bias voltages; the R1, R2 and R3 were used to label the three repeated MD simulations.

Figure 3. Both of the original (grey line) and smoothed (red line) ionic current were plotted as function of simulation time. The insets (a-h) show the local conformations of DNA in graphene nanopore, which is corresponding to the undulate of ionic current (marked with arrows a-h).

Figure 4. (a) The representation of in-pore DNA (colored in violet), ΔZ was set to 1 361 nm. (b) The time evolutions of the accumulated number of atoms of DNA 362 accumulated in graphene nanopore (blue line) and ionic current signals (red line and 363 grey line) of the simulation [2V, R1]. (c) The time evolution (0-4 ns) of the interaction 364 energy between DNA and graphene of simulation [2V, R1]. The DNA-graphene 365 interaction energy of whole trajectory was also showed as inset (0-8ns). (d) The time 366 evolution of the root-mean-square distance (RMSD) of graphene nanopore of 367 simulation [2V, R1]. The yellow band highlighted that the magnitude of RMSD of 368 graphene nanopore was reduced after the translocation of DNA has finished (about 369 370 6-8ns).

372

Figure 5. (a) The ionic current was plotted as function of the separation between DNA fragment and graphene nanopore. (b) The blockage effect of DNA to ionic current (I/I_o) with two orientations was plotted as function of interval between DNA and graphene nanopore. I_o is the open pore ionic current of the graphene nanopore. The schematic diagrams of the position and orientation altering of DNA fragment in ionic current calculations were shown as insets.
