Efficiency of Entanglement Concentration by Photon Subtraction

Wulayimu Maimaiti[∗] and Stefano Mancini

School of Science and Technology, University of Camerino, I-62032 Camerino, Italy

We introduce a measure of efficiency for the photon subtraction protocol aimed at entanglement concentration on a single copy of bipartite continuous variable state. We then show that iterating the protocol does not lead to higher efficiency than a single application. In order to overcome this limit we present an adaptive version of the protocol able to greatly enhance its efficiency.

PACS numbers: 03.65.Bg, 42.50.Dv

I. INTRODUCTION

The most used states in continuous variable quantum information processing are Gaussian states, such as coherent states, squeezed states, or Einstein-Podolsky-Rosen like states [\[1\]](#page-5-0). The latter type of entangled states are two mode squeezed vacuum and represents a common source for most quantum communication protocols, such as quantum teleportation [\[2\]](#page-5-1), quantum key distribution [\[3\]](#page-5-2), quantum dense coding [\[4\]](#page-5-3), etc. However due to the exponential decay of the entanglement over the length of quantum communication channels [\[5\]](#page-5-4), protocols such as entanglement concentration are needed to ensure faithful quantum communication [\[6\]](#page-5-5). They deserve to enhance the amount of entanglement by using local operations (exploiting ancillary systems) and eventually classical communication.

Entanglement concentration involves several copies of bipartite states each having a low amount of entanglement and aims at producing a smaller number of copies possessing a higher amount of entanglement [\[6\]](#page-5-5). However, it could also work on a single copy of a bipartite entangled state [\[7\]](#page-5-6), but unfortunately it cannot be realized within continuous variable by Gaussian operations [\[8\]](#page-5-7). Hence methods like "photon subtraction" have been proposed [\[9,](#page-5-8) [10\]](#page-5-9), where non-Gaussian operations are realized by photon number measurements after beam splitter transforms with ancillary modes. However the photon subtraction protocol is probabilistic since its success depends on the probability of getting 'good' measurement outcomes. Hence in characterizing it one should take into account both entanglement enhancement and probability of success. To this end we introduce here a measure of efficiency for the photon subtraction protocol and show that iterating it does not lead to higher efficiency than a single application. In order to overcome this limit we present an adaptive version of the protocol able to greatly enhance its efficiency. We restrict our analysis to the case of weak fields so to consider only few relevant measurements outcomes.

II. PHOTON SUBTRACTION PROTOCOL

The standard entanglement concentration scheme with photon subtraction is shown in figure [1](#page-1-0) (Left). The initial state $|\psi_0\rangle_{AB}$ is a two-mode squeezed vacuum state

$$
|\psi_0\rangle_{AB} = \sqrt{1 - \lambda^2} \sum_{n=0}^{\infty} \lambda^n |n\rangle_A |n\rangle_B, \quad \lambda \in \mathbb{R}_+.
$$
 (1)

The non-Gaussian operation in photon subtraction scheme is induced by photon number measurement on ancillary modes C and D that interact with entangled modes A and B through beam splitters of transmittance T. In Fock space the effect of the beam splitter unitary transformation is [\[10\]](#page-5-9)

$$
|n\rangle_A|0\rangle_C \stackrel{\hat{U}_{AC}}{\longmapsto} \sum_{k=0}^n \xi_{nk}|n-k\rangle_A|k\rangle_C,\tag{2}
$$

where

$$
\xi_{nk} = (-1)^k \sqrt{\binom{n}{k}} (T)^{(n-k)/2} (1-T)^{k/2},\tag{3}
$$

[∗] ibrahimdulani@gmail.com

FIG. 1: Entanglement concentration scheme with photon subtraction. (i) The standard protocol. (ii) The standard protocol iterated N times.

with $\begin{pmatrix} n \\ k \end{pmatrix}$ $\binom{n}{k}$ the binomial coefficient. Analogous considerations hold true for BD modes. Now consider the photon number detection of ancillary modes C, D . Suppose the number of photons detected are c, d respectively, then the corresponding probability operator value elements [\[11\]](#page-5-10) are

$$
\hat{M}_{cd} = |c\rangle_C \langle c| \otimes |d\rangle_D \langle d|.
$$
\n(4)

As a consequence, the a posteriori state to this measurement reads

$$
\frac{1}{\sqrt{P_{cd}}} \hat{M}_{cd} \hat{U}_{AC} \hat{U}_{BD} |\psi_0\rangle_{AB} |0\rangle_C |0\rangle_D, \tag{5}
$$

where P_{cd} is the joint probability of detecting c (resp. d) photons in C (resp. D) mode

$$
P_{cd} = \sum_{n=\max[c,d]}^{\infty} (\alpha_n \xi_{nc} \xi_{nd})^2,
$$
\n(6)

with $\alpha_n =$ $\sqrt{1-\lambda^2}\lambda^n$. Tracing the state of Eq.[\(5\)](#page-1-1) together with its dual over modes C and D we get the following still pure, though non-Gaussian, conditional state

$$
|\psi_{cd}\rangle_{AB} = \frac{1}{\sqrt{P_{cd}}} \sum_{n=\max[c,d]}^{\infty} \alpha_n \xi_{nc} \xi_{nd} |n-c\rangle_A |n-d\rangle_B.
$$
 (7)

III. EFFICIENCY OF THE PROTOCOL

In order to evaluate the effectiveness of the entanglement concentration protocol we need to compare the prior and posterior amount of entanglement. A useful entanglement measure is the so called negativity defined as [\[12\]](#page-5-11)

$$
\mathcal{N}(\rho_{AB}) := \frac{||\rho^{\mathsf{T}_B}||_1 - 1}{2},\tag{8}
$$

where $||\hat{O}||_1 = \text{Tr}\sqrt{\hat{O}^\dagger\hat{O}}$ is the trace norm of the operator \hat{O} and T_B denotes the partial transposition with respect to subsystem B . For pure states with Schmidt decomposition as in Eq.[\(7\)](#page-1-2) the negativity reads

$$
\mathcal{N}(|\psi_{cd}\rangle_{AB}) = \frac{1}{2} \left(\sum_{n=\max[c,d]}^{\infty} \frac{\alpha_n \xi_{nc} \xi_{nd}}{\sqrt{P_{cd}}} \right)^2 - \frac{1}{2}.
$$
\n(9)

Analogously, the negativity of the initial two mode squeezed vacuum state of Eq.[\(1\)](#page-0-0) reads

$$
\mathcal{N}_0 \equiv \mathcal{N}(|\psi_0\rangle_{AB}) = \frac{\lambda}{1 - \lambda}.\tag{10}
$$

Thus, for a specific measurement outcome cd we can calculate the negativity difference $\mathcal{N} - \mathcal{N}_0$ and check if it is positive thus witnessing entanglement enhancement. However this is not enough to evaluate the performance of the scheme. We should also account for the outcome probability. Hence we define the efficiency as

$$
\mathcal{E} := \sum_{m} P_m \frac{\Delta \mathcal{N}(|\psi_m\rangle)}{\mathcal{N}(|\psi_m\rangle)},\tag{11}
$$

where the index m runs overall possible measurement outcomes and $\Delta\mathcal{N}(|\psi_m\rangle)$ is defined as

$$
\Delta \mathcal{N}(|\psi_m\rangle) := \begin{cases} \mathcal{N}(|\psi_m\rangle) - \mathcal{N}_0 & \text{if } \mathcal{N}(|\psi_m\rangle) - \mathcal{N}_0 > 0 \\ 0 & \text{if } \mathcal{N}(|\psi_m\rangle) - \mathcal{N}_0 \le 0 \end{cases} \tag{12}
$$

Notice that only the measurement outcomes with increased negativities contribute to the efficiency. Furthermore it is $0 \leq \mathcal{E} \leq 1$.

IV. ITERATION OF THE PROTOCOL

In this Section we consider the iteration of the standard photon subtraction scheme as shown in Figure [1](#page-1-0) (Right). This means to have N ancillary modes C_i , $i = 1, ..., N$ (resp. D_j , $j = 1, ..., N$) on arm A (resp. B) and couple each of them sequentially with A mode (resp. B mode).

Suppose in the A (resp. B) arm c_i (resp. d_i) photons are detected in the *i*-th (resp. *j*-th) ancilla and zero everywhere else, then the resultant state can be straightforwardly computed following Eq.[\(7\)](#page-1-2)

$$
|\psi_{c_i d_j}\rangle_{AB} = \frac{1}{\sqrt{P_{c_i d_j}}}\sum_{n=\max[c_i,d_j]}^{\infty} \alpha_n \xi_{n,0}^{i+j-2} \xi_{n,c_i} \xi_{n,d_j} \xi_{n-c_i,0}^{N-i} \xi_{n-d_j,0}^{N-j}
$$

$$
\times |n-c_i\rangle_{A} |n-d_j\rangle_{B},
$$
 (13)

where P_{c_i,d_j} is the probability of detecting c_i photons in *i*-th ancilla in A arm and d_j photons in *j*-th ancilla in B arm

$$
P_{c_i,d_j} = \sum_{n=\max[c_i,d_j]}^{\infty} (\alpha_n \xi_{n,0}^{i+j-2} \xi_{n,c_i} \xi_{n,d_j} \xi_{n-c_i,0}^{N-i} \xi_{n-d_j,0}^{N-j})^2.
$$
 (14)

Of course we should consider not only the photons detected in the *i*-th ancilla of A arm and j-th ancilla of B arm, but on all ancillary modes of the A arm as well as of the B arm. For the sake of convenience we put some limits in our consideration of the number of detected photons. Actually we restrict our attention to $\lambda \in (0, 0.325)$ which according to Eq.[\(1\)](#page-0-0) guarantees that the probability of having two or more photons on each arm is negligible small (smaller than 1%). This is also consistent with the fact that entanglement purification is usually required when the amount of initial entanglement (value of parameter λ) is quite low.

Therefore from now on we will consider single photon detection in each arm. Then, we can divide the possible outcomes into two classes: *symmetric* having single photon detection in both arms $(\sum_{i=1}^{N} c_i = \sum_{j=1}^{N} d_j = 1)$ and asymmetric having single photon detection only in one arm (either $\sum_{i=1}^{N} c_i = 0$, $\sum_{j=1}^{N} d_j = 1$ or $\sum_{i=1}^{N} c_i = 1$, $\sum_{j=1}^{N} d_j = 0$).

1. Symmetric case

We can use Eq. (14) to evaluate the probability of detecting one photon in the *i*-th ancilla of A arm and one photon in the i -th ancilla of B arm. It results

$$
P_{1_i,1_j} = \frac{(1-T)^2 T^{-2+i+j} \lambda^2 (1-\lambda^2)(1+T^{2N}\lambda^2)}{(1-T^{2N}\lambda^2)^3}.
$$
\n(15)

Clearly the probability of detecting one photon in first ancillary modes $(i = j = 1)$ is the highest. The evaluation of negativity for single photon detected on each arm turns out to be equivalent to the evaluation of negativity for the state of Eq.[\(13\)](#page-2-1). Actually we have

$$
\mathcal{N}(|\psi_{1_i,1_j}\rangle_{AB}) = \frac{T^N \lambda (2 + T^N \lambda + T^{2N} \lambda^2)}{(1 - T^N \lambda)(1 + T^{2N} \lambda^2)},\tag{16}
$$

no matter on which ancilla the photon is detected. Notice that this negativity decreases by increasing N.

2. Asymmetric case

Using Eq. (14) we can get the probability of detecting one photon in *i*-th ancilla in one arm

$$
P_{1_i,0} = P_{0,1_i} = \frac{T^{-1+i+N}(1-T)\lambda^2(1-\lambda^2)}{(1-T^{2N}\lambda^2)^2}.
$$
\n(17)

The negativity of the state (13) corresponding to a photon detection in *i*-th ancilla in one arm results

$$
\mathcal{N}(|\psi_{1_i,0}\rangle_{AB}) = \frac{(T^{2N}\lambda^2 - 1)^2}{2\lambda^2 T^{2N}} \left[\text{Li}_{-\frac{1}{2}}\left(\lambda T^N\right) \right]^2 - \frac{1}{2},\tag{18}
$$

where $Li_{-\frac{1}{2}}(\bullet)$ is the polylogarithm function of order $-\frac{1}{2}$. Also in this case the negativity does not depend on the outcome and decreases with N.

3. Overall efficiency

According to the definition of Eq.[\(11\)](#page-2-2), we write the overall efficiency of iteration protocol as

$$
\mathcal{E} = \sum_{i,j=1}^{N} P_{1_i,1_j} \frac{\Delta \mathcal{N}(|\psi_{1_i,1_j}\rangle_{AB})}{\mathcal{N}(|\psi_{1_i,1_j}\rangle_{AB})} + 2 \sum_{i=1}^{N} P_{1_i,0} \frac{\Delta \mathcal{N}(|\psi_{1_i,0}\rangle_{AB})}{\mathcal{N}(|\psi_{1_i,0}\rangle_{AB})}.
$$
(19)

where $\Delta\mathcal{N}(|\psi_{1_i,1_j}\rangle_{AB}$ and $\Delta\mathcal{N}(|\psi_{1_i,0}\rangle_{AB})$ are as defined in Eq.[\(12\)](#page-2-3). The factor 2 in front of the second term come from the fact that $|\psi_{1_i,0}\rangle_{AB} = |\psi_{0,1_i}\rangle_{AB}$ and $P_{1_i,0} = P_{0,1_i}$.

Using Eqs.[\(15\)](#page-2-4), [\(16\)](#page-2-5) and Eqs.[\(17\)](#page-3-0), [\(18\)](#page-3-1) we get $\mathcal E$ as function of (λ, N, T)

$$
\mathcal{E} = \frac{(1 - T^N)\lambda^2 (1 - \lambda^2)}{1 - \lambda^2 T^{2N}} \left[\frac{(1 - T^N)(1 + \lambda^2 T^{2N})}{1 - \lambda^2 T^{2N}} E_1 + 2T^N E_2 \right],\tag{20}
$$

with

$$
E_1 = \max\left[0, 1 - \frac{(1 - \lambda T^N)(1 + \lambda^2 T^{2N})}{T^N (1 - \lambda)(2 + \lambda T^N + \lambda^2 T^{2N})}\right],\tag{21}
$$

$$
E_2 = \max\left[0, 1 - \frac{\lambda}{1 - \lambda} \frac{2\lambda^2 T^{2N}}{(1 - \lambda^2 T^{2N})^2 \left[\text{Li}_{-\frac{1}{2}}(\lambda T^N)\right]^2 - T^{2N} \lambda^2}\right].\tag{22}
$$

In Figure [2](#page-3-2) (Left) we show the loci in the $N-T$ plane where $\mathcal E$ reaches its maximum for given values of λ . Interestingly the maximum values taken by $\mathcal E$ are the same for fixed λ . This means that for a given value of λ the same efficiency can be reached for many pair values of $N - T$ including a pair with $N = 1$.

FIG. 2: Loci of the points in the $N - T$ plane giving maximum efficiency for iteration of the standard protocol (Left) and adaptive protocol (Right) when $\lambda = 0.15$ and 0.32. The values of efficiency are reported beside the points.

V. ADAPTIVE SCHEME

In this section we introduce a possible way to avoid the reduction of negativity increment by N while keeping high success probability. The idea is to apply on each arm a beam splitter conditionally to no photon detection in the previous one. Whenever there is a detection no more beam splitters will be applied afterwards. This can be done with the help of some feed-forward control system.

According to this strategy all the terms related to no photon detection will be eliminated from the coefficients of the state in Eq.[\(13\)](#page-2-1) and from the detection probability in Eq.[\(14\)](#page-2-0) after a photon detection, namely the state in Eq.(13) becomes

$$
|\psi_{c_i d_j}\rangle_{AB} = \frac{1}{\sqrt{P_{c_i d_j}}}\sum_{n=\max[c_i,d_j]}^{\infty} \alpha_n \xi_{n,0}^{i+j-2} \xi_{n,c_i} \xi_{n,d_j} |n-c_i\rangle_A |n-d_j\rangle_B, \tag{23}
$$

with P_{c_i,d_j} now reading

$$
P_{c_i,d_j} = \sum_{n=\max[c_i,d_j]}^{\infty} (\alpha_n \xi_{n,0}^{i+j-2} \xi_{n,c_i} \xi_{n,d_j})^2.
$$
 (24)

Limiting the maximum number of detected photons to 1, we have likewise the previous Section symmetric and asymmetric cases.

4. Symmetric case

Setting $c_i = d_j = 1$ in Eqs.[\(23\)](#page-4-0), [\(24\)](#page-4-1) we get

$$
P_{1_i,1_j} = \frac{(1-T)^2 T^{-2+i+j} \lambda^2 (1-\lambda^2)(1+T^{i+j}\lambda^2)}{(1-T^{i+j}\lambda^2)^3},\tag{25}
$$

and the negativity of symmetric outcomes

$$
\mathcal{N}\left(|\psi_{1_i,1_j}\rangle_{AB}\right) = \frac{(1 - T^{i+j}\lambda^2)^3}{2(1 - T^{(i+j)/2}\lambda)^4(1 + T^{i+j}\lambda^2)} - \frac{1}{2}.\tag{26}
$$

5. Asymmetric case

In the same way, setting $c_i = 1, d_j = 0$ in Eqs.[\(23\)](#page-4-0), [\(24\)](#page-4-1) yields

$$
P_{1_i,0} = P_{0,1_i} = \frac{T^{-1+i+N}(1-T)\lambda^2(1-\lambda^2)}{(1-T^{i+N}\lambda^2)^2},\tag{27}
$$

and the negativity of asymmetric outcomes

$$
\mathcal{N}(|\psi_{1_i,0}\rangle_{AB}) = \frac{(1 - T^{i+N}\lambda^2)^2}{2\lambda^2 T^{(i+N)}} \left[\text{Li}_{-\frac{1}{2}}\left(\lambda T^{(i+N)/2}\right) \right]^2 - \frac{1}{2}.
$$
\n(28)

6. Overall efficiency

To evaluate the overall efficiency of adaptive scheme we can insert Eqs.[\(25\)](#page-4-2), [\(28\)](#page-4-3) and Eqs.[\(27\)](#page-4-4), (28) into Eq.[\(19\)](#page-3-3). However in this case is not possible to get a compact expression for it. Results from numerical evaluation are shown in Figure [2](#page-3-2) (Right). In this case the maximum values taken by $\mathcal E$ for fixed value of λ are not the same, and monotonically increase towards $\mathcal{E} = 1$ for $N \to \infty$ and $T \to 1$ (though not along a unique line in the $N - T$ plane).

VI. CONCLUSION

We have considered the efficiency of entanglement concentration by photon subtraction defined as the average of entanglement increments weighted by their success probability. While entanglement increment diminishes by iterating the protocol, its success probability auguments. It results that these two behaviors compensate each other so that optimal efficiency can be already reached in one step of the protocol.

In contrast, iteration of photon subtraction becomes meaningful when no photon have been previously detected. Thus adaptive strategy can in principle enhances the efficiency up to one. Implementing it is challenging because light should be stored during the feedforward time, however quantum memories [\[13\]](#page-5-12) are promising for achieving significant values of efficiency in this way.
