In Boettiger & Hastings [1] we demonstrated that conditioning on observing a purely stochastic transition from one stable basin to another could generate time-series trajectories that could be mistaken for an early warning signal of a critical transition (such as might be due to a fold bifurcation [2]), when instead the shift is merely due to chance. While the goal was to highlight a potential danger in mining historical records for patterns showing sudden shifts when seeking to test early warning techniques, Drake [3] draws attention to a potentially more interesting consequence of our analysis. Drake argues that the bias observed could be used to forecast purely stochastic transitions – a task previously thought to be impossible [4]. We feel this interpretation is too generous. The pattern Drake points to arises in any large deviation, regardless of whether a system is or is not at elevated risk for a transition. We illustrate this pattern in systems with and without bistability, demonstrating that early warning signals do not exist for purely stochastic transitions.

Here we provide a numerical demonstration that the pattern in question for consideration of an early warning signal appears not only before purely stochastic transitions (as seen in Reference 1) but during any large deviation. As large deviations can occur even in stochastic systems that have only a single stable point, these patterns cannot be considered indicators of stochastic transitions. We demonstrate this in two scenarios: first using the Allee model of alternative stable states considered in Reference 1, Eqn 2.1 - 2.2 and Figure 2, and then in a simple Ornstein-Uhlenbeck (OU) model which has only a single stable state. Rather than condition on a stochastic transition having occurred (as in Reference 1), we now condition on having merely observed a sufficiently large deviation. It does not matter precisely what “large” deviation is considered, only that the larger the deviation the more replicates or longer simulation times will be needed to sufficiently populate the sample. We pick values such that we get a sample of a few hundred large deviation events in a sample of 20,000 replicates.

The OU model is defined by a stochastic differential equation in which there is only a single optimum whose strength is proportional to the displacement,

$$dX_t = -\alpha X_t dt + \sigma dB_t,$$

29 where the state  $X_t$  oscillates around a stable point (at zero in these arbitrary units), driven by Brownian noise  
 30  $dB_t$  of intensity  $\sigma$  and restorative force  $\alpha$ .

31 The analysis for each model proceeds exactly as in Reference 1: For each model we generate 20,000 replicate time  
 32 series. We condition upon only those experiencing a deviation of size  $L$  ( $X \leq 250$  in the Allee model and  $X \leq -4$   
 33 in the OU model). For the sequence of observations immediately leading up to the large deviation we compute  
 34 the warning signals of variance and autocorrelation over a sliding window of half the length of the time-series, and  
 35 we summarise the increasing or decreasing trend observed in the variance and autocorrelation using Kendall's  $\tau$   
 36 rank correlation coefficient (all following the method for early warning indicators outlined in Reference 5). We  
 37 repeat this analysis on the entire set of time-series under each model to obtain null distributions for  $\tau$  statistic.

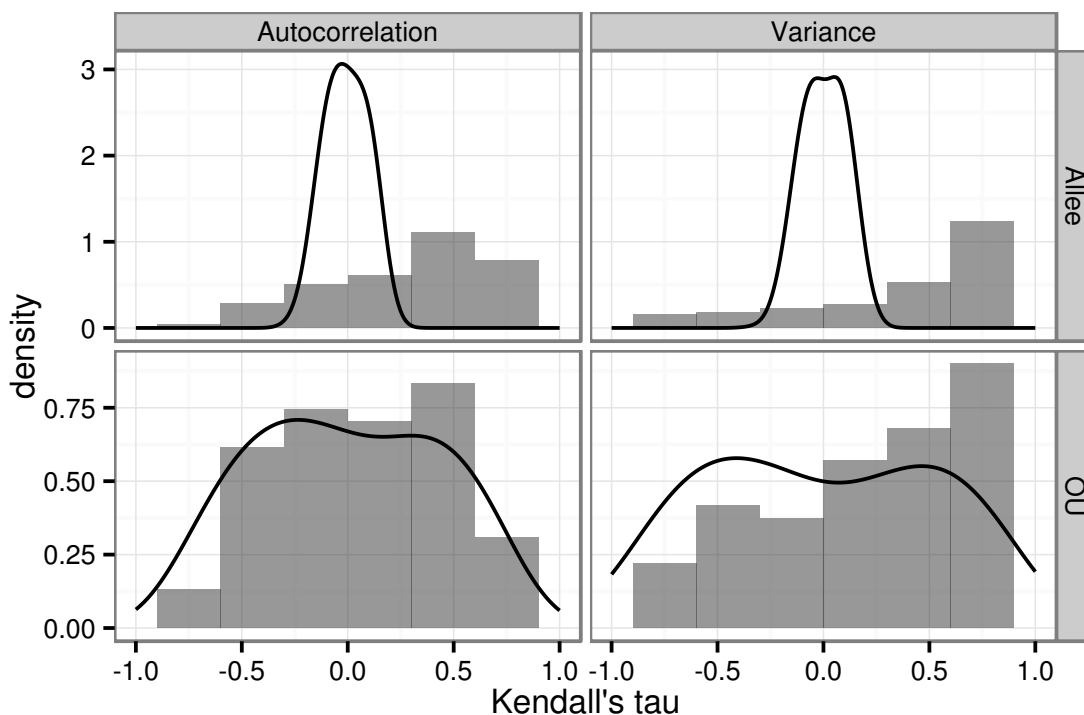

Figure 1: Figure 1. Histogram shows the frequency the correlation statistic  $\tau$  observed for each warning signal (variance, autocorrelation coefficient) on the large deviation samples from each model. Background distribution of all samples show by smooth line (kernel density estimate). More positive values of tau are supposed to indicate a rising indicator which can be a signal of an approaching transition [2]. The OU model uses  $\alpha = 5$ ,  $\sigma = 3.5$ ,  $t \in (0, 10)$ , 2000 replicates, 20,000 sample points each. Conditionally selected trajectories experiencing a deviation of at least -4, and analyzed the 1,500 data points prior to the threshold to determine a warning signal (following Reference 5). (Code at: <https://raw.githubusercontent.com/cboettig/earlywarning/resubmission/inst/doc/Figure1.Rmd>, data at: <https://raw.githubusercontent.com/cboettig/earlywarning/resubmission/inst/doc/Figure1.csv> (Once published, code and data will appear in Dryad via doi: 10.5061/dryad.1dj62)

38 We find (Figure 1) that  $\tau$  is significantly skewed towards positive values when conditioning on large deviations in  
39 both models. This demonstrates that it is the presence of the large deviation, not the presence of the stochastic  
40 transition we condition on in Reference 1, that is responsible for this pattern (just as we claimed without example  
41 then).

42 Observing the bias shown in the figures here depends on having a rapid enough sample frequency to capture  
43 the escape trajectory and a long enough trajectory for the statistic to demonstrate an increase over time. Since  
44 large deviations due to stochastic forces alone must be fast, so must the accompanying warning signal and  
45 management response (which will show up on the time scale of the perturbation). Note that fast relative to the  
46 system dynamics may or may not be fast relative to the timescale of management (just as with bifurcation-driven  
47 warning signals, Reference 6). The wider null distribution in the OU model results from the sample window being  
48 shorter relative to the system timescale.

49 One might consider this a corollary of the Prosecutor’s Fallacy we originally presented, which demonstrated that  
50 examples of sudden transitions historically selected from the literature could be mistaken for positive evidence of  
51 early warning signals when they were in fact due to purely stochastic transitions. Here we have seen how any  
52 large deviation could be similarly misleading, whether or not it results in a stochastic transition to an alternative  
53 stable state. From a classical result of the large deviation theory one can gain considerable intuition about  
54 why these chance deviations show much higher variance and autocorrelation than expected from the stationary  
55 distribution of a stable point. Though large deviations are rare – the time we must wait to observe a deviation of  
56 size  $L$  in the system above scales as  $\exp(L^2/\sigma^2)$  (the familiar Arrhenius relationship), when these deviations  
57 occur they occur very rapidly. The expected time for an excursion to a distant point  $L$  that does not again  
58 cross the stable point before reaching  $L$  scales as  $\log(L/\sigma)$ , just as a trajectory returning down the gradient of  
59 the attractor from  $L$  to the stable point (proofs in Reference 7 or Reference 8). While most trajectories in the  
60 stationary distribution take steps in each direction with equal probability, these large deviations moving rapidly  
61 to the boundary will consequently show the greater autocorrelation. In achieving a much greater deviation than  
62 typically observed, these trajectories will also show an increase in variance, as observed. That such trajectories  
63 appear to be pulled in the direction of their escape rather than climbing away against a restorative force has led  
64 to confusion before. Reference 8 argues how this shows how a “punctuated equilibrium” pattern of stasis followed  
65 by rapid change could arise entirely from small steps, and Reference 9 empirically demonstrates this phenomenon  
66 in the trajectories of local population extinctions.

67 In conclusion, we heartily agree with the need for a decision-theoretic approach to early warning signal questions  
68 [10]. Central to a decision-theoretic approach is enumerating alternative scenarios that are possible given the  
69 observed data. We have highlighted how purely stochastic transitions and large deviations are such possibilities.  
70 The challenge of sufficient or unique early warning indicators is not limited to stochastic shifts, but includes  
71 the more typical critical transitions. For instance, rising variance or autocorrelation patterns typical of fold  
72 bifurcations can be observed in more benign bifurcations or smooth transitions [11]. Early warning signals may

73 offer a promising technique that will one day allow us to avoid seemingly unpredictable catastrophes – but we  
74 must not lose sight of just how difficult are the challenges involved. A key step here and for early warning  
75 indicators more generally is to understand these other circumstances in which they can arise, that we may then  
76 develop ways to eliminate those possibilities. Though we may never be able to detect purely stochastic transitions,  
77 perhaps these approaches in this discussion may lead to more unique and sufficient indicators for true critical  
78 transitions.
