ABSTRACT

Gross chromosomal rearrangements have the potential to be evolutionarily advantageous to an adapting organism. The generation of a hybrid species increases opportunity for recombination by bringing together two homologous genomes. We sought to define the location of genomic rearrangements in three strains of *Saccharomyces pastorianus*, a natural lager-brewing yeast hybrid of *Saccharomyces cerevisiae* and *Saccharomyces eubayanus*, using whole genome shotgun sequencing. Each strain of *S. pastorianus* has lost species-specific portions of its genome and has undergone extensive recombination, producing chimeric chromosomes. We predicted 30 breakpoints that we confirmed at the single nucleotide level by designing species-specific primers that flank each breakpoint, and then sequencing the PCR product. These rearrangements are the result of recombination between areas of homology between the two subgenomes, rather than repetitive elements such as transposons or tRNAs. Interestingly, 28/30 *S. cerevisiae*- *S. eubayanus* recombination breakpoints are located within genic regions, generating chimeric genes. Furthermore we show evidence for the reuse of two breakpoints, located in *HSP82* and *KEM1*, in strains of proposed independent origin.

INTRODUCTION

Hybridisation in *Saccharomycetous* yeast occurs readily in natural and industrial environments [1,2,3,4,5,6,7], and may be a swift mechanism for evolutionary innovation. Investigating the genomics of successful natural hybrid species can provide valuable evolutionary insight into how the union of diverged genetic material can sculpt a genome

more suited to its new environmental niche. These adaptations may include chromosomal rearrangements such as duplication, translocation, inversion and selective loss of genes or even whole chromosomes. The lager yeast *Saccharomyces pastorianus*, previously classified as *Saccharomyces carlsbergensis*, is a natural hybrid between *Saccharomyces cerevisiae* and a *Saccharomyces uvarum*-like species [4,8,9,10]. The *S. uvarum*-like species has most recently been identified as the Argentinean-isolate *Saccharomyces eubayanus*, which shows 99.5% identity to the non-*S. cerevisiae* portion of *S. pastorianus* [11]. *S. pastorianus* is thought to have arisen by spontaneous hybridisation in brewery conditions, maintained by human selection for colder brewing temperatures, a preference that is conferred by its *S. uvarum*-like parent [12].

So far, there is only one strain of lager yeast sequenced [9] and most of our knowledge of the genome composition of these natural hybrids derives from previous array-comparative genomic hybridisation studies (Array-CGH) performed on 17 strains of *S. pastorianus* [10]. This particular work identified two groups of lager yeasts: Group 1 strains contain roughly one haploid *S. cerevisiae* and one haploid *S. eubayanus* genome with significant loss of *S. cerevisiae* genes, whereas Group 2 strains contain one haploid *S. eubayanus* genome and a diploid *S. cerevisiae* genome. The differences between these two groups suggest that they may have had independent evolutionary origins, a theory given weight by both the aforementioned array-CGH analysis [10] and the differing distribution of transposons between the two groups [13]. Additionally, strains within each group are highly variable in their patterns of chromosomal loss, aneuploidy and gross chromosomal rearrangements. probably

reflecting either evolutionary pressure from diverse brewery conditions or random genetic drift. [9,10],

Lager yeast chromosomes have been shown to have undergone recombination, generating chimeric chromosomes composed of genetic material from both parental species [10,14,15,16]. Typically, recombination between chromosomes within a non-hybrid yeast species is thought to be mediated primarily by transposons (Ty elements) [14,17,18,19], tRNAs [17,18], duplicated genes [18] or, as more recently proposed, origins of replication [20]. However, breakpoint formation in *S. pastorianus* is thought to be either Ty-mediated [10,14] or the result of recombination between homologous regions [15]. Studies have also demonstrated the role of high stress brewery conditions in promoting genomic rearrangements, such as localised areas of gene amplification and recombination [21]. Significantly, chromosomal rearrangements have been shown to confer adaptive traits in both wild and industrial yeasts including highly sulphite-resistant wine yeast [22], *flor* wine yeast [23] and wild copper-tolerant yeast [24]. Furthermore, rearrangements have been shown to contribute to speciation between species of yeast [25].

We sequenced three *S. pastorianus* strains to both characterise genomic breakpoints and shed further light on their formation and retention. We chose strains that have been used in a previous microarray study to provide a source of validation for our sequencing [10]. These strains have also been pre-classified into one of the two aforementioned groupings of *S. pastorianus*: two of the chosen strains of *S. pastorianus* are of Group 1 (DBVPG 6033 and DBVPG 6261) and one is of Group 2 (DBVPG 6257) [10]. These particular strains have the

greatest level of differential gene loss and therefore the least amount of redundancy. The latter group is thought to have an independent evolutionary origin from the former group, allowing us to investigate similarities between non-related strains.

We have confirmed the location of each *S. cerevisiae*- *S. eubayanus* breakpoint at the single nucleotide level and identified both nearby repetitive elements and regions of homology. Significantly, we found that the majority of genomic breakpoints occurred within protein coding regions, generating chimeric genes. Furthermore, the presence of identical breakpoints in *KEM1* and *HSP82* is evidence of breakpoint reuse between strains of proposed independent origin.

RESULTS AND DISCUSSION

Genome assembly and analysis

The genomic DNA of three strains of *S. pastorianus*, DBVPG 6033 (*Saccharomyces carlsbergensis* type strain), DBVPG 6261 (*Saccharomyces monacensis* type strain) and DBVPG 6257 were sequenced using the SOLiD 4 Next Generation Sequencing platform and mapped to *S. cerevisiae* (sacCer2) and *S. uvarum* (sacBay MIT), which are representative of the *S. pastorianus* subgenomes. We used sacBay MIT as the reference genome for *S. eubayanus* due to its fully available sequence which is purportedly 7% diverged from *S. eubayanus* [11]. Visualisation of the *S. cerevisiae* chromosomes in the UCSC Genome Browser (<http://genome.ucsc.edu/>) is reported in Figure 1. *S. eubayanus* reads were viewed as contigs in the Integrative Genomics Viewer (<http://www.broadinstitute.org/igv>).

SOLiD sequencing allowed us to ascertain the approximate chromosomal copy number derived from relative read quantity. In total, DBVPG 6033, 6261 and 6257 are estimated to have between 32-38, 34-39 and 45-48 chromosomes respectively (Table 1). These chromosomes map to *S. cerevisiae*, *S. eubayanus* or a combination of both *S. cerevisiae* and *S. eubayanus* sequence (chimeric chromosomes). We estimated the *S. eubayanus* chromosome number by viewing multiple contigs (whole chromosome assembly was not available). When viewing these contigs, we accounted for the fact that *S. uvarum*-like chromosomes show reciprocal rearrangements between three sets of chromosomes: II-IV, VI-X and VIII-XV, comparative to *S. cerevisiae* [26].

S. pastorianus shows a high degree of aneuploidy and the chromosomal composition between strains is highly variable. Strains DBVPG 6033, 6261 and 6257 have eight, seven and sixteen complete *S. cerevisiae* chromosomes, respectively. They also have an estimated 16-21, 13-17 and 13-15 complete *S. eubayanus* chromosomes, and 11, 16 and 18 chimeric chromosomes, composed of both *S. cerevisiae* and *S. eubayanus* sequence (Table 1). The approximate number of total chromosomes in DBVPG 6033 and 6261 (Group 1) is 32-38 and 34-39 respectively, both roughly equal to a diploid with a few extra chromosomes ($16 \times 2 = 32$). The total number of chromosomes in DBVPG 6257 (Group 2) is 45-48, and roughly equates to a triploid ($16 \times 3 = 48$). These data support previous estimates of Group 1 strains generally being diploid-derived and Group 2 strains being triploid-derived [10]. Both Group 1 strains have lost their *S. cerevisiae* version of chromosomes VI and XII, i.e. there is no evidence of this sequence, even on a chimeric chromosome. DBVPG 6261 has additionally lost its *S.*

cerevisiae chromosome III and XIV sequence, whereas DBVPG 6033 has lost its *S. cerevisiae* chromosome XI sequence. In the Group 2 strain DBVPG 6257, there was no detection of *S. cerevisiae* chromosome V.

All three strains of *S. pastorianus* show evidence of homologous recombination between *S. cerevisiae* and *S. eubayanus* chromosomes IV, VII, XIII and XVI. Additionally, chromosome VIII and XV have recombined in both Group 1 strains. Chromosomes IX, X, and potentially XII, have recombined in Group 2 strain DBVPG 6257. Chromosomes I, VI and XVI remain largely stable, showing no evidence of *S. cerevisiae*- *S. eubayanus* recombination in any of the sequenced strains. Reciprocal recombination and inversion events could not be identified in this study since these rearrangements are copy-number neutral.

In agreement with previous analysis of these three strains of *S. pastorianus* [10], we did not detect any *S. cerevisiae* mitochondrial DNA. The restriction analysis of COX2 in the three strains of *S. pastorianus* has indicated a *S. uvarum*-like mitochondrial sequence (data not shown), supporting the widely held notion that lager yeasts tend to inherit and/or retain only their *S. eubayanus* mitochondria [27]. The 2-micron plasmid maps to *S. cerevisiae* sequence in strains DBVPG 6033 and DBVPG 6257 but not DBVPG 6261. It is unknown if any 2-micron plasmids are *S. eubayanus*-derived.

Chromosomal rearrangements

We used the UCSC genome browser (<http://genome.ucsc.edu/>) to identify candidate breakpoints based on variations in *S. cerevisiae* read copy number across each chromosome

(Figure 1). Using this technique, we were able to detect a total of 13 *S. cerevisiae*- *S. eubayanus* breakpoints in DBVPG 6033, 13 in DBVPG 6261 and 15 in DBVPG 6257. We used species-specific primers to confirm the presence of each breakpoint by PCR (Figure 2). Each successfully amplified PCR product was sequenced at GATC Biotech (Germany) (Figure S1). All the sequenced breakpoints were then aligned to the *S. cerevisiae* and the *S. uvarum* reference genomes (Figure S2). A total of 9/13 *S. cerevisiae*- *S. eubayanus* breakpoints were confirmed by PCR in DBVPG 6033, another 11/13 in DBVPG 6261 and 10/15 in DBVPG 6257 (Table 2). In DBVPG 6033, three of these breakpoints were located on chromosome XVI, two on VIII and the remaining four on chromosomes II, IV, VII and XIII. In DBVPG 6261, three were located on chromosome XV, two on chromosome XI, two on chromosome XIII and the remaining four on chromosomes IV, V, VII and XVI. In DBVPG 6257, three breakpoints were located on chromosomes XVI, two on XIII and the remaining five on chromosomes IV, VII, IX, X and XI. Breakpoints occurred most commonly but not exclusively at the subtelomeric regions of chromosomes.

The majority of the sequenced *S. cerevisiae*- *S. eubayanus* breakpoints occur within coding regions (Table 2), despite breakpoints in yeast usually being located in intergenic rather than intragenic regions [28]. A total of seven, eleven and ten intragenic breakpoints were located in DBVPG 6033, 6261 and 6257 respectively. In each strain there were a small number of candidate breakpoints which could not be amplified (Table S1). There are four unconfirmed breakpoints in DBVPG 6033 (one of which was within in a coding region), two in DBVPG 6261 (both of which were within in a coding region) and five in DBVPG 6257 (one of which was within a coding region). Notably, we detected a breakpoint at the MAT locus on

chromosome III in strains DBVPG 6033 and 6257. Breakpoints to the right of the MAT locus in chromosome III have been noted previously in many strains of lager yeast [14,15,29]. There are two breakpoints that are in close proximity on chromosome X in strain DBVPG 6257, are in the vicinity of numerous Ty elements. A further three candidate breakpoints, one in each strain (at the far right of each chromosome X) could not be amplified, possibly due to their close proximity to both an AT-rich ARS element and the right telomeric region. The four remaining unsequenced candidate breakpoints are on chromosome XIII and XV in DBVPG 6033, chromosome VIII in DBVPG 6261 and chromosome XIII in DBVPG 6257.

The analysis of the chromosome copy number of *S. cerevisiae* and *S. eubayanus* (Table 1) showed that the majority of chimeric chromosomes were most likely formed as a result of either a single non-reciprocal recombination event from the *S. eubayanus* chromosome to the *S. cerevisiae* chromosome leaving both a chimeric copy and a full *S. eubayanus* copy of the sequence or a reciprocal event followed by a deletion. There are triplicate copies of seven breakpoint genes, four of which are in the purportedly diploid-derived Group 1 strains. These likely have formed through either gene conversion involving three chromosomes or duplication of subtelomeric regions, which are known to be sites of rapid gene duplication [30].

Chimeric genes

As a result of homologous recombination between chromosomes, several chimeric genes were formed (Table 2, see Figure S2 for full sequence alignments). Two of these genes, *KEM1*, a 5'-3' exonuclease, and *HSP82*, a molecular chaperone, are chimeric in all three

strains. Interestingly, these two breakpoints occur in the same gene position in all three hybrids. The *KEM1* *S. eubayanus*>*S. cerevisiae* breakpoint occurs 460(±4)/4587bp after the start of the gene and the *HSP82* *S. eubayanus*>*S. cerevisiae* breakpoint occurs 1592(+15,-14)/2130bp after the start of the gene. Another chimeric gene, *UTP4*, is shared between both Group 1 strains, yet the position of the *S. eubayanus*>*S. cerevisiae* breakpoint differs between each strain: in DBVPG 6033, the breakpoint occurs 460(±16)/2259bp after the start of the gene, whereas in DBVPG 6261, the breakpoint occurs 868(+/-7)/2259bp of the gene. A previous whole genome sequencing of a strain of *S. pastorianus*, Weihenstephan 34/70 also identified breakpoints within these two shared genes [15]. Microarray data further indicated that both of these breakpoints are also shared between many of the other Group 1 and Group 2 strains [10]. Four additional breakpoints located in DBVPG 6257 were also found in identical gene positions in Weihenstephan 34/70: *KEM1*, *PRI2*, *GPH1* and *QCR2*. A further breakpoint gene, *PRP12*, identified in the study was also observed in our SOLiD sequencing data. However, although the sequencing of Weihenstephan 34/70 shows a reciprocal breakpoint within *TDH2*, we found that rearrangements at this site altered copy number. Either there has additionally been a chromosomal deletion or the event was non-reciprocal in DBVPG 6257. Furthermore, since reciprocal recombination events could not be detected in this study, it is possible that the breakpoint may have occurred twice in this location, once as a reciprocal event and once as a non-reciprocal event.

Interestingly, two of the chimeric genes are involved in ethanol metabolism, a key biochemical pathway in lager fermentation. *ALD2* is involved in the oxidation of ethanol and *TDH2* is a component of the tetramer glyceraldehyde-3-phosphate dehydrogenase, which is required for

gluconeogenesis. Two further chimeric genes also play a role in energy metabolism. *GPH1* is involved in glycogen mobilisation and *GAL80* is a repressor of *GAL* genes in the absence of galactose. With the large genetic redundancy in all three strains of *S. pastorianus*, especially DBVPG 6257, which contains approximately two *S. cerevisiae* sets of chromosomes, chimeric gene copies may or may not significantly affect the hybrid organism. We investigated whether additional complete *S. cerevisiae* or *S. eubayanus* copies of each chimeric gene were present in the sequencing data. Seven of the sequenced chimeric genes, *HSP82* in all three strains, *CDH1*, *IRR1*, *KEM1* within DBVPG 6261, and *QCR2* are present in the chimeric form only since both full parental copies have been lost. *IRR1* is also an essential gene in *S. cerevisiae*, as well as being non-redundant. If it is presumed that *IRR1* is also essential in *S. pastorianus*, it can be deduced that *IRR1* is a functioning chimeric gene, given that this strain is viable. Only the chimeric form of *HSP82*, a molecular chaperone of protein complexes, is present in each strain of *S. pastorianus*, but its homologue *HSC82* has been retained in both parental forms. The remaining 21 chimeric genes have one or more non-chimeric homologues. Two chimeric genes, *KEM1* in DBVPG 6033 and *TDH2* have additional homologous copies of both *S. cerevisiae* and *S. eubayanus* genes present in the genome. A further two chimeric genes, *FKS3* and *KEM1* in DBVPG 6257 have at least one additional *S. cerevisiae* homologue remaining in the genome. The final 17 chimeric genes are complemented by at least one additional complete *S. eubayanus* homologue. The identification of chimeric genes within *S. pastorianus* is of importance in phylogenetic analysis, since they have the potential to weaken phylogenetic signal and contribute to incongruence [31,32].

Previous studies on the functionality and fitness of chimeric genes show mixed results. The chimeric gene *GPH1* in the lager strain CMBS-33 contains a disruptive base insertion within

its initial *S. eubayanus* sequence, and the resultant gene is not expressed [33]. However, a recent study located a recurrent in-frame breakpoint within *MEP2*, an ammonium permease, in clones of lab-created hybrids of *S. cerevisiae* and *S. uvarum* that were evolved under nitrogen-limiting conditions [34]. The experimentally evolved strains bearing the rearrangement were fitter than the non evolved ones in nitrogen-limiting competition experiments. A number of studies have also examined the fitness effects of rearrangements involving non-homologous genes. The *LG-FLO1*, involved in flocculation appears to have been inactivated in non-flocculent lager yeast by a non-reciprocal translocation of *S. cerevisiae* YIL169c into its C-terminal region in various non-flocculent strains [16]. However, a sulphite-resistant gene found in wine yeast, *SSU1-R* was generated by recombination between the promoter regions of *SSU1* and *ECM34* genes and has been found to grant increased sulphite resistance compared to the wild type allele [22,35].

The reuse of breakpoints

The reuse of breakpoints is a relatively new hypothesis that challenges the long held random breakage model of chromosomal rearrangements [36] and is gaining momentum in studies of mammalian and fly genomes. Studies of mammalian genomes have indicated that breakpoint regions may be reused throughout evolution at a rate between 7.7% and 20% [37,38,39]. The term breakpoint reuse, first coined by Pevzner and Tesler [40], applies to regions of overlapping breakpoints and is not limited to breakpoints shared at the nucleotide level. Although it is unclear whether this overlap in usage is random or non-random, there is increasing evidence of association of these evolutionary breakpoint regions with fragile sites (heritable regions prone to breakage and reorganization) [40,41], with telomeric and

centromeric regions [37], with segmental duplications [37,38], and gene dense regions [37,39]. Moreover, fragile sites prone to breakage, rather than functional constraints on genes, are thought to have been instrumental in shaping gene organisation, at least in *Drosophila* [42]. In our study, we see the reuse of two breakpoints, *HSP82* and *KEM1* in all three sequenced strains of *S. pastorianus* (Table 2). Interestingly, mutagenized lager yeast strains selected under heat stress and high osmotic stress showed a rearrangement in *YGL172w*, which is adjacent to *KEM1* [21], a further indication of breakpoint reuse in this region of the genome. Furthermore, the aforementioned study detected four other rearrangements in or around breakpoint genes that were identified in our study: *TDH2*, *GPH1* and in ORFs adjacent to *PRP8* and *CDH1*. Interestingly, a fully sequenced *S. cerevisiae*- *S. eubayanus* breakpoint in *GPH1*, in the lager strain CMBS-33, differs in location from a breakpoint found in DBVPG 6257 [33]. The breakpoint identified in our study occurs after the first 1496(+6,-5)bp of the gene, whereas the breakpoint in CMBS-33 occurs after the first 330-360bp of the gene. Finally, a breakpoint present in both Group 1 strains in *UTP4* was resolved into two distinct breakpoints at the nucleotide level, and are in close proximity to a breakpoint approximately 30kb upstream of this site in DBVPG 6257 (Table 2, Figure 2). This region on chromosome IV is potentially a site of independent evolutionary breakpoint reuse.

Mechanisms of breakpoint formation

Chromosomal translocation requires the induction of double-stranded DNA breaks followed by incorrect repair of these breaks using an erroneous homologous and repetitive sequence [43]. A recent study found that the potential of a double stranded break in the genome to cause changes in genome copy number increases when the breakage occurs within non-

repetitive DNA rather than repetitive DNA [44]. This effect was far more pronounced in hybrid diploids comparative to non-hybrid diploids. This would suggest that any breakpoint that was to randomly occur within a coding region may be more likely to promote a genomic rearrangement in *S. pastorianus* than if the break was to occur within a repetitive element.

We looked for the presence or absence of Ty elements, their flanking LTRs, tRNAs and origins of replication in proximity to each identified breakpoint. Using the sequence data mapped to each *S. cerevisiae* SacCer2 chromosome in UCSC genome browser (<http://genome.ucsc.edu/>), we manually recorded the nearest repetitive genomic feature to each breakpoint (Table S2). The majority of breakpoints, having occurred within coding regions, were not immediately flanked by repetitive elements, although Dunn and Sherlock [10] have observed clustering of breakpoints near repetitive features in the genomes of lager yeast. Breakpoint proximity to a repetitive element ranges between 0.6kb and 39kb with a mean of 11.4kb. Five sequenced breakpoints were less than 5kb from an element; eleven were between 5 and 10kb away, eight between 10kb and 20kb away and four that are father than 20kb from a repetitive element. Despite the lack of proximity of repetitive elements to breakpoints as a trend, one breakpoint gene, *TDH2* on chromosome XII in DBVPG 6257 is situated adjacent to an ARS, a feature known to promote chromosomal translocation [20]. Eight breakpoints genes, *HSP82* and *KEM1*, in all three strains; *CHD1* in DBVPG 6261 and *QCR2* in DBVPG 6257 are located adjacent to subtelomeric *S. cerevisiae* regions on chromosomes XVI, VII, V and XVI respectively. These regions appear to have undergone significant duplication.

Large areas of homology are known to induce recombination in yeast, and this mechanism is utilised widely for yeast gene deletion in the laboratory [45]. More recently however, very small areas of microhomology have also been indicated in the formation of chromosomal breakpoints in wine yeast [3,22]. Since the reference parental species of *S. pastorianus* are closely related, with an average of 80% nucleotide identity in coding regions [26] we view the induction of recombination via homologous regions in lager yeast a likely hypothesis. Furthermore recombination has occurred more frequently in these coding regions than in non-coding regions, which have an average nucleotide identity of only 62% [26]. We identified areas of microhomology between the two subgenomes (Table S2).

Whatever the underlying sequence that facilitates breakpoint formation, it is likely that one of three events is potentiating breakpoint formation: the unstable nature of newly formed hybrids, an increase in the occurrence of double stranded breaks or an evolutionary pressure for recombination. The double stranded breaks required to initiate recombination are induced at a higher frequency in stressful brewery conditions. A previous study investigating the formation of breakpoints in lager yeast under high stress conditions isolated a number of heat stress and high-gravity stress tolerant mutants generated by EMS-mutagenesis of an existing lager strain, CMBS-33 [21]. The mutants were found to contain breakpoints that are at or near those observed in other natural strains of *S. pastorianus*. Breakpoints arose in a gene directly adjacent to *KEM1*, and within *PRP8*, *CHD1*, *TDH2* and *GPH1*, all of which have been identified as existing breakpoints in our sequenced strains of *S. pastorianus*. These findings promote the existence of breakpoint hotspots in the *S. pastorianus* genome and give evidence for the role of stress in promoting and maintaining genomic breakpoints.

Conclusion

Our whole genome sequencing of three strains of *S. pastorianus* allowed the identification of *S. cerevisiae*- *S. eubayanus* chromosomal breakpoints at a single nucleotide resolution. The majority of *S. cerevisiae*- *S. eubayanus* breakpoints are located within coding regions and were most likely formed as a result of homology and microhomology between the two parental subgenomes, rather than via repetitive elements in the genome. PCR sequencing of breakpoints enabled the further characterisation of these recombination-generated chimeric genes. The greater resolution granted by PCR sequencing allowed us to verify that the breakpoints within *HSP82* and *KEM1* have occurred at an identical genomic location in all three strains. We determined that two different breakpoints have occurred within *UTP4* in the two Group 1 strains. Although the breakpoints are in different positions, this will still be regarded as an example of breakpoint reuse. Interestingly, we note the presence of a chimeric gene *IRR1* in DBVPG 6257 of *S. pastorianus* has lost both parental homologues. Since *IRR1* is also an essential gene, this indicates that the chimeric gene is efficiently utilised by the hybrid. The presence of chimeric genes in the genome also has the potential to weaken the phylogenetic signal of these genes, which could promote incongruence in phylogenetic analyses [32]. Future studies on the function and fitness of chimeric genes may reveal their evolutionary role in facilitating the adaption of *S. pastorianus* to high stress brewery conditions.

MATERIALS AND METHODS

Strains and media

Saccharomyces pastorianus strains DBVPG 6033 (GSY129), DBVPG 6261 (GSY134) and DBVPG 6257 (GSY132) were obtained from DBVPG Industrial Yeasts Collection, University of Perugia, Italy. Yeast was grown at 25°C, 200rpm for 20 hours in YPD (1% yeast extract, 2% peptone, 2% glucose) and genomic DNA extracted using Wizard Genomic DNA Purification Kit (Promega).

Genome sequencing reference strain for *Saccharomyces cerevisiae*, sacCer2 was obtained via the UCSC Genome Browser (<http://genome.ucsc.edu/>). Genome sequencing reference strain for *Saccharomyces uvarum*, sacBay MIT was obtained from the *Saccharomyces* Genome Database (SGD, <http://www.yeastgenome.org>).

SOLiD sequencing

The genomic DNA of three strains of *S. pastorianus* was sequenced using Next Generation Sequencing Applied Biosystems SOLiD 4 platform. Using BFAST (<http://sourceforge.net/projects/bfast/files/>), the reads were mapped to the *S. cerevisiae* reference genome “sacCer2” obtained from UCSC (<http://genome.ucsc.edu/>), which includes 16 chromosomes, the mitochondrial genome and the 2 micron plasmid. The ‘-a 3’ flag of the post-process step was used to obtain unique best scoring alignments. The *S. cerevisiae* ORFs were used to find *S. eubayanus* consensus ORFs in the *S. uvarum* reference strain “sacBay MIT” obtained from SGD (<http://www.yeastgenome.org>). BFAST files were filtered to retrieve sets of reads with 0, 0 to 1 or 0-5 mismatches to each reference genome. Generally,

0 to 1 mismatches was found to be the most suitable cut-off value, having the best agreement to previous microarray data by Dunn and Sherlock (2008).

Data deposition

Raw reads from this study have been deposited at the European Nucleotide Archive under the accession number PRJEB4654.

Chromosomal analysis and breakpoint identification

We used the *S. pastorianus* SOLiD sequence mapped to the pre-annotated *S. cerevisiae* genome sequence via the UCSC Genome Browser (<http://genome.ucsc.edu/>) to identify both *S. cerevisiae* chromosome copy number and potential chimeric chromosomes comprising both *S. cerevisiae* and *S. eubayanus* sequence. These candidate breakpoint regions were identified visually by their abrupt and sustained reduction in *S. cerevisiae* reads along a chromosome. Due to difficulties in mapping and analysing repetitive regions, telomeres were excluded. Similarly, changes in read number due to the presence of a yeast transposon (Ty) or other repetitive element were noted.

Copy number of *S. eubayanus* chromosomes was estimated using the Integrative Genomics Viewer (<http://www.broadinstitute.org/igv/>) to view multiple *S. eubayanus* contigs. Naturally existing rearrangements between chromosomes within the *S. uvarum* genome (chromosomes II-IV, VI-X and VIII-XV) were taken into account when estimating copies of *S. eubayanus* chromosomes.

Primer design and PCR

Species-specific primers were designed to flank each predicted breakpoint area. The *S. cerevisiae* primers were designed using *S. cerevisiae* sequence obtained directly from the UCSC Genome Browser (<http://genome.ucsc.edu/>). The *S. eubayanus* primers were designed by finding the *S. uvarum* orthologue of the nearest *S. cerevisiae* gene using the SGD Synteny Viewer (<http://www.yeastgenome.org>). This orthologue was then mapped to *S. pastorianus* to find consensus sequences for the *S. eubayanus* portion of the *S. pastorianus* genome. The *S. eubayanus*-specific primer was then designed within this consensus sequence. Candidate primers were generated for both *S. cerevisiae* and *S. eubayanus* sequences using Primer 3 (<http://frodo.wi.mit.edu>). To circumvent the potential for non-specific binding between the two closely related subgenomes, these primers were then carefully selected for species-specificity using the Fungal BLAST tool in SGD (<http://www.yeastgenome.org>). For ease of amplification, primers were designed to anneal no more than a few thousand base pairs apart but with sufficient sequence either side of the breakpoint for clear identification of each subgenome. Primer sequences are available in Table S3.

PCR conditions were optimised for each breakpoint to obtain pure homogeneous chimeric sequence. The PCR product was separated by electrophoresis on 1% (w/v) agarose gel. PCR products were purified prior to sequencing using QIAquick PCR Purification Kit (Qiagen, UK).

Sequencing of breakpoint PCR product

Purified PCR products were sequenced at GATC Biotech (Germany). The resulting sequences were analysed using the Fungal BLAST tool in SGD (<http://www.yeastgenome.org>) to identify DNA with high identity to that of either *S. uvarum* or *S. cerevisiae* either side of the predicted breakpoint.

Analysis of sequence identity

Percentage nucleotide identity between each subgenome and *S. pastorianus* was calculated using *S. cerevisiae* and *S. uvarum* sequences obtained from SGD (<http://www.yeastgenome.org/>) and Clustal Omega (<http://www.ebi.ac.uk/Tools/msa/clustalo/>). Amino acid identity was calculated similarly but chimeric nucleotide sequences were first converted to protein sequences using Expasy Translate Tool (<http://web.expasy.org/translate/>).

ACKNOWLEDGEMENTS

The authors wish to thank Dr Casey Bergman for help in designing the bioinformatics approach and suggesting analysis of breakpoint reuse.

FIGURE LEGENDS

Figure 1. Representation of *S. pastorianus* reads mapped to *S. cerevisiae* chromosomes in the UCSC Genome Browser. Full set of *S. cerevisiae* chromosomes is displayed for each strain using the UCSC Genome Browser. Depth of track corresponds to read number so potential *S. cerevisiae*- *S. eubayanus* breakpoints can be located and ploidy can be deduced. An abrupt and sustained reduction in read number is indicative of a *S. cerevisiae*- *S. eubayanus* breakpoint. Track depth window is set to accommodate three copies of a chromosome, since *S. cerevisiae* chromosome copy number in these strains generally varies between zero and three.

Figure 2. Diagram showing different breakpoint positions in *S. pastorianus* chromosome IV. To locate the breakpoint at the nucleotide level, species-specific primers are designed on the Watson strand around putative breakpoints (SC F: *S. cerevisiae* forward primer, SU F: *S. uvarum* forward primer. SC R: *S. cerevisiae* reverse primer. SU R: *S. uvarum* reverse primer). Strains are labelled Group 1 or Group 2 according to their previous assignment [10].

SUPPORTING INFORMATION

Figure S1. Full set of sequences across each breakpoint in all three strains of *S. pastorianus*. The region covering each breakpoint was amplified using species-specific primers. The PCR products were sequenced on the Watson strand at GATC (Germany).

Figure S2. Multiple sequence alignment of each *S. pastorianus* breakpoint sequence to parental species. *S. cerevisiae* (Scer, Saccharomyces Genome Database), *S. uvarum* (MIT_Sbay or WashU_Sbay, Saccharomyces Genome Database) and the region sequenced over the breakpoints in each *S. pastorianus* strain were aligned using Clustal Omega. Note that ORF sequences obtained from the Saccharomyces Genome Database are taken from Cliften *et al.*[46] and Kellis *et al.*[26]. Low quality ends of breakpoint sequences were trimmed before alignment. Breakpoint area is demarcated in grey with central position underlined. All gene sequences are 5'-3'.

Table S1. Breakpoints which were not successfully amplified by PCR.

Table S2. Analysis of the breakpoint region in each strain of *S. pastorianus*.

Table S3. Primer sequences for amplification of breakpoint regions.

^aBased on *S. cerevisiae* sequence UCSC SacCer2 June 2008; ^bNucleotide identity between *S. cerevisiae* and *S. uvarum* homologues (<http://www.yeastgenome.org/>) ; ^cRegions of microhomology between 5-30bp observed between *S. cerevisiae* and *S. uvarum* homologues at the breakpoint site using SGD Fungal Alignment (<http://www.yeastgenome.org/>) ;

^dRegions of local homology over 30bp observed between *S. cerevisiae* and *S. uvarum* homologues at or within a few hundred bp of the breakpoint site using SGD Fungal Alignment (<http://www.yeastgenome.org/>) ; ^eNearest repetitive feature to the site of breakpoint formation annotated in the *S. cerevisiae* genome. Feature distance obtained using the UCSC Genome Browser (<http://genome.ucsc.edu/>).

Table S3. Primer sequences for amplification of breakpoint regions.
