ABSTRACT

We analyze 60 months of all sky data from the Fermi-LAT. The Fermi Bubble structures discovered previously are clearly revealed by our analysis. With more data and, consequently, better statistics we can now divide each bubble into 12 constant longitude slices to investigate their gross γ-ray spectral morphology. While the detailed spectral behaviour of 13 each slice derived within our analysis is somewhat dependent on the assumed background model, we find, robustly, a relative deficit of the flux at low energies (i.e., hardening) towards the top of the South Bubble. In neither Bubble does 15 the spectrum soften with longitude. The morphology of the Fermi Bubbles is also revealed to be energy dependent: at high energies they are more extended. We conclude from the gamma-ray spectrum at high latitudes that a low energy 17 break in the parent cosmic ray population is required in both leptonic and hadronic models. We briefly discuss possible leptonic and hadronic interpretation of this phenomenology.

Key words. Gamma rays: diffuse background, ISM: cosmic rays

11 The constant longitude slices to each slice derived with a Two huge, bubble-like structures have been reported by [Su et al. \(2010\)](#page-7-0), [Dobler et al. \(2010\)](#page-7-1), and [Su & Finkbeiner \(2012\)](#page-7-2) $\frac{1}{21}$ in Fermi-LAT gamma ray data to extend ∼50° above and below the Galactic center. The gamma ray emission from these $\overline{22}$ structures, dubbed the 'Fermi Bubbles' (FBs), exhibits a E^{-2} type spectrum, significantly harder than the spectrum of the diffuse gamma-ray emission from the Galactic disk. Remarkably, structures coincident or similar to the FBs can be seen at other wavelengths, including the (total intensity) microwave haze found in WMAP [\(Finkbeiner 2004\)](#page-7-3) and, most recently, in Planck data [\(Planck Collaboration et al. 2013](#page-7-4)); the polarized microwave structures reported by [Jones et al.](#page-7-5) [\(2012\)](#page-7-5); the large-scale, biconical structures found [\(Bland-Hawthorn & Cohen 2003](#page-7-6)) in ROSAT X-ray data [\(Snowden et al.](#page-7-7)); and the giant polarised radio lobes recently found at 2.3 GHz [\(Carretti et al. 2013](#page-7-8)). Several models have been proposed to explain both the morphology and spectral properties of the FBs [\(Cheng et al. 2011;](#page-7-9) [Mertsch & Sarkar](#page-7-10) [2011](#page-7-10); [Crocker & Aharonian 2011;](#page-7-11) [Crocker 2012;](#page-7-12) [Zubovas et al. 2011;](#page-8-0) [Zubovas & Nayakshin 2012;](#page-8-1) [Guo & Mathews 2012;](#page-7-13) [Guo et al. 2012;](#page-7-14) [Yang et al. 2012;](#page-8-2) [Crocker et al. 2013](#page-7-15)). These models predict different energy dependent morphologies. For example, in the simplest IC model (e.g., discussed by Su et al. 2010) with a spatially-independent electron spectrum described by a power law electron population with a low energy cutoff at 500 GeV, one expects a tendency for softening of the gamma-ray spectra at high latitudes. This is due to the gradual reduction of the IC components produced via upscattering of the optical and UV photons - the main target fields contributing to the production of gamma-rays above 10 GeV that also decline towards high latitudes. On the other hand, in a simple one-zone hadronic model (e.g., [Crocker & Aharonian 2011\)](#page-7-11) the protons' steady state distribution should produce a similar spectrum of gamma rays at all latitudes. Thus, studies of the energy-dependent morphology of the FBs may shed light on the nature of the gamma ray emission mechanism(s). This is the basic motivation for the current study.

39 Here we present an analysis based on 60 months' $Fermi-LAT$ data. We find a similar overall morphology and spectrum 40 for the FBs to those obtained by [Su et al. \(2010\)](#page-7-0). The FBs exhibit a rather homogeneous *surface* brightness. Importantly, 41 this implies non-homogeneous *volumetric* emissivities considering projection effects [\(Su et al. 2010\)](#page-7-0). The FBs, however, 42 are not completely uniform: they exhibit some 'hot spots' (referred to by [Su et al. \(2010\)](#page-7-0); [Su & Finkbeiner \(2012](#page-7-2)) as the 43 'jet', 'donut' and 'cocoon').

 In this paper the significantly larger photon statistics and the availability of the recently updated Fermi science software tools [\(Ackermann et al. 2012\)](#page-7-16) allow us to investigate the gross spectral morphology of the FBs. A somewhat similar study has recently been conducted by [Hooper & Slatyer \(2013\)](#page-7-17). However, they concentrate spectral features in low latitudes while we focus on the high latitude, especially the top of the bubble. We proceed by dividing each bubble into several slices to investigate possible gamma-ray spectral change with latitude. Employing different background models, we find, robustly, a spectral hardening, or more specifically, a deficit of low energy flux towards the top of the SFB. We are also able to extend the spectrum of the FBs to lower energy than previously attempted because of the improvement of the analysis software and the instruments response functions. The paper is structured as follows: in section 2 we present

 the results of our data analysis, in section 3 we discuss the fitting of leptonic and hadronic models to the gamma ray data, and in section 4 we set out our conclusions.

2. Data Analysis

55 We use the publicly-available data obtained by the Fermi-LAT in the gamma-ray energy interval from 100 MeV to 300 GeV over the period of 4 Aug 2008 and 17 July 2013 (MET 239557417 - MET 395797613). To avoid contamination from 57 charged particles we use the ULTRACLEAN data set in the analysis. We adopt the instrument response function version P7V6 [\(Ackermann et al. 2012\)](#page-7-16). All events are binned in the all-sky map in HEALPIX format with NSIDE=256. The sources in the 2^{nd} Fermi catalog [\(Abdo et al. 2012\)](#page-7-18) are subtracted from the counts map using the flux in the catalog. 60 To take into account the energy dependent point spread function (PSF) of the $Fermi_{LAT}$, we use the functional form [1](#page-1-0) described in the LAT homepage¹ when masking sources in the catalog.

 We use a likelihood method for determining the FBs' apparent morphology and spectral features for different diffuse 64 emission templates. The likelihood function has the form $log(L) = \sum_{k_i} log(\mu_i) - \mu_i - log(k_i!)$, where k is the number 65 of photons in the *i*-th bin in the counts map and μ_i is the predicted number of photons within a particular linear combination of the templates. The sum is over all the spatial bins in the map. The likelihood function is determined in different energy bins to derive the energy spectrum. For fitting different energy bins, rather than smoothing the map to an universal FWHM (full width at half maximum) as used in [Su et al. \(2010\)](#page-7-0), we only smooth the diffuse templates with the Fermi PSF and then fit the counts map as a linear combination of these smoothed diffuse templates. The normalization of each diffuse template is left free in the likelihood fitting. We do not assume a priori the existence of a 71 pair of bubble-like structures. We only use the spatial templates for π^0 decay and IC gamma-rays generated by GALPROP [\(Vladimirov et al. 2011\)](#page-8-3) in addition to the isotropic template related to the extragalactic gamma ray background and cosmic ray contamination. Finally, we take into account the large diffuse structure high above the plane to Galactic north which may be connected with the nearby ISM feature Loop 1 [\(Su et al. 2010\)](#page-7-0). In generating the diffuse templates with GALPROP, we adopt the default Galdef webrun setting, the 2D plane diffusion model that was tuned to fit the ACE data.

 After subtracting the best-fit linear combination of the diffuse templates, we find residual maps. By summing over all energy bins above 1 GeV we obtain the image in Fig. [1](#page-2-0) in which two bubble-like structures are clearly seen. Next we generate spatial templates for the FBs from the residual map. In the second step of our analysis these Bubble templates are included. We employ the likelihood method mentioned above once again and obtain the spectrum of all the diffuse templates.

To derive the spectrum in different parts of the FBs, we divide the SFB $(-55° < b < -25°)$ into four slices and the 83 North Fermi Bubble $(25[°] < b < 50[°]; 'NFB')$ into three. To avoid contamination from the Galactic plane, in the fitting we mask out the inner $\pm 25^{\circ}$ region. The position of each analysis slice can be found in Fig. [3.](#page-3-0) The SED of each slice is shown in Fig. [2](#page-2-1) where the numbers 1 to 4 run from lowest to highest latitude. From the SEDs it is evident that the spectrum of the highest southern slice is in deficit at low energies relative to the other slices. It is important to note that this same slice suffers little from geometric projection effects and is thus a true reflection of the spectrum at the top of the SFB. The spectrum at the top of the SFB is, therefore, significantly different from that in the interior. Fig. [3](#page-3-0) reveals the different morphologies of the FBs in different energy bins; at high energies the SFB is clearly more extended than at low energies. This is highlighted in Fig. [4.](#page-3-1) It should also be noted that in the top slice of the SFB (South 4) there are no 91 known point sources from the 2^{nd} Fermi catalog, making our conclusion about the spectral variation quite robust.

 Regarding the energy-dependent morphology of the FBs, we also flag the following point to be dealt with in further work: as evident from figs. [3](#page-3-0) and [4,](#page-3-1) the SFB is also relatively more extended to Galactic west at high energies than low energies implying a spectral hardening going from east to west. As far as we are aware, no model for the FBs currently accounts for this effect. It is interesting that, because of this extension to the west, at high energies, the FBs come to 96 more closely resemble the polarised radio lobes detected at [2](#page-1-1).3 GHz (Carretti et al. $(2013)^2$).

 Accurate determination of the morphology and spectral features of the Bubbles strongly depends on reliable modeling of the diffuse background. Unfortunately, because of uncertainties in the distributions of cosmic rays and interstellar gas, our knowledge about the diffuse gamma-ray background is imperfect. In such circumstances, one can only introduce 100 different templates that instantiate different estimates of the background and try to derive the true Bubble flux with them using a likelihood method. Unfortunately, different choices of background templates alter the final result significantly and this may lead to significant systematic errors. To study such possible errors, we investigate the 128 GALPROP models listed by [Ackermann et al. \(2012\)](#page-7-19). The aim of [Ackermann et al.](#page-7-19) [\(2012\)](#page-7-19) was to study the origin and propagation of cosmic-rays and the distribution of the interstellar medium by simultaneously fitting diffuse gamma ray emission and cosmic ray data. Although all their models underestimate the GeV emission at low latitudes [\(Ackermann et al. 2012](#page-7-19)), 106 this has little influence on our results given our masking of the inner $\pm 25^\circ$ when deriving spectra. The 128 models 107 are different in cosmic ray (CR) source distribution, CR halo size, HI spin temperature and $E(B - V)$ magnitude cut. 108 Following perusal of the the online material for [Ackermann et al. \(2012](#page-7-19)), we found that 64 models with $z = 8$ kpc and $z = 10$ kpc do not fit the ${}^{9}Be/{}^{10}Be$ data well (the derived curves fall outside of the error bars of nearly all the data

110 points), where z is the height of the CR halo. Therefore we abandon these, and investigate the other 64 models as diffuse 111 emission templates.

 With the same procedure as described above, we find the SEDs in different slices with all chosen templates; the results are summarized in Fig. [5.](#page-3-2) Because of the large systematic errors, we may not claim a deficit at low energies and high latitude in the NFB. However, in the SFB the low energy deficit of the top slice is significant for every template. It should be noted that, due to the slight differences in overall flux normalisation for the different templates choices, differences of spectral shape are smeared out if we plot them all together as in Fig. [5](#page-3-2) which, therefore, suggests a smaller difference between the top and bottom slices than exists in reality. In Fig. [6](#page-4-0) we show 8 examples of SEDs for the slices in the SFB which give the extreme cases of the gamma ray flux. From these individual examples the low energy deficit in the top slice is much more evident. Results for the northern slices are also shown in Fig. [7](#page-5-0) which reveal the low energy part of the top slice has very large uncertainties. The large systematics in the NFB are likely due to the fact that it is partially coincident with the extended Loop 1 structure whose physical origin and exact morphology and spectral features are still uncertain.

123 3. Discussion

124 The gamma-ray residual maps obtained in the current study – based on six years' Fermi-LAT data – confirm that the surface brightness of each bubble is homogeneous at a gross level. This implies that the volumetric emissivity is not homogeneous, otherwise we would detect a higher brightness in the center of each bubble due to projection [\(Su et al.](#page-7-0) [2010](#page-7-0)). One possible explanation of this may be higher turbulence in the bubbles' edges generating more efficient particle acceleration or stronger confinement of high energy particles there with a resulting increase in the local gamma ray

Fig. 3. Residual maps for different energy bins. The left and right panels correspond to energy intervals 1 − 2 GeV and $10-30 \text{ GeV}$, respectively. The inner disk of the Galaxy (|b| < 2^o) is masked. The boxes laid over the residual maps show the position of each slice.

Fig. 4. Zoom in of Fig. [3](#page-3-0) for the SFB region. Left panel $1 - 2$ GeV and right panel $10 - 30$ GeV.

129 emissivity; alternatively, in a non-saturation hadronic model, higher gas densities towards the edges may have the same 130 effect [\(Crocker et al. 2013\)](#page-7-15).

131 Below we assume the low energy deficit of the gamma ray spectrum at high latitudes found above is a real effect and 132 discuss its possible implications.

134 To simplify our modeling, we assume each bubble is a sphere with a radius 3.4 kpc. The 2-d projection of each 135 bubble can be approximated as a half sphere in the region $b > 30°$ for the NFB and $b < -30°$ for the SFB. The

133

Fig. 6. Six examples of SEDs for slices in the SFB.

136 center of each bubble is located at $(0.0,\pm 5\text{kpc})$ in Galactic coordinates. Assuming an *intrinsic* north-south symmetry, 137 we only analyse the SFB and, to reveal most starkly the spectral change with latitude, we consider only slice South 1 138 $(-33° < b < -25°)$ and South 4 $(-55° < b < -47°)$ in detail. Slice South 1 covers the center of the SFB. We use the ISRF value in Galprop at $(0.0,5 \text{ kpc})$ for the average value of the slice South 1 in the calculation, $w_{IR} = 0.18 \text{ eV/cm}^3$ 139 140 and $w_{opt} = 0.9 \text{ eV/cm}^3$. The height of South 4 is about 7 kpc, thus we adopt the ISRF energy density from Galprop 141 at $(0.0.7 \text{ kpc})$, 0.7 eV/cm^3 for the optical component and 0.15 eV/cm^3 for the IR component. The IR and optical 142 photon fields are modeled as diluted blackbody (gray body) spectra with temperatures of 100 K and 5000 K, respectively. 143

 In the hadronic scenario, motivated by the relative low energy deficit of the gamma ray flux in the top slice, we fit the SED in South 1 with a pure power law proton spectrum while for South 4 we use a power law with a low energy break that we find needs to be at 20 GeV to fit the data. We assume the proton flux below the break is zero for simplicity (see Fig. [8\)](#page-6-0). Our results are shown in Fig. [9.](#page-7-23) The required low energy break may arise naturally due to energy-dependent diffusion effects in a non-steady-state scenario: given South 4 is far from the (assumed) injection source in the plane, it may be that only high energy particles (which diffuse faster) have had time to travel there since a previous injection event or given the age of the structure. The formalism describing these energy-dependent diffusion effects can be found in [Aharonian & Atoyan \(1996\)](#page-7-24) where both impulsive and continuous injection cases are described. The position of the low energy break can be estimated by equating the age of the bubble (or the time since a previous burst) with the diffusion

Fig. 7. Six examples of SEDs for slices in the NFB.

153 time, i.e., the beak energy is $E_{\text{bk}} \simeq (d^2/(D_0 t))^{\frac{1}{\delta}}$, where d is the distance of the top slice from the injection source, t is 154 the age of the bubble (or burst) and $D(E) = D_0 E^{\delta}$ is the energy dependent diffusion coefficient. If we assume protons 155 are injected at the Galactic center, d is about 7 kpc. Notice that in the kinetic equations which govern proton diffusion 156 only the combination D_0 t appears. Thus any timescale can be obtained if we tune the diffusion coefficient D_0 . If $D(E)$ 157 takes a value similar to that in the Galactic plane, say 4×10^{28} cm² s⁻¹ at 1 GeV and $\delta = 0.3$, the age of the FBs should 158 be $t \sim 10^8$ yr (cf. [Crocker et al. 2013\)](#page-7-15). Alternatively, if there is continuous proton injection into the FBs over 10^{10} yrs 159 we need a rather small diffusion coefficient, $D_0 \sim 10^{26}$ cm² s⁻¹ at 1 GeV, which is about 1/100 of that in the Galactic 160 plane.

161 If we assume the injection is impulsive and the ISM density is 0.005 cm^{-3} the total energy in protons needed to light the Bubbles is of the order 10^{56} erg. Note that if we assume the simple geometry mentioned above and a magnetic field 163 B ∼ 10 μ G as suggested by [Carretti et al. \(2013](#page-7-8)), then the energy densities of cosmic rays and magnetic fields are close 164 to equipartition. A burst-like injection event requires that the duration of the injection is much smaller than the age of 165 the structure which is $t \sim 10^8$ yr (for $D_0 = 4 \times 10^{28}$ cm² s⁻¹ at 1 GeV), i.e., the duration of the injection event would 166 have to be of order 10^7 yr or less in this case. Then the injection rate is of the order 10^{41} erg/s, two orders of magnitude 167 larger than the the X-ray luminosity of a X-ray reflection nebulae near the Galactic center (e.g., [Gando Ryu et al. 2012](#page-7-25)), 168 but still only one thousandth of the Eddington Luminosity of Sgr A^* , ~ 5 × 10⁴⁴ erg/s.

 A possible concern for an energy-dependent diffusion scenario is that, in the high energy range for which the diffusion length is much larger than the distance to the source, the predicted proton density should be the same at all latitudes 171 for the impulsive case, or scale as $1/R$ (where R is the distance to the injection source) for the continuous case. Thus, given the (expected) relatively smaller line of sight through the top of the SFB, one naively anticipates that the gamma ray flux in South 4 is smaller than that in South 1. The observed data reveal a similar total flux in both slices at high

Fig. 8. Assumed CR proton (left) and electron (right) distributions in Slices 1 and 4 of the SFB

 energy, however. One possible resolution to this tension may be that the target gas density is higher at high latitudes. It is also likely that the geometry of the FBs is different from our simple assumption of sphericity thereby entailing non-trivial projection effects.

.

 In a leptonic scenario the low energy deficit of gamma ray flux in the top slice also requires a corresponding low energy break in the electron distribution (see Fig. [8](#page-6-0) right). This can, again, be produced by several mechanisms. Firstly, the energy-dependent diffusion effects mentioned above also work for electrons in principle (cf. [McQuinn & Zaldarriaga](#page-7-26) [2011](#page-7-26)). However the much faster cooling of electrons relative to protons tends to prevent such effects playing an important 182 role. To fit the high energy gamma ray data we need TeV electrons, whose cooling time scale is about 10^5 yrs in the 183 circumstances of the FBs. Thus, even if we assume very fast diffusion with the diffusion coefficient of 4×10^{29} cm²/s at 184 1 GeV (and an index of 0.6), the diffusion distance of TeV electrons in 10^5 yrs is only 2 kpc, significantly less than the distance of South 4 from the plane (which is more than 5 kpc). This implies high energy electrons accelerated at low latitudes can never reach South 4 and, as a result, if we want to explain the radiation of the FBs in a leptonic scenario, the electrons should be accelerated in situ.

 The second problem related to electrons concerns the interpretation of the very hard energy spectrum of radiation below 5 GeV. Such a hard spectrum formally can be explained by assuming a low energy break in the electron spectrum. However, if the electrons are cooled, no matter how hard the injection spectrum is, because of the radiative $(dE/dt \sim E^2)$ type) losses the resulted steady-state distribution below the break in the injection spectrum, will have have a standard, E^{-2} power law-spectrum. The latter will result in IC gamma-ray spectrum with a photon index 1.5 which is still not sufficient to explain the observed gamma-ray spectrum of South 4; below 5 GeV the photon index of the latter is as small as 1. One can formally overcome this problem assuming that the electrons stay uncooled in FBs. However in order to reproduce the break in the gamma-ray spectrum, one would need a corresponding break at 100 GeV. The corresponding synchrotron cooling time at this energy, $t \sim 8 \times 10^5 \left(\frac{100 \text{ GeV}}{E}\right)$ 197 synchrotron cooling time at this energy, $t \sim 8 \times 10^5 \left(\frac{100 \text{ GeV}}{E} \right) \left(\frac{B}{10 \mu \text{G}} \right)^{-2}$ yr, appears significantly shorter than the age of FBs within any reasonable model of the latter. Thus we need very efficient continuous acceleration acceleration of electrons which would dominate over the rate of energy losses and in that way keep very hard the steady-state spectrum. 200 This in principle can be realized with stochastic acceleration which can produce Maxwellian type steady-state energy 201 distribution of electrons. Indeed adopting an electron distribution like $N(E) \sim E^2 exp(-E/E_0)$ with $E_0 = 300$ GeV, we can have a reasonable fit to the detected gamma-ray spectrum in South 4, as it is shown in Fig. [9.](#page-7-23) For comparison, we also show IC emission at the position of South 1 and South 4 by adopting a broken power law electron distribution with an index 2 below the break at 200 GeV and 3 above. The results fit the SED of South 1 well, but fail to fit that of South 4, which are also shown in Fig. [9.](#page-7-23)

 Anisotropy effects may, in principle, increase the IC gamma ray flux at high latitudes since most of seed photons come from regions in the Galactic plane; thus gamma-rays we detect at high latitudes are a result of (almost) head-on collisions. To probe this effect we use the formalism described in [Moskalenko & Strong \(2000\)](#page-7-27). The enhancement factor is defined by the flux ratio of the anisotropic IC to the isotropic IC assuming the the same ISRF energy density. Results for the positions of South 1 and South 4 are shown in Fig. [9.](#page-7-23) We can see that although the anisotropic IC effect may cause a spectral a hardening, however the difference between South 1 and South 4 is rather small, less than 10%. It appears not sufficient to explain the very hard spectrum of South 4.

4. Summary

 In this paper we re-analyze the Fermi-LAT data covering the FB region. With an improved instrumental response function and more data, we are able to extend the previously obtained spectrum to lower energies. Furthermore we divide each bubble into slices to investigate possible variation of the spectrum with latitude. Given the improved data, for the first time, we can determined robustly that the spectrum of the top of South Bubble drops appreciably at low

Fig. 9. Left and Middle panel: Fitting the FBs' SED with the hadronic model (left panel) and the leptonic model (middle panel) described in the text. The red curve shows the fitted spectrum and the red hatched region spans all spectra resulting with from different templates for South 1; blue curve and hatched region are for South 4. For leptonic models, for South 1 we assume the broken power law described in the text and the ISRF value given by GALPROP. For South 4, the black curve is for the same broken power law with the ISRF floating while for the gray curve we use the ISRF in GALPROP at the position of South 4 and a Maxwellian type electron distribution with $E_{\rm bk} = 300$ GeV. In our hadronic scenario energy dependent diffusion effects are considered as described in the text. Right panel: The enhancement factor due to anisotropic IC. The IR and Opt/UV components of the ISRF have effective temperatures of 100 K and 5000 K, respectively. Results for $z = 5$ kpc and $z = 7$ kpc are shown (approximate heights of South 1 and South 4 above the Galactic plane).

218 energies relative to the spectrum determined at lower latitudes. We also show that the morphology of the South Bubble 219 is energy dependent; at high energy the structure is relatively more extended to both Galactic south and west.

 We have also investigated the influence of different choices of background model on the results of our analysis. We found that background models may significantly alter the apparent gamma-ray signal from the FBs. Nevertheless, the spectral hardening with latitude in the South Bubble remains a robust result. In neither Bubble do we find a spectral steepening with latitude.

 The relative suppression of the low energy gamma ray spectrum may be explained within a hadronic model for the FBs wherein energy-dependent diffusion leads to a relative deficit of low energy protons at high latitudes. Specifically, if protons are injected in the plane, the finite age of the FBs may only allow high energy protons to propagate to high latitude thereby predicting a gradual hardening of the gamma ray spectrum with latitude.

 In leptonic models the fast cooling of electrons means they cannot move too far from their accelerators and distributed acceleration inside the FBs seems to be favored. For the case of stochastic acceleration the maximal electron energy might be expected to be 1 TeV, implying the optical/UV and IR component of the ISRF may play an important role in gamma ray production inside the FBs. However, the attenuation of these components of the ISRF at high latitudes is, at least naively, in conflict with the observed hardening of the gamma ray spectrum in the highest slice of the South Bubble unless a very specific electron spectrum evolution is realized. 234
