Abstract

Resolving in time the dynamics of light absorption by atoms and molecules, and the electronic rearrangement this induces, is among the most challenging goals of attosecond spectroscopy. The attoclock is an elegant approach to this problem, which encodes ionization times in the strongfield regime. However, the accurate reconstruction of these times from experimental data presents a formidable theoretical challenge. Here, we solve this problem by combining analytical theory with ab-initio numerical simulations. We apply our theory to numerical attoclock experiments on the hydrogen atom to extract ionization time delays and analyse their nature. Strong field ionization is often viewed as optical tunnelling through the barrier created by the field and the core potential. We show that, in the hydrogen atom, optical tunnelling is instantaneous. By calibrating the attoclock using the hydrogen atom, our method opens the way to identify possible delays associated with multielectron dynamics during strong-field ionization.

I. INTRODUCTION

Advances in attosecond technology have opened up the intriguing opportunity to time electron release during photoionization. New experimental techniques such as the attosecond streak camera[1], high harmonic spectroscopy[7], attosecond transient absorption[3] and the attoclock[4, 5, 7, 11] are now able to provide the exceptional time-resolution – down to the level of tens of attoseconds (1 asec = 10^{-18} s) – needed to time-resolve ionization. The removal of an electron from an atom or molecule during one-photon ionization creates a non-equilibrium charge distribution which evolves on the attosecond time scale[8]. Ionization time then serves as a sensitive measure encoding the dynamics of core rearrangement triggered by electron removal (see e.g.[9, 10]).

While the use of intense IR fields as either pump or probe in time-resolved ionization experiments provides access to the time scale of electronic motion, it also introduces a hurdle in interpreting such experiments [6, 9–11, 13, 14]. Identifying and disentangling time delays related to multielectron dynamics from the apparent delays induced by the interaction with the IR field is challenging both technically and conceptually. In one-photon ionization [1], understanding the nature of the measured delays required the accurate calibration of the measurement schemes, with the hydrogen atom used as a benchmark, see e.g. [6, 11, 13, 14].

Looking beyond the weak field one-photon case, multiphoton ionization can also excite rich multielectron dynamics, which calls for the accurate measurement of ionization times in the strong field regime. What's more, strong field ionization is often viewed as a tunnelling process, where the bound electron passes through the barrier created by the laser field and the core potential. Consequently, time resolving this process opens the intriguing opportunity [4, 5, 7] to revisit the long-standing problem of tunnelling times.

The measurement of tunnelling times in strong-field ionization has been pioneered by the group of U. Keller [4, 5, 7, 11] using the attoclock technique. The attoclock set-up measures angle- and energy- resolved photoelectron spectra produced by ionization in strong, nearly circularly polarized infrared (IR) fields. Essentially, the rotating electric field vector serves as the hand of a clock, deflecting electrons in different directions depending on their moment of escape from the atom. The tunnelling perspective provides a simple picture of how this works. The strong circularly polarized field combined with the binding potential of the atom together create a rotating barrier through which an electron can tunnel (Fig.1a). Due to the

rotation of the barrier, the electron tunnels in different directions at different times, and is subsequently detected at different angles after the end of the pulse (Fig.1b).

Suppose the field rotates counterclockwise and reaches its maximum at t = 0 when the field vector $\mathbf{F}_L(t)$ points at an angle of $\phi = 90^\circ$ (Fig.1b). In the tunnelling picture, this instant is associated with the thinnest tunnelling barrier and the highest probability of ionization. In the absence of (i) electron-core interaction after tunnelling and (ii) tunnelling delays, we expect that an electron which escapes at time $t_0 = 0$ will be detected at an angle of $\phi = 0^\circ$, orthogonal to $\mathbf{F}_L(t)$. Indeed, if the electron is released from the barrier with zero initial velocity as suggested by the tunneling picture (Fig.1(a)), its final momentum at the detector will be $\mathbf{p} = -\mathbf{A}_L(t_i)$, where $\mathbf{A}_L(t_i)$ is the vector-potential of the laser field at the moment of ionization. For circularly polarized pulses, \mathbf{A}_L is orthogonal to \mathbf{F}_L (up to effects of the ultrashort envelope).

An observed deviation of the photoelectron distribution maximum from $\phi = 0^{\circ}$ could come from the deflection of the outgoing electron by the attractive core potential (Fig.1b) and, possibly, from tunnelling delays[4, 5]. This deviation is characterised by the offset angle θ (Fig.1c). Experimentally, θ can be measured with high accuracy ($\delta\theta \sim 2^{\circ}$), which implies the potential to measure ionization delays with accuracy $\delta\tau = \delta\theta/\omega_L \sim 15$ asec for 800 nm radiation.

However, the reconstruction of ionization times from experimentally measured offset angles is sensitive to the assumptions made about the underlying process. To date, the theoretical approaches used to interpret attoclock results have relied on three assumptions [4, 5, 7, 11, 15]. (A1) First, based on exponential sensitivity of strong-field ionization to the electric field, it is assumed that the highest probability for the electron to tunnel is at the peak of the electric field. (A2) Second, ionization is assumed to be completed once the electron emerges from the barrier. (A3) Third, electron dynamics after the barrier exit are described classically, assuming some point of exit and initial distribution of velocities [7, 16]. Within this classical model, the accuracy of extracting time delays from attoclock measurements depends on the initial conditions assumed for the classical electron dynamics. These initial conditions, however, cannot be established unambiguously. The resulting ambiguity in interpreting attoclock measurements is a major bottleneck for reconstructing ionization times with attosecond precision.

In light of this, we provide a consistent interpretation and calibration for attoclock mea-

FIG. 1. The attoclock setup. (a) The tunnelling perspective on the attoclock: the laser field and the core potential together create a rotating barrier through which the bound electron can tunnel. As the barrier rotates, the electron will escape in different directions at different times. (b) A cartoon illustrating our ionization geometry. The laser field rotates counter-clockwise and reaches its maximum value when the electric field \mathbf{F}_L points up at an angle of 90°. When the electric field points up, the electron tunnels down, and in the absence of electron-core interaction, we would expect to detect it at an angle of $\phi = 0^\circ$. An offset θ from this angle could be due to the attractive potential of the core (force \mathbf{F}_C) as shown in the figure, and/or possible tunnelling delays. (c) The experimental observable: the angle- and energy- resolved photoelectron spectrum, shown for ionization from the ground state of the hydrogen atom induced by a single-cycle circularly polarized infrared pulse. Dashed lines show the offset angle θ .

surements of ionization times, making no ad hoc assumptions. We do this by combining analytical theory with ab-initio simulations. To calibrate the attoclock, we focus on the hydrogen atom. Doing so, we (i) find very good agreement between our analytical theory and numerical experiments, (ii) show that, for one-electron systems, purely tunnelling delays during strong-field ionization are equal to zero and (iii) reconstruct ionization times for the hydrogen atom, finding deviations from the conventional tunneling picture expressed by assumptions A1-A3. We also show how the calibration based on single active electron dynamics can be used to identify multielectron contributions to the attoclock observable in multi-electron systems.

II. RESULTS

A. Theoretical description.

Our theoretical approach is based on the Analytical R-Matrix (ARM) method [2–5]. The key mathematical approximations of this theory and its application to nearly singlecycle pulses are described in the Appendix. In ARM, the probability $w(p, \phi)$ of detecting an electron at an angle ϕ with momentum p is described by an integral over all possible instants of ionization[2–5]. By calculating this time-integral using the saddle point method, we express $w(p, \phi)$ via the contribution of 'quantum trajectories' that start from the atom at complex times $t_s(\phi, p)$. Mathematically, the saddle point approach is justified when the electron action S accumulated along the 'quantum trajectory' is large, $S \gg \hbar$, which is naturally satisfied in strong low-frequency fields. ARM also requires sufficiently thick tunnelling barriers, restricting analytical work to circularly polarized fields with intensities $I < 4 \times 10^{14}$ W/cm². Comparison with ab-initio calculations allows us to judge the accuracy of the analytical approach.

Since time arises naturally along each 'quantum trajectory', establishing a connection between the attoclock observable $w(\phi, p)$ and the associated time $t_s(\phi, p)$ becomes possible. It is this mathematically established connection that allows us to calibrate the attoclock. The real part $t_i(\phi, p) \equiv \text{Re}t_s(\phi, p)$ is the 'ionization time'. In the tunnelling picture, this time corresponds to the moment at which the electron emerges in the classically allowed region. For a 'zero-range' binding potential, which supports only a single bound state, we obtain:

$$\operatorname{Re} t_s^{(0)}(\phi, p) \equiv t_i^{(0)}(\phi, p) = \frac{\phi}{\omega} + \Delta t_i^{\operatorname{env}}(\phi, p).$$
(1)

Here the superscript (0) denotes the 'zero-range' potential. The small correction Δt_i^{env} is due to the ultrashort pulse envelope. It accounts for the fact that, for very short circular pulses, the electric field and the vector potential are not orthogonal at all times during the pulse; Δt_i^{env} disappears for ionization at the peak of the field. In the geometry of Fig.1, the offset angle θ is the angle ϕ associated with the highest photoelectron signal.

For an arbitrary potential, ARM yields (see Appendix):

$$t_i(\phi, p) = \frac{\phi}{\omega} + \Delta t_i^{\text{env}}(\phi, p) + \Delta t_i^C(\phi, p), \qquad (2)$$

where $\Delta t_i^C = \text{Re}\Delta t_s^C$ is given by the following expression:

$$\Delta t_s^C = -\frac{dW_C(\phi, p)}{dI_p},\tag{3}$$

Here W_C is the phase acquired by the laser-driven electron due to its interaction with the core and I_p is the ionization potential (see Appendix for detailed derivation and explicit expression for W_C , including its dependence on the core potential). The derivative is taken with respect to the electron binding energy I_p , keeping the initial and the final electron momenta constant (see Appendix).

B. Attoclock ab-initio.

We can now (i) test the ability of ARM to quantitatively describe attoclock measurements, (ii) apply the results Eq. (A15,3) to reconstruct ionization times t_i , (iii) investigate the presence of tunnelling delays associated with the electron's motion in the classically forbidden region. To this end, we perform ab-initio numerical simulations of attoclock measurements for a benchmark system: a hydrogen atom interacting with a perfectly circularly polarized, nearly single-cycle laser pulse with central wavelength $\lambda = 800$ nm. The merit of using ab-initio simulations for hydrogen is the unprecedented accuracy this affords when analysing the attoclock observables: the hydrogen atom is unique in allowing an exact numerical solution of the full time-dependent Schroedinger equation (TDSE) in a circularly polarized field, requiring no approximations beyond the standard non-relativistic and dipole approximations. Approaching the problem numerically gives us full control of all pulse parameters – intensity, ellipticity, pulse shape and carrier-envelope phase – which is important when time-resolving highly nonlinear processes at the 10 asec level.

Since every numerical scheme must deal with convergence issues related to the finite discretization step, the size of the simulation box, time-propagation routines, etc, we compare three independent calculations of the angle- and energy- resolved photoelectron spectra, done using three different methods and propagation algorithms [15, 21, 22] (see Methods). The results are in very good agreement. We then compare the numerical results with the analytical theory, to check its validity, and again find very good agreement across a wide range of intensities. Fig.2 shows this comparison for I = 1.75, 2.5 and $3.4 \times 10^{14} \text{ W/cm}^2$. The laser field is defined by $\mathbf{F}_L(t) = -\partial \mathbf{A}_L(t)/\partial t$, where

$$\mathbf{A}_{L}(t) = -A_{0} \cos^{4}(\omega t/4) \left(\cos(\omega t) \,\,\mathbf{\hat{x}} + \sin(\omega t) \,\,\mathbf{\hat{y}}\right). \tag{4}$$

The field rotates counter-clockwise and points at an angle of 90° when it reaches its maximum at time t = 0.

The offset angle θ is extracted by finding the peak of the photoelectron distribution. Fig.3a shows the offset angles calculated using the three numerical methods and the ARM approach as a function of laser intensity. The numerical results agree within 0.5°, and the deviation between the analytical and numerical results is within 2°. This slight discrepancy is analysed further in Fig.3(b), where we zoom into the region of intensities between 1×10^{14} W/cm² and 3×10^{14} W/cm². The vertical lines indicate the angles at which the distribution falls by a mere 0.1% compared to the peak of the signal intensity. Within this deviation, the analytical and numerical offset angles agree. These vertical lines highlight the extremely flat nature of the distribution around the maximum, even for the single-cycle pulse we have used and gauge the accuracy one has to reach to locate the maximum of photoelectron distribution. The flatness of the spectrum we see here may also challenge the accuracy of identifying θ in experiments.

All calculations show a very interesting trend in intensity. At lower intensities, when the barrier for tunnelling is thicker, there is a bigger deflection angle. Does this trend represent a tunnelling delay, as suggested recently [16, 23]?

FIG. 2. Angle- and energy- resolved photoelectron spectra produced by the strong field ionization of the hydrogen atom using a single-cycle circularly polarized laser pulse with wavelength $\lambda = 800$ nm and intensity (a) $I = 1.75 \times 10^{14}$ W/cm², (b) $I = 2.5 \times 10^{14}$ W/cm², and (c) $I = 3.4 \times 10^{14}$ W/cm². The form of the laser pulse is specified in Eq.(B13). Solid red contours show spectra obtained analytically using the ARM theory. Dashed black contours are the results of ab initio numerical calculations performed using the method labelled TDSE H1 (see Methods section). The distributions are normalized to 1, and contours correspond to signal intensity changing from 0.1 to 0.9 in steps of 0.1, with the innermost contour at 0.9.

FIG. 3. Offset angles θ extracted from photelectron spectra as a function of intensity. (a) A comparison of the offset angles obtained for the hydrogen atom using the three different numerical methods (black circles, blue diamonds and green triangles correspond to TDSE H1, H2 and H3 respectively, see Methods) and the ARM theory (red and yellow squares, the latter include effect of the ground state depletion, see Appendix for details). Violet circles show the numerically obtained offset angles for the short-range Yukawa potential. (b) A close up of the analytical (red and yellow squares) and numerical (blue circles, TDSE H 1) results for the offset angle for hydrogen. The vertical lines indicate the angles at which the signal intensity is reduced by a mere 0.1% compared to the peak value.

FIG. 4. A comparison of the photoelectron spectra calculated numerically using method TDSE H1 for (a) hydrogen and (b) the short-range Yukawa potential. Each contour corresponds to the same signal strength, but a different laser intensity. Pulse shape and wavelength are the same as in Fig.2 and 3. In (b), the offset angle is zero at all intensities, and hence the attoclock measures no tunneling delays for the Yukawa potential.

C. Delays in tunnelling.

In the hydrogen atom, the angular offset may come from two sources: tunnelling delay and the interaction between the departing electron and the nucleus. As a first step towards distinguishing these two possibilities, we replace the Coulomb potential of the hydrogen atom by a short range potential. In this case, the tunnelling barrier will still be present; however, electron-nucleus interaction after tunnelling is turned off. To investigate this, the numerical calculations were repeated for a short-range Yukawa potential, $U_Y = -Ze^{-r/a}/r$, with Z = 1.94 and a = 1.0 a.u. chosen to yield the ionization potential of the hydrogen atom. The results are summarized in Fig.3a and Fig.4. At all intensities, we find that the offset angle θ is equal to zero in this instance. That is, the attoclock measures no tunnelling delays for the short-range Yukawa potential. We now move to the hydrogen atom, where the presence of multiple excited states can, in principle, alter the tunneling process via electronic excitations before tunnelling.

D. Reconstruction of ionization times in hydrogen.

Having demonstrated very good agreement between photoelectron spectra calculated using the ARM method and ab initio TDSE calculations, we can now apply the mapping (Eq.(A15)) to reconstruct ionization times from ab-initio data. In particular, for a given photoelectron spectrum, we extract the most probable time of ionization by evaluating Eq.(A15) at the spectrum peak (θ , p_{peak}):

$$t_i(\theta, p_{\text{peak}}) = \frac{\theta}{\omega} - |\Delta t_i^{\text{env}}(\theta, p_{\text{peak}})| - |\Delta t_i^C(\theta, p_{\text{peak}})|,$$
(5)

where we have used the fact that Δt_i^C is negative and $\Delta t_i^{\text{env}} < 0$ for $\theta > 0$.

Fig.5(a) shows the results of applying this reconstruction procedure for offset angles θ and momenta p_{peak} obtained numerically using methods TDSE H1 and H2 (see Methods). Black circles represent the first term in Eq.(5) above: the numerically calculated offset angles, divided by the laser frequency. They correspond to the ionization times we would have reconstructed had we neglected the Coulomb effects and assumed the long pulse limit: $t_i^0 = \theta/\omega$. Orange diamonds represent the above offset angles with the envelope correction $|\Delta t_i^{\text{env}}|$ subtracted: the first two terms in Eq.(5). Essentially, the envelope correction removes the effects of pulse shape from the data: within the analytical approach, we have verified that offset angles corrected in this way become virtually independent of the shape of the envelope used. Blue inverted triangles show the Coulomb correction to the ionization time, the final term in Eq.(5). Finally, green triangles show the reconstructed ionization times t_i themselves.

Across all intensities, we find that the reconstructed ionization times are never positive. The absence of such positive times, in turn, implies the absence of tunnelling delays in the strong field ionization of the hydrogen atom in IR fields.

For $I > 1.5 \times 10^{14}$ W/cm², ionization times become negative, which indicates that the dominant contribution to ionization occurs just before the field reaches its maximum. What could the origin of this effect be? One possible explanation is the depletion of the ground state: a loss of population before the peak of the field would enhance the relative contribution of early ionization events, decreasing the off-set angle as shown in Fig. 3(a) within the ARM theory. The depletion of the ground state, calculated numerically, is shown in Fig. 5(b) (see Appendix for details). As expected, depletion increases with intensity, which in turn should

FIG. 5. Reconstruction of ionization times. (a) Ionization times (left axis) reconstructed using the ARM theory from offset angles (right axis) obtained numerically using methods TDSE H1 and H2. Black circles are the numerically calculated offset angles, divided by the laser frequency, θ/ω . Orange diamonds show the offset angles with the correction due to the pulse envelope subtracted, $t_i^0 = \theta/\omega - |\Delta t_i^{\text{env}}(\theta, p_{\text{peak}})|$. Blue inverted triangles show the Coulomb correction to the ionization time evaluated at the peak of the photoelectron distribution, $|\Delta t_i^C(\theta, p_{\text{peak}})|$. Green triangles show the ionization times we obtain by applying reconstruction procedure defined by Eq.(5). In terms of the figure, this is simply the result of subtracting the blue curve from the the orange curve. (b) Population of the ground state of the H-atom after the end of the laser pulse as a function of intensity. (c) Ionization times reconstructed using the ARM theory, based on numerically derived offset angles (green triangles), vs corrections to zero ionization times due to effects of depletion alone (red circles) (see Appendix for details). (d) Identification of multi-electron effects in attoclock measurements: difference $\delta \theta = \theta_2 - \theta_1$ between the deflection angles for the two-electron (θ_2) and the one-electron (θ_1) systems with the same ionization potential. Black dots: results for a 'rigid' model system with high energy of ionic excitations $\Delta E = 0.47$ a.u. Red triangles: results for a model system with reduced energy of ionic excitations $\Delta E = 0.21$ a.u.

give rise to negative t_i . However, as Fig. 5(c) shows, if we calculate the expected negative shift of the ionization times based on depletion alone (red circles) (see Appendix), we find that it is not sufficient to explain the observed negative ionization times (green triangles). This implies that either the analytical expression Eq.(3) becomes less accurate at higher intensities, or there is another physical effect at play. The latter possibility is explored in the Appendix using additional numerical tests, which are entirely independent of the analytical theory. These tests confirm the appearance of negative ionization times and show that they may be related to 'frustrated tunnelling', a phenomenon well documented for the case of ionization in linearly polarized pulses [1]. Recent theoretical work has suggested that this can also occur in circular fields [25, 26], and the negative ionization times we reconstruct may be a signature of this.

In one-photon ionization, the accurate calibration of time delays for the hydrogen atom has made it possible to access delays associated with multielectron effects [6, 11, 13, 27, 28]. The same applies to multiphoton ionization time-resolved by the attoclock. It is natural to expect that, as in the one photon case, these may also lead to delays during multiphoton ionization in strong laser fields. The ability to account for the time-shift Δt_i^C asociated with single-electron dynamics allows one to identify multielectron contributions in attoclock measurements.

Fig. 5 (d) shows the difference $\delta\theta$ between the numerically calculated offset angles (θ_2, θ_1) for a two-electron and a single electron system with the same binding energy and the same long-range core potential, $\delta\theta = \theta_2 - \theta_1$ (see Appendix for details). We observe two complementary effects. The first is core polarization[7], which shields the core and therefore slightly *reduces* the deflection angle caused by electron-core attraction. This leads to negative $\delta\theta$ (see Fig. 5(d), black circles). This is the only effect we see in our numerical simulations when electronic excitations in the ion lie far above the ionization threshold ($\Delta E = 0.47$ a.u. in our model system).

However, if we reduce the energy of electronic excitation in the ion (to $\Delta E = 0.21$ a.u), and thereby also the energy of two-electron excitations, while keeping the ionization potential of the neutral fixed at $I_p = 0.5$ a.u., the picture changes (Fig. 5d, red triangles). As laser intensity increases, the multielectron correction $\delta\theta$ of the deflection angle starts to rise quickly and becomes positive. This sharp increase of $\delta\theta$ coincides with onset of double ionization.

This trend is accompanied by a decrease in the relative delay between the removal of the two electrons during double ionization (see Appendix Fig. 10), and is consistent with twoelectron excitations formed during the first ionization step [3, 11] (termed 'pre-collision' in [11]). Thus, electronic excitations during ionization may indeed lead to additional positive delays in attoclock measurements of single ionization.

III. CONCLUSIONS AND OUTLOOK

As we have seen, because the ARM method naturally includes the concept of trajectories, it makes it possible to reconstruct ionization times from the experimentally observed offset angles. Applying this method to the single electron system, the hydrogen atom, in turn, has allowed us to calibrate the attoclock, revealing the contribution coming purely from the attractive force of the core. We can conclude that any additional offset observed in multielectron systems must then be due to multielectron effects.

The presence of trajectories within ARM also makes it possible to assess the accuracy of the commonly used assumptions (A1)-(A3). In contrast to (A3), trajectories in ARM are never fully classical. Although the measured quantity (the electron momentum) is real, the trajectories retain an imaginary component of the coordinate all the way to the detector (see Appendix). This property is directly related to the fact that, for long range potentials, ionization is not yet completed at the moment the electron exits the tunnelling barrier, in contrast to (A2), see discussion and ab-initio numerical tests in Appendix. At high intensities, the dominant contribution to the photoelectron spectrum may come from ionization that starts before the maximum of the electric field, even after effects of depletion are taken into account, in contrast to (A1). One should therefore be cautious when using assumptions (A1)-(A3) to interpret attoclock measurements at the ~ 10 asec level.

Our results indicate no tunnelling delays associated with the ionization of the ground-state of the hydrogen atom by a strong low-frequency field. However, the situation may be different when real electronic excitations during ionization are involved. For two-electron systems, our results have shown that the two types of multielectron response to the infrared laser field – namely the adiabatic polarization of the electronic cloud and real two-electron excitations – leave distinct and different traces in attoclock measurements, leading to additional delays, either negative or positive. Thus, attoclock experiments with molecules or alkaline-earth atoms, where doubly excited states lie below the first ionization threshold, may uncover rich multi-electron response manifested in non-trivial, intensity dependent ionization delays caused by correlation-driven excitations during strong-field ionization.

IV. METHODS

Our numerical simulations have used three different algorithms to produce ab-initio spectra of strong-field ionization induced by a nearly single-cycle 800 nm laser pulse. The data labeled 'TDSE H 1' (F. Morales and H. G. Muller) have used the numerical procedure and the code described in detail in [21]. The data labeled 'TDSE H 2' (A. Zielinski and A. Scrinzi) were obtained using the t-SURFF method described in [22]. The data labelled 'TDSE H 3' (I. Ivanov and A. Kheifets) have used the numerical procedure and the code described in detail in [15].

The method used for the calculations labeled 'TDSE H 1' (F. Morales and H. G. Muller) has been monitored for convergence by changing the maximum angular momentum up to $L_{max} = 120$, while the radial grid size was increased up to $r_{max}=2700$ a.u. The spectrum was obtained by projection on the exact field-free continuum states of the H-atom after the end of the laser pulse. The step size of radial grid was $\delta r=0.15$ a.u. and the time-step was $\delta t=0.05$ a.u. Convergence was monitored by varying δr down to 0.05 a.u. and the time-step δt down to 0.04 a.u.

T-SURFF ('TDSE H 2', A. Zielinski and A. Scrinzi) combines numerical solutions in an inner region with approximate analytical solutions in terms of Volkov states outside. The method is efficient since the numerical part of the solution can be kept comparatively small: converged results were obtained with an inner region $|\vec{r}| < r_{\text{max}} = 120$ a.u. using a finite-element radial discretization with 310 coefficients and an expansion into spherical harmonics up to $L_{\text{max}} = 95$. The dominant error in the offset-angle θ arises from the absence of electron-ion interaction in the Volkov states. It is $\leq 0.3^{\circ}$ at the lowest intensities and drops below 0.01° for intensities $> 10^{14} \text{ W/cm}^2$. A detailed description of method and code, as well as numerical examples can be found in [22, 30].

The method used for the calculations labeled 'TDSE H 3' (I. Ivanov and A. Kheifets) has been monitored for convergence by changing the maximum angular momentum up to $L_{max} = 80$, while the radial grid size was increased up to $r_{max}=300$ a.u. for calculations in both the length and the velocity gauge (with full agreement between the two). The spectrum was obtained by projection onto the exact field-free continuum states of the H-atom after the end of the laser pulse. The step size of radial grid was $\delta r=0.1$ a.u. and the time-step was $\delta t=0.01$ a.u.. Convergence was monitored by varying δr down to 0.05 a.u. and the time-step δt down to 0.005 a.u.

The method used for two-electron systems has been described in detail in [9] and is based on the Heidelberg MCTDH code, adapted to two electrons. It uses time-dependent basis functions, variationally optimized to the electron dynamics, see [9]. The electrons are treated in two dimensions each, with basis functions set on the Cartesian grid with step-size $\delta x=0.2$ a.u., covering ± 280 a.u. for each dimension. To achieve convergence 30 time-dependent basis functions per dimension are used, leading to leading to 810,000 total configurations propagated at each time step.

Appendix A: The ARM theory applied to short circularly-polarized pulses

1. General expressions.

The ARM approach has been described in detail in Refs.[2–5], where it was originally developed for long laser pulses. Here we apply the same method for short pulses, taking into account effects of the pulse envelope. These effects are very important when considering the nearly-single cycle pulses required to perform atto-clock measurements.

The ARM method yields the following expression for the photoelectron spectrum [4, 5]:

$$|a_{\mathbf{p}}(T)|^{2} = |R_{\kappa lm}(\mathbf{p})|^{2} |e^{-iS(T,\mathbf{p},t_{s})}|^{2} = |R_{\kappa lm}(\mathbf{p})|^{2} e^{2\mathrm{Im}S(T,\mathbf{p},t_{s})},$$
(A1)

where $T \to \infty$. The first term, $R_{\kappa lm}(\mathbf{p})$, encodes the angular structure of the initial state. For the spherically symmetric ground state of hydrogen, which we focus on in this work, $R_{\kappa lm}(\mathbf{p})$ does not impact the angle-resolved spectra. The action S in the second term is comprised of three components,

$$S(T, \mathbf{p}, t_s) = S_V(T, \mathbf{p}, t_s) + W_C(T, \mathbf{p}, t_s) - I_p t_s.$$
(A2)

The first of these is the so-called Volkov phase, the phase accumulated by the electron in the laser field only:

$$S_V(T, \mathbf{p}, t_s) = \frac{1}{2} \int_{t_s}^T dt \ [\mathbf{p} + \mathbf{A}(t)]^2.$$
 (A3)

The second component is the phase accumulated due to the interaction of the departing electron with the core:

$$W_C(T, \mathbf{p}, t_s) = \int_{t_s - i\kappa^{-2}}^T dt \ U(\mathbf{r}_s(\mathbf{p}, t, t_s)), \tag{A4}$$

where $U(\mathbf{r}_s)$ is the potential of the atom or molecule evaluated along the electron's laserdriven quantum trajectory,

$$\mathbf{r}_{s}(\mathbf{p}, t, t_{s}) = \int_{t_{s}}^{t} dt' \ (\mathbf{p} + \mathbf{A}(t')). \tag{A5}$$

The third component comes from the evolution of the initial bound state, where I_p is the ionization potential of this state. Finally, $\kappa = \sqrt{2I_p}$ in the lower limit of the integral in Eq.(A4) comes from the matching of inner and outer region solutions. Each of the terms

above is evaluated at the complex time $t_s = t_i + i\tau_T$, which is the solution to the saddle-point equation

$$\frac{\partial S(T, \mathbf{p}, t')}{\partial t'}\Big|_{t_s} = \frac{\partial S_V(T, \mathbf{p}, t')}{\partial t'}\Big|_{t_s} + \frac{\partial W_C(T, \mathbf{p}, t')}{\partial t'}\Big|_{t_s} - I_p = 0$$
(A6)

The time t_s defines the starting point of the electron trajectory, and the presence of the imaginary component in t_s reflects the quantum nature of the electron's motion.

The above expressions are obtained by solving the time-dependent Schroedinger equation for the problem of strong-field ionization. The solution makes no assumptions about the nature of the ionization process and is gauge-invariant [2, 3]. The core part of the method relies on the rigorous R-matrix-type separation of coordinate space into inner and outer regions, with the wavefunction transferred between the two using the Bloch operator – a standard R-matrix technique. The approximations used by the analytical method are as follows: (B1) The wavefunction in the inner region is approximated by the bound state from which ionization occurs. (B2) In the outer region, the method uses strong-field eikonal-Volkov states [8] to describe the electron dynamics. The validity of the eikonal approximation sufficiently far from the core has been throroughly checked in [8]. Its accuracy has been further verified for the case of delays in one-photon ionization measured by the attosecond streak-camera [6] – the use of eikonal-Volkov states in the continuum yielded excellent agreement between analytical and ab-initio results. (B3) The derivation also makes use of the saddle point method when evaluating the integrals that arise. Our ability to do so stems from the large action accumulated by the electron in the presence of a strong laser field.

The key to our ability to reconstruct ionization times from photoelectron spectra comes from the fact that $t_i = \text{Re}[t_s]$, the real part of the saddlepoint solution above, is naturally interpreted as the time of ionization (see e.g.[7] and references therein). Consequently, the analysis of ionization times in strong-field ionization is concerned with saddle-point times and the corrections to these times introduced by the core potential.

2. Coulomb corrections to saddle-point times.

It is instructive to start with the case where the electron-core interaction is negligible, which is appropriate e.g. for the short-range Yukawa potential. If we neglect the term due to the Coulomb phase, Eq.(A6) reduces to

$$\frac{\partial S_V(T, \mathbf{p}, t')}{\partial t'} \Big|_{t_s^0} - I_p = 0, \tag{A7}$$

which can be easily solved with no approximations. For electron momentum $\mathbf{p} = \{p, \phi\}$, we obtain

$$\omega t_i^0(\mathbf{p}) = \omega \operatorname{Re}[t_s^0(\mathbf{p})] = \phi + \Delta \phi^{\operatorname{env}}(\mathbf{p}), \qquad (A8)$$

where ϕ is the angle at which the electron is detected and $\Delta \phi^{\text{env}}$ is a small correction due to the shape of the pulse envelope. The sign of this correction depends on ϕ : it is negative for $\phi > 0$, positive for $\phi < 0$, and zero for $\phi = 0$. For sufficiently long pulses, $\Delta \phi^{\text{env}}$ vanishes, and we are left with the simple mapping $t_i^0 = \phi/\omega$. That is, if we neglect electron-core interaction, we find that the angle of detection is orthogonal to the direction of the field at the moment of ionization. This is fully consistent with the ab-initio numerical results obtained for the Yukawa potential, where the majority of the electrons are detected orthogonal to the field direction at the peak of the laser pulse.

In the absence of electron-core interaction, the real part t_i^0 of the saddle point solution t_s^0 has a clear meaning. It corresponds to the so-called ionization time, since for all times $t > t_i^0$ both the photoelectron spectrum $|a_{\mathbf{p}}^0(t)|^2 \propto e^{2\mathrm{Im}S_{SFA}(t,\mathbf{p},t_s^0)}$ and the ionization probability $\int |a_{\mathbf{p}}^0(t)|^2 d\mathbf{p}$ remain constant: ionization is completed by time t_i^0 . Indeed, the imaginary component of the action $S_{SFA}(t,\mathbf{p},t_s^0)$ is only accumulated while integrating from t_s^0 to t_i^0 in Eq.(A3). This property of the integral in Eq.(A3) has prompted the perspective that tunnelling corresponds to motion in imaginary time from $\mathrm{Im}t_s^0$ to zero. Re $t_s^0 = t_i^0$ then corresponds to the exit time: the time at which the electron leaves the tunnelling barrier. Within this approach, in the absence of electron-core interaction, tunnelling from the bound state starts and finishes at the same real time t_i^0 . This result is fully consistent with the ab-initio calculations for the Yukawa potential presented in the main body of the paper. We note that the potential used in the numerical calculations has a single bound s-state, which ensures that scattering phases in all ionization channels other than the s-channel are equal to zero.

With this result in mind, we can express the full solution to Eq.(A6) as

$$t_s = t_s^0 + \Delta t_s^C, \tag{A9}$$

where t_s^0 is the solution of the Coulomb-free saddle point equation (Eq.(A7)) and Δt_s^C is the correction due to the electron-core interaction. Expanding Eq.(A6) in a Taylor series around t_s^0 and keeping all terms up to first order in the electron-core interaction W_c , we obtain

$$\Delta t_s^C = -\frac{\partial W_C(T, \mathbf{p}, t_s^0)}{\partial t_s^0} \left(\frac{\partial^2 S_V(T, \mathbf{p}, t_s^0)}{(\partial t_s^0)^2}\right)^{-1}.$$
 (A10)

Next, we note that Eq.(A7) establishes a functional dependence $t_s^0 = t_s^0(I_p)$. With this in mind, differentiating both sides of Eq.(A7) with respect to I_p , we have

$$\left(\frac{\partial^2 S_V(T, \mathbf{p}, t_s^0)}{(\partial t_s^0)^2}\right)^{-1} = \frac{dt_s^0}{dI_p}.$$
(A11)

Combining Eq.(A10) and (A11), we obtain

$$\Delta t_s^C = -\frac{\partial W_C(T, \mathbf{p}, t_s^0)}{\partial t_s^0} \frac{d t_s^0}{d I_p}.$$
(A12)

To derive a practical way of calculating Δt_s^C , we recall that $W_C(T, \mathbf{p}, t_s^0)$ (Eq.(A4)) depends on I_p only via $t_s^0 = t_s^0(I_p)$ and $\kappa = \sqrt{2I_p}$ in the lower limit of the integral. The full derivative of $W_C(T, \mathbf{p}, t_s^0)$ with respect to I_p can therefore be expressed as

$$\frac{dW_C(T, \mathbf{p}, t_s^0)}{dI_p} = \frac{\partial W_C(T, \mathbf{p}, t_s^0)}{\partial t_s^0} \frac{dt_s^0}{dI_p} + \frac{\partial W_C(T, \mathbf{p}, t_s^0)}{\partial \kappa} \frac{d\kappa}{dI_p}.$$
(A13)

Thus, we can evaluate Δt_s^C by differentiating $W_C(T, \mathbf{p}, t_s^0)$ with respect to I_p , while keeping κ in the lower limit of the integral constant:

$$\Delta t_s^C = -\frac{dW_C(T, \mathbf{p}, t_s^0)|_{\kappa=const}}{dI_p}.$$
(A14)

Recalling that the real part of the saddlepoint solution, $t_i = \text{Re}[t_s]$, represents the time of ionization, our analysis has established a mapping between the angle and momentum at which the electron is detected and its ionization time $t_i = \text{Re}[t_s]$:

$$t_i(\phi, p) = \frac{\phi}{\omega} + \Delta t_i^{\text{env}}(\phi, p) + \Delta t_i^C(\phi, p),$$
(A15)

where Δt_i^{env} is obtained by solving Eq.(A7), and $\Delta t_i^C = \text{Re}\Delta t_s^C$ is calculated using Eq.(A14) above.

Finally, we discuss the dependence of W_C (SM, Eq.(A4)) on the range a of the shortrange Yukawa potential. The integral Eq.(A4) is calculated from t_s down to the real time axis, $t_i = \text{Re}(t_s)$, and then along the real time axis. In the classically forbidden region, between t_s and t_i , the differential dt is purely imaginary and thus, for real-valued U(r), no real-valued contribution to W_C is accumulated. (The potential U evaluated along the complex trajectory remains real-valued in the classically forbidden region between t_s and t_i as long as $\operatorname{Re} r_s > \operatorname{Im} r_s$. This condition is met for the peak of the electron distribution.) The real-valued contribution to W_C accumulates at $t > t_i$. If $r_s(p, t_i, t_s)$ exceeds the range of the potential, then $U(r_s(p, t \ge t_i, t_s) = 0$, and $\operatorname{Re} W_C = 0$, leading to no correction to the real part of the saddle point. Obviously, the same applies to the zero-range potential. As the range a of the potential becomes comparable to $r_s(p, t_i, t_s)$, $\operatorname{Re} W_C$ will start to deviate from zero, leading to non-zero Δt_i .

Appendix B: Origins of the negative ionization times.

Fig. 5 in the main body of the paper shows that for the parameters of the numerical experiments, ionization times become negative at intensities $I > 1.5 \times 10^{14} \text{W/cm}^2$, i.e. for electric field strengths $F_L > 0.0465$ a.u. One of the possible explanations for this trend could be the depletion of the ground state. Indeed, if the ground state population is significantly reduced before the peak of the laser field, the maximum ionization signal may precede the field maximum. Thus, we first check the role of the depletion of the ground state in this trend.

1. Effect of ground state depletion on ionization times.

Fig. 5 (b) (see main text) shows the population of the ground state after the end of the pulse, calculated using the 'TDSE H1' approach (F. Morales and H. Muller). The population is obtained by projecting the wavefunction of the system on the ground state after the end of the pulse. The depletion of the ground state remains very small until $I = 2 \times 10^{14} \text{W/cm}^2$, and is below 10^{-3} when negative ionization times become apparent. However, these times (Fig. 5 (a,c)) are also small. At higher intensities, ionization reaches a few percent and depletion of the ground state population must contribute to the increasing values of negative ionization times. To quantify this effect, we take advantage of the attoclock mapping between the ionization times t_i and the electron deflection angle θ . We also take into account that both the depletion of the ground state and the negative ionization times are very small.

Consider the photoelectron distribution integrated over energy, $P(\phi)$, and let us denote

by $P_0(\phi)$ the photoelectron distribution in the absence of depletion. According to the ARM theory, their relationship is $P(\phi) = P_0(\phi)W_g(t_i(\phi))$, where $W_g(t_i(\phi))$ is the ground state population at the moment of ionization $t_i(\phi)$, which is mapped to the detection angle ϕ . If ground state depletion is the sole origin of the negative ionization times, then $P_0(\phi)$ should have its maximum at the angle which corresponds to an ionization time of zero: that is, at the angle $\phi = \theta_0$ which satisfies $t_i(\theta_0) = 0$. The decreasing function $W_g(t_i)$ will then skew this distribution towards $t_i < 0$. Note that, according to the attoclock principle, $\phi - \theta_0 = \omega t_i$, where ω is the laser frequency.

For small ionization times near the peak of the laser field t = 0, we have $W_g(t_i) = W_g(0)[1 - \Gamma_0 t_i]$, where $\Gamma_0 = \Gamma(t = 0)$ is ionization rate at the peak of the field, and $W_g(0)$ is the ground state population at the peak of the field. To determine how the decreasing value of $W_g(t_i)$ shifts the maximum of $P(\phi)$, we expand $P(\phi)$ in a Taylor series around θ_0 , the angle at which $P_0(\phi)$ is maximized:

$$P(\phi) = P_0(\phi) W_g(0) [1 - \Gamma_0 t_i]$$
(B1)

$$= \left[P_0(\theta_0) - \frac{1}{2} P_0''(\phi - \theta_0)^2 \right] W_g(0) \left[1 - \Gamma_0 t_i \right].$$
 (B2)

Here we have used the fact that $P_0(\phi)$ has its maximum at $\phi = \theta_0$ and hence $P'_0(\theta_0) = 0$. Using $\phi - \theta_0 = \omega t_i$ we obtain:

$$P(\phi) = P_0(\phi) W_g(0) [1 - \Gamma_0 t_i]$$
(B3)

$$= \left[P_0(\theta_0) - \frac{1}{2} P_0'' \omega^2 t_i^2 \right] W_g(0) \left[1 - \Gamma_0 t_i \right].$$
 (B4)

We can now find the maximum of the function $P(\phi)$ by solving the equation $dP(\theta)/d\phi = 0$, or equivalently $dP/dt_i = 0$, given the linear dependence $\phi - \theta_0 = \omega t_i$. For small time shifts t_i , where $\Gamma_0 t_i \ll 1$, this yields

$$\omega t_i = -\frac{P_0(\theta_0)}{P_0''(\theta_0)} W_g(0) \Gamma_0 \frac{1}{\omega}$$
(B5)

In our numerical simulations, $\Gamma_0 t_i \leq 4 \times 10^{-3}$ for all intensities shown in Fig.5. We can now use our ab-initio photoelectron distributions to extract the required quantities, the ratio P_0/P_0'' and the ionization rate Γ_0 .

First, we integrate each ab-initio energy- and angle- resolved photoelectron distribution over energy to obtain an angle-resolved electron yield, to which we fit a Gaussian:

$$P(\phi) = C \exp\left[-\frac{(\phi - \theta_{\max})^2}{2\Delta^2}\right],\tag{B6}$$

where θ_{max} corresponds to the maximal photoelectron signal. Again, making use of $\Gamma_0 t_i \ll 1$, and using Eq.(B1), we have

$$\frac{P_0(\theta_0)}{P_0''(\theta_0)} = \frac{P(\theta_{\max})}{P''(\theta_{\max})} = \Delta^2, \tag{B7}$$

where the relative error in the first equality in the above equation is $\Gamma_0 t_i/2 \leq 2 \times 10^{-3}$. Eq.(B7) yields the following expression for ωt_i :

$$\omega t_i = -\frac{\Delta^2}{\omega} \Gamma_0 W_g(0). \tag{B8}$$

Finally, we note that the attoclock mapping $\theta(t_i)$ reflects the sub-cycle dependence of the ionization rate, which follows the same Gaussian-shaped distribution as the photoelectron spectrum,

$$\Gamma(\theta) = \Gamma_0 \exp\left[-\frac{(\phi - \theta_0)^2}{2\Delta^2}\right] = \Gamma_0 \exp\left[-\frac{(\omega t_i)^2}{2\Delta^2}\right] \quad . \tag{B9}$$

Here, we explicitly use the assumption that Γ is maximized at the peak of the field, i.e. depletion is the only reason for negative ionization times (θ_0 corresponds to the peak of the field t = 0). For a circularly polarized field, we can obtain the total ionization yield W_i by integrating $\Gamma(\phi)$ over all angles ϕ or, equivalently, over all t_i . This yields

$$W_i = \Gamma_0 \sqrt{2\pi} \frac{\Delta}{\omega}.$$
 (B10)

This equation can be used to obtain the ionization rate Γ_0 from the total ionization signal or from the depletion of the ground state $W_{\text{Loss}} \simeq W_i$ (in all our numerical simulations these quantities differ by less than 1%):

$$\Gamma_0 = \frac{W_{\text{Loss}}}{\sqrt{2\pi}} \frac{\omega}{\Delta},\tag{B11}$$

Thus, numerically finding the depletion of the ground state and the angular width of the photoelectron distribution, we have all the quantities necessary to obtain the negative ionization times due to ground state depletion:

$$\omega t_i = -W_g(0)W_{\text{Loss}}\frac{\Delta}{\sqrt{2\pi}}.$$
(B12)

The equation above was used to obtain the depletion-corrected ionization times in Fig. 5 (c) of the main text (red circles). We have used $W_g(0) = 1$, which provides an upper bound for the effect: at the highest intensity shown, substituting $W_g(0) = 1$ leads to an error below 0.25° (at lower intensities, the error is considerably less). The same equation can also be

FIG. 6. Offset angles shown as a function of intensity. Red squares represent the angles obtained using the ARM method with depletion neglected. Orange squares show the same ARM results, corrected for depletion according to Eq.(B12) using numerically derived values for W_{Loss} (the depletion of the ground state) and Δ (the width of the photoelectron distribution). Blue diamonds show the offset angles extracted from ab-initio photoelectron spectra calculated using method TDSE H2. At higher intensities, the depletion-corrected ARM angles are better able to reproduce the trend we see in the numerical results.

used to correct the ARM offset angles as shown in Fig. 3 (orange squares) of the main text. The results of doing so are also shown in Fig.6. Figure 5 (c) of the main text indicates that although depletion is indeed partially responsible for the appearance of negative times, it cannot explain them fully. This suggests that there could be additional effects at play.

2. Additional effects contributing to negative ionization times.

One possible additional effect is suggested by the ARM theory. Within the ARM picture, we find that, for a long-range potential, the total ionization yield continues to change even after the electron has emerged from the barrier. That is, ionization is not fully completed during the tunnelling step. This signifies the post-tunnelling step in ionization. Such a situation, in fact, is familiar in the context of ionization in linearly polarized fields: in 'frustrated tunnelling' the liberated electron returns to its parent ion and can become trapped in excited states. As discussed below, our numerical tests suggest that the negative ionization times we reconstruct could point to a similar effect for circularly polarized fields, where such an effect becomes possible for nearly single cycle pulses.

If ionization yield depended on the tunnelling step only, we would expect the highest yield to be associated with the peak of the field, since this corresponds to the thinnest tunnelling barrier. That is, once effects of depletion have been taken into account and in the absence of any tunnelling delays, we would expect an optimal ionization time $t_i = 0$. However, since the 'post-tunnelling' step also contributes to the yield, *both* steps must be optimized at the maximum of the photoelectron distribution. ARM shows that the post-tunnelling step favours ionization at earlier times $t_i < 0$. This could explain the negative ionization times we reconstruct in Figure 5 of the main text. We would expect that features associated with the post-tunnelling step would become more pronounced at higher intensities, where deviation from the maximum of the field has a relatively smaller impact on the efficiency of the tunnelling process. Indeed, this is where we observe the largest negative ionization times. It is possible to test this idea further by investigating the CEP dependence of ground state depletion and total ionization yield in elliptical fields. Such tests are discussed below.

3. Numerical tests of additional effects: CEP control in elliptical fields.

Changing the ellipticity of the laser pulse from perfectly circular to nearly circular adds an important control parameter: the carrier-envelope phase (CEP) of the ultrashort pulse, ϕ_{CEP} . Changing ϕ_{CEP} varies the direction of the electric field vector at the peak of the intensity envelope. For perfectly circular polarization, CEP does not affect the peak value of the electric field nor the shape the photoelectron spectra – it merely rotates the spectra by an angle equal to ϕ_{CEP} . For $\epsilon < 1$ on the other hand, assuming the orientation of the polarization ellipse is fixed, ϕ_{CEP} controls the peak value of the electric field strength.

In the simulations carried out, the laser field was defined by $\mathbf{F}_L(t) = -\partial \mathbf{A}_L(t)/\partial t$, where

$$\mathbf{A}_{L}(t) = -\frac{A_{0}}{\sqrt{1+\epsilon^{2}}} \cos^{4}(\omega t/4) \left(\epsilon \cos(\omega t + \phi_{\text{CEP}}) \, \hat{\mathbf{x}} + \sin(\omega t + \phi_{\text{CEP}}) \, \hat{\mathbf{y}}\right) \quad , \quad (B13)$$

FIG. 7. A schematic illustration of the way in which carrier-envelope phase (CEP) controls the peak field strength for elliptically polarized pulses. (a) $\phi_{\text{CEP}} = 0$ maximizes the peak field strength, (b) For $\phi_{\text{CEP}} \neq 0$, the peak field strength is reduced.

and $\epsilon = 0.85$. The electric field polarization ellipse has its major axis along the *y*-direction in this case. For $\phi_{\text{CEP}} = 0$, the peak of the electric field envelope coincides with the orientation of the major axis of the polarization ellipse, ensuring the maximum value of the electric field, see Figure 7 (a). Changing ϕ_{CEP} changes the direction of the electric field vector at the peak of the intensity envelope and reduces the peak field strength, see Figure 7 (b).

The standard tunnelling perspective, expressed in the attoclock postulates A1-A3 (see main text), states that tunnelling is optimized at the maximum of the electric field, when the tunnelling barrier is at its thinnest. Based on this perspective, we would expect $\phi_{\text{CEP}} = 0$ to lead to the maximal total ionization yield, which is the commonly made assumption when interpreting attoclock experiments. If, however, negative ionization times reflect the fact that ionization is not completed during the tunnelling step and the electron's motion must be optimized throughout both the classically forbidden and classically allowed regions, then $\phi_{\text{CEP}} = 0$ may not be optimal, depending on the relative contribution from the classically

allowed region. Indeed, $\phi_{\text{CEP}} = 0$ will only optimize the tunnelling step, since it maximizes the instantaneous value of the electric field.

In light of this, we have performed a CEP-scan of angle- and energy-photoelectron spectra across a range of laser intensities from $I = 1 \times 10^{14}$ W/cm² to $I = 3 \times 10^{14}$ W/cm² for a fixed carrier wavelength of λ =800 nm, with $\epsilon = 0.85$. We find that at lower intensities, $\phi_{\text{CEP}} = 0$ is indeed optimal. It yields the maximum total ionization signal and the highest peak in the angle-and-energy resolved photoelectron distribution. However, at higher intensities we find that the optimal CEP starts to deviate from zero. This change occurs at the same intensity at which ionization times became negative.

The results are presented in the Figure 8. Panels (a,b) show the angle- and energyresolved spectra for a laser pulse with $F_L = 0.06$ a.u., (a) $\phi_{\text{CEP}} \simeq 0^\circ$ and (b) $\phi_{\text{CEP}} \simeq 20^\circ$. We find that the peak in the photoelectron spectrum is slightly higher for $\phi_{\text{CEP}} \simeq 20^\circ$. Panel (c) shows the total ionization yield as a function of ϕ_{CEP} . This curve reaches its maximum near $\phi_{\text{CEP}} \simeq 20^\circ$, when the maximum electric field is lower than for $\phi_{\text{CEP}} = 0^\circ$. Panel (d) shows the depletion of the ground state vs ϕ_{CEP} , which is indeed maximized at $\phi_{\text{CEP}} = 0^\circ$.

Given the high nonlinearity of the tunnelling process, if the tunnelling step was the only deciding factor in determining the ionization probability, the total ionization yield would have been optimized for $\phi_{CEP} = 0$. The deviation of the optimal ϕ_{CEP} from zero in panel (c), while depletion is indeed maximized at $\phi_{CEP} = 0$ (panel (d)), is consistent with the idea that the ionization process is not completed by the end of the tunnelling step. After the tunnelling step is completed, the electron may again be trapped by the ion, permanently or transiently (in which case it would again be re-released by the atom). In both cases, the shape of the photoelectron distribution at the detector (the attoclock observable) is affected since a fraction of photoelectrons either never reach the detector or reach it with different momenta due to transient trapping. We find that, for the parameters of these numerical experiments, about 0.01% of the electrons are trapped in Rydberg states after the end of the laser pulse, corresponding to about 1% of the number of the electrons that have left the ground state. The fact that this effect is nevertheless visible in the reconstructed ionization times shows that these times can serve as a highly sensitive probe of ionization dynamics.

FIG. 8. Sensitivity of strong-field ionization to the carrier-envelope phase ϕ_{CEP} for elliptically polarized fields. The calculations were done for $\lambda = 800$ nm, $F_L = 0.06$ a.u and $\epsilon = 0.85$ using method TDSE H1. Panels (a,b) show angle- and energy- resolved spectra for $\phi_{\text{CEP}} = 0^{\circ}$ and $\phi_{\text{CEP}} = 20^{\circ}$ respectively. Although the maximum value of the instantaneous electric field is lower in the second case, the overall strength of the photoelectron signal is higher. Panel (c) shows the total ionization signal as a function of ϕ_{CEP} , integrated over all electron energies and angles, and normalized to 1 (black curve). The error bars reflect the accuracy of the numerical calculations. The red curve shows the optimal sinusoidal fit to the numerical data. This fit shows that the optimal ϕ_{CEP} , which maximizes the total ionization signal, is 0.25 ± 0.15 rad. Panel (d) shows the depletion of the ground state as a function of ϕ_{CEP} .

Appendix C: Multielectron effects

To demonstrate how the calibration of the attoclock measurements for the one-electron system can be used to identify multi-electron contributions, we have performed ab-initio calculations for several model two-electron systems, where the system parameters were adjusted to change the role of two-electron processes. The motion of both electrons was restricted to 2D each, making it a 4D system. We used the soft-core Coulomb potential for

FIG. 9. Comparison of attoclock observables for one-electron and two-electron systems. Panels (a,b,c) show angle- and energy- resolved spectra for the hydrogen atom (a), a model 2D hydrogen atom with the same ionization potential as hydrogen (b), and a model 4D two-electron system with the same ionization potential as hydrogen (c). The calculations were done for $\lambda = 800$ nm, $F_L = 0.055$ a.u, $\epsilon = 1$, and the same pulse shape as in the main text.

the electron-electron and electron-core interactions,

$$V(Z, \mathbf{r}_1, \mathbf{r}_2) = -\frac{Z}{\sqrt{\mathbf{r}_1^2 + a^2}} - \frac{Z}{\sqrt{\mathbf{r}_2^2 + a^2}} + \frac{1}{\sqrt{|\mathbf{r}_1 - \mathbf{r}_2|^2 + a^2}} \quad , \tag{C1}$$

First, we consider a two-electron atom with the doubly charged core, Z=+2, with a = 1.12a.u. to yield the same ionization potential as the hydrogen atom, $I_p = 0.5$ a.u. The calculations are done using the method described in [9]. It is based on the Heidelberg MCTDH code, adapted to two electrons. It uses time-dependent basis functions, variationally optimized 'on-the-fly' to the electron dynamics, see Ref.[9]. The electrons are treated in two dimensions each, with basis functions set on the Cartesian grid with step-size $\delta x=0.2$ a.u., covering ± 280 a.u. for each dimension. To achieve convergence, 30 time-dependent basis functions per dimension are used, leading to 810,000 total configurations propagated at each time step. We have also performed calculations for the 2D H-atom, setting Z=1 and a=0.8 a.u., again to yield the same ionization potential as hydrogen atom, $I_p = 0.5$ a.u. The sample photo-electron spectra for the three systems are shown in the Fig. 9, for $I = 2.1 \times 10^{14}$ W/cm². Comparing the spectra, which are extremely similar, demonstrates that single-electron effects are indeed dominant and that the ionization potential and the long-range interaction with the core determine the attoclock offset angle as long as the ionization yields are close.

Both 2D and 4D soft-core systems ionize more easily than real 3D hydrogen, with ionization reaching 10% at $I = 2.3 \times 10^{14} \text{W/cm}^2$. However, the ionization yield is virtually identical in both the one-electron and the two-electron soft-core systems, making their comparison straightforward and unambigous. The difference in the deflection angle between the 2D and 4D system is shown in Fig.5(d) of the main text. It deviates slightly from zero, with a small *negative* $\delta\theta$ for the two-electron system relative to the one-electron case.

The fact that we do not see any substantial positive delays due to two-electron effects in this case is not surprising. Indeed, for this model two-electron system, the first excited state of the ion is 0.47 a.u. above the ground ionic state, i.e. at almost twice the first ionization potential. Therefore, two-electron excitations in the IR laser field are very unlikely. The small reduction of the deflection angle is fully consistent with the adiabatic polarization of the ionic core by the laser field, which reduces the attraction of the outgoing electron to the ion.

Next, we have explored the conditions under which two-electron excitations in the IR field may play a bigger role. To this end, we have considered a substantially less 'rigid' model 4D two-electron system with a = 2.925 a.u. and Z = +3. The substantially softer interaction reduces excitation energies in the system, while Z = +3 maintains the same first ionization potential $I_p = 0.5$ a.u. as before. Now the first excited ionic state is only 0.213 a.u. above the ionization threshold. Once again, we have paired this model system with a one-electron 2D system that has the same long-range core potential (Z=+2), the same $I_p = 0.5$ a.u. (a = 2.7 a.u.), and a very similar ionization yield vs laser intensity. When single ionization approaches 50%, electron-electron correlation leads to a substantial positive $\delta\theta$ for the two-electron system compared to the one-electron system, as shown in the Fig.5(d) of the main text.

Very interesting are results for double ionization. The two-electron spectra corresponding to double ionization, are shown in Fig.10. At lower intensities, we see that the ejection of the second electron is delayed relative to the first by about half a cycle. At higher laser intensities, the ejection angle between the two electrons is reduced. The two electrons depart with a delay of just about a quarter-cycle, consistent with the excitation of the second electron during the removal of the first[3, 10, 11]. Overall, we see correlation between the onset of positive additional deflection angle $\delta\theta$ in one-electron ionization and the one-set of double ionization.

FIG. 10. Angle- and energy- resolved spectra of two-electron ionization, for the same pulse shape as in the main text, for two-electron ionization of the model 4D two-electron system with Z = +3, and $I_p=0.5$ a.u. The calculations were done for $\lambda = 800$ nm, $\epsilon = 1$, and the same pulse shape as in the main text, using MCTDH method. The fields strengths are F = 0.04 a.u. (a) and F = 0.0725a.u. (b)
