Abstract. We study the environmental stability of mechanically exfoliated fewlayer black phosphorus (BP). From continuous measurements of flake topography over several days, we observe an increase of over 200% in volume due to the condensation of moisture from air. We find that long term exposure to ambient conditions results in a layer-by-layer etching process of BP flakes. Interestingly, flakes can be etched down to single layer (phosphorene) thicknesses. BP's strong affinity for water greatly modifies the performance of fabricated field-effect transistors (FETs) measured in ambient conditions. Upon exposure to air, we differentiate between two timescales for doping of BP FETs: a short timescale (minutes) in which n-type doping occurs due to physisorbed oxygen and nitrogen, and a long timescale (hours) in which p-type doping occurs from water absorption. Continuous measurements of BP FETs in air reveal eventual degradation and break-down of the channel material after several days due to the layer-by-layer etching process.

The two-dimensional (2D), elemental semiconductor black phosphorus (BP) has ignited recent interest from the material science community [1–8]. Unlike graphene, the prototype 2D material, BP presents a direct band-gap that is capable of manifesting large ON/OFF ratios and high mobilities when used as a channel material in a field effect transistor (FET) [1,4]. In addition, the direct band-gap of BP varies with thickness from ≈ 2 eV in single layer, phosphorene, to ≈ 0.3 eV in bulk making it attractive for optoelectronic applications [9–14]. This is in contrast to the semiconducting transition metal dichalcogenides (TMDC) such as MoS₂ and WSe₂ which only present a direct band-gap in single layers [15–17]. While the accolades for BP seem promising, a serious consideration that remains is degradation under ambient conditions [3,4]. At its first sythesis [18] and in subsequent studies [19], hints have been made at the possibility of water absorption at the surface of BP but a thorough study on the environmental stability of BP is lacking.

Here, we study the environmental stability of few-layer black phosphorus in ambient conditions. First, we characterize water absorption at the surface of thin, isolated flakes of black phosphorus by continuous AFM measurements of the topography over several days. We also study the effect of long term exposure to ambient conditions on the topography of the few-layer flakes and find that it yields a layer-by-layer etching process which can even reduce flakes to single layer thicknesses. The role of atmospheric adsorbates on the electrical properties are also studied by systematically comparing the field-effect characteristics of black phosphorus flakes in vacuum and air. We find that an initial exposure to air results in an n-type doping of the black phosphorus. Longer exposure to air results in a strong p-type doping of the flakes which we attribute to the presence of absorbed water.

BP is the only layered, van der Waals material of the phosphorus allotropes and can be created by heating white phosphorus under high pressure [18]. It has an orthorhombic crystal structure with phosphorus atoms covalently bonded to three neighboring atoms to form a puckered, single-layer honeycomb lattice [20]. Single layers are bonded through van der Waals interaction which allows exfoliation of the bulk material into thin flakes much like graphite. Recent ab initio calculations reveal that the van der Waals interaction is mainly Keesom forces from out-of-plane dipole interaction [21]. Further DFT calculations have shown that the out-of-plane dipole moment makes BP highly hydrophilic as it can interact with the dipole moment of water molecules [3]. This suggests that water plays a significant role in the degradation of BP flakes.

Preparation of isolated few-layer BP flakes is carried out using a modified mechanical exfoliation technique outlined in Ref 3. By employing a viscoelastic stamp (Gelfilm from Gelpak) as an intermediate substrate for exfoliation, thin BP flakes are transfered to a Si substrate (with 285 nm of SiO₂ capping layer) leaving less residue than when compared with using Scotch tape. Thin flakes are then identified by contrast under an optical microscope and subsequently chosen to track water absorption. We measured three flakes, of varying thicknesses, in detail over time. One is presented in the main text and the two others can be found in the Supplemental Information.

Water condensation at the surface of few-layer BP is studied using an atomic force microscope (AFM). The AFM is operated in tapping mode to reduce tip-sample interaction and image droplet formation on the flake surface over time [22]. In Figure 1 we summarize the water absorption over a five day period for a BP flake ranging in thickness from 8 nm to 30 nm (average relative humidity was 60% during measurements taken in ambient light conditions). A video clip made of the collected images is available in the Supporting Information. Selected AFM scans over the total measurement period are shown in Figures 1(a)-(d). At 3 hours, Figure 1(a), water droplets (100 nm in diameter and 5 nm tall) have already formed at the flake surface and after five days, Figure 1(d), water completely covers the flake and results in a large convex meniscus. Line profiles taken at the same flake position for the scans in Figs. 1(a)-(d) are shown in Figure 1(e) as well as a line profile from the first AFM scan 30 mins after exfoliation. The height across the flake more than doubles over the measurement period. Using the AFM scans, the total volume of the flake and absorbed water is recorded with time and shown in Figure 1(f). The volume increases rapidly in the first 10 hours at which point it stays relatively constant as larger droplets that completely cover the surface start to coalesce to form one large bubble. After five days the volume increases by more than 200%. We note that the thinner part of the flake absorbs water faster than the thicker

Figure 1. (a)-(d) Selected AFM scans of a BP flake in air taken at (a) 3 hours, (b) 46 hours, (c) 69 hours, and (d) 122 hours after exfoliation. Dotted white lines indicate the position of the line profiles shown in (e). (e) Line profiles taken across the BP flake from the scans in (a)-(d) as well as a line profile for the AFM scan taken directly after exfoliation. (f) Total volume of the flake and water over the measurement period.

part (see video clip and additional flakes in the Supplemental Information for further details) indicating a thickness depended wettability also recently reported for MoS_2 [23].

After continuous AFM scanning, the samples are subsequently put in vacuum (10^{-6} mbar) and heated (> 100° C) to remove absorbed water. From optical images and AFM scans after exposure and water removal, we find that the flakes have changed considerably from their exfoliated form. The optical images (see Supplemental Information) and AFM images in Figure 2 before and after exposure for the same flake in Figure 1 reveal an apparent removal of the material from the thinnest part of the flake as well as the presence of left-over residues (white bubble in panel (b)). The thinning of the flake can also be seen in the line profiles in Figure 1(e) at the location of the arrow.

The thinnest part of the flake (8 nm) nearly disappears after 46 hours of exposure. As was stated above, the thinner part of the flakes collect water faster and this may be the reason for an increased degradation rate. Full line profiles from AFM scans before and after exposure, shown in Figure 2(c), also show the greatest degradation for the thinner part of the flake. The overall reduction in thickness suggests that exposure to ambient conditions results in a sort of layer-by-layer thinning of the flakes from the top down.

To further highlight this thinning effect, Figures 2(d)-(f) show optical and AFM images of another BP flake on the same substrate and subjected to the same ambient exposure as the flake in Figures 2(a)-(b). Color contrast difference of the optical images of the flake (78% before exposure, 34% after) indicate a drastic reduction in thickness as well as a reduction in flake area (marked by the white dotted line in panel (e)). An AFM image of the flake in Figure 2(e) reveals that the original area is preserved but the edges have been reduced to single layer thicknesses (≈ 0.7 nm). Residues are again found on this flake and they can be seen as white saturated regions in the AFM image in Figure 2(f). The phase image from the AFM scan in Figure 2(e) (see Supplemental Information) shows a clear distinction between the BP flake, the left-over residues, and the SiO_2 substrate, all having different material densities, suggesting that the last layer of the flake is still BP but further investigation is required [24]. Recent DFT calculations from Ziletti et al. suggest that oxygen could also be responsible for degradation [25]. At large enough concentrations, interstitial oxygen creates stress in the crystal lattice and can break it apart forming phosphorus trioxide or phosphorus pentoxide which could be an explanation for the degradation and left-over residue observed here. By controlling atmospheric conditions, one could envision control over the thickness of BP flakes using this observed oxygen-induced layer-by-layer thinning process.

In the following, we discuss the the effect of the unique hydrophilic behavior of BP on the electrical performance of FETs. Few-layer BP FETs are fabricated on Si/SiO_2 substrates with pre-patterned electrodes (the SiO_2 is used as a gate dielectric and the heavily doped Si substrate is used as a back gate electrode). Source and drain

Figure 2. (a). AFM image taken approximately 30 mins after exfoliation for the same flake shown in Figure 2. (b) AFM image of the same flake in (a) after exposure and pumping/heating. The white saturated region shows the left-over residues. White dotted lines show the location of the line profile shown in (c). Note: scale for AFM scans is -10 nm (black) to 45 nm (white). (c) AFM height scans taken at the locations of the dotted lines in (a) and (b). Black curve shows the height before exposure and the blue curve after. (d). Optical image for a second flake on the same substrate taken directly after exfoliation and before 5 days of ambient exposure. (e) Same flake in (d) after exposure and pumping/heating. White dotted line marks the edge of the original flake. (f) AFM scan of (e). The white line marks the location of the line profile shown in the inset (white curve).

electrodes are created using a shadow mask and deposition of 30 nm of Au with a 5 nm Ti adhesion layer. Few-layer BP flakes are then transferred onto the pre-patterned electrodes (contact is made to the top of the gold electrodes) using a recently developed deterministic transfer method outlined in Ref. 26. Transferring BP flakes to pre-patterned electrodes considerably reduces the time that the flakes are exposed to air between exfoliation and characterization. Typical devices are fabricated and put in vacuum 10 minutes after flake transfer ensuring the measurement of nearly pristine flakes. Twelve devices were fabricated and measured in ambient conditions and we focus on one device in the main text for consistency.

After deterministic transfer of a few-layer BP flake, FETs are characterized in vacuum and at room temperature. Figure 3(a) shows the two terminal transconductance in vacuum at a bias voltage of 100 mV (black curve). The device displays ambipolar transport with current saturation and estimated hole (electron) mobilities of $6.5 \text{ cm}^2/\text{Vs}$ (1.2 cm²/Vs) calculated from the measured transconductance and estimated insulator capacitance using a parallel plate capacitance model [27]. Note that we determine the mobilities from two terminal measurements which are known to underestimate the BP FET mobilities by about a 50% [2]. The mobility value of this device is slightly lower than that expected for BP devices with a comparable thickness (5 to 100 cm²/Vs, according to Ref. 1). This might be due to a higher contact resistance between the flake and the top gold electrode due to the fabrication process, based on directly stamping onto pre-patterned electrodes. However, while we sacrifice interface contact for stamped flakes, we believe stamp transfer is the most efficient method to study pristine BP flakes that have had minimal exposure to the environment.

Once exposed to air, there is an instant n-doping and an overall decrease in conductance (red curve). We find that this short timescale doping is reversible over several cycles (see vacuum to air cycling for another device in the Supplemental Information), indicating that the doping is caused by physisorption of atmospheric species such as oxygen and nitrogen before the condensation of water. To investigate

Figure 3. (a) I-Vg characteristics of the FET device in vacuum before exposure (black curve) and directly after breaking the vacuum (red curve) taken at $V_b = 100$ mV. Inset shows an optical image of a BP flake before longterm ambient exposure (scale bar is 10 μ m). (b) I-Vg characteristics at selected times over the first hour of exposure (curves are offset by 100 nA for clarity). (c) Conductance vs. time after long term exposure to air taken at $V_b = 100$ mV, $V_g = 40$ V. Upper inset shows an optical image of the device after measurement (scale bar is 10 μ m). Lower insert shows the two terminal estimated hole mobility (scaled by the initial vacuum hole mobility) vs. time.

further this effect, BP FETs were measured separately in oxygen and nitrogen environments (see Supplemental Information for details). We find that the initial doping is a combination of the physisorption of oxygen which broadens and decreases the OFF state current and the physisorption of nitrogen which shifts the transconductance to the left producing an n-type doping. These two effects are responsible for the instant ndoping and decrease in conductance shown in Figure 3(a) (red curve). As the BP flake starts to absorb water, a transition occurs from the instant n-type doping to p-type doping (Figure 4(b)). This evolution in doping occurs over the first hour of continuous measurement. Figure 3(c) shows the measured current vs. time after the crossover and for the further collection of water and final breakdown (see Supplemental Information for transfer curves). The conductance steadily increases by two orders of magnitude over 5 hours after which degradation starts to take over and the conductance begins to drop. The transconductance curves become almost featureless and the the current through the device reaches zero after ≈ 80 hours in air. An optical image of the device after measurement is shown in the inset of Figure 4(c). The material on the electrodes has been etched away as well as some of the material in the channel. We note that the degradation appears to be more severe on the electrodes and could be due to the higher catalytic behavior of gold as compared to SiO_2 . This violent degradation is in contrast to FETs made with other 2D materials such as graphene and MoS_2 which show comparatively subtle changes in ambient conditions [28,29]. Preliminary studies on topsided encapsulation of BP FET devices using boron nitride (BN) to preserve the BP flake proved unsuccessful (see Supplemental Information). We suspect that water enters at the $BN-SiO_2$ and BN-Au interfaces leading to eventual breakdown. Full encapsulation between two layers of BN, as shown for graphene, could be a method to preserve BP FET devices [30]. We found, however, that single BP flakes could be preserved over 1 week simply by sandwiching them between two layers of PDMS (see Supplemental Information).

We have studied the environmental stability of few-layer BP flakes through two

methods. Isolated BP flakes were exfoliated and continuously scanned using an AFM in tapping mode. We find that BP has a strong affinity for water and observe an increase of over 200% in volume due to water absorption. In addition, after longterm exposure to air, we observe a layer-by-layer etching of the BP flakes which can be potentially used to obtain single layer BP. Finally, few-layer BP FETs were fabricated and the FET characteristics were measured in vacuum and air. These devices show a significant effect of the environment on their doping, initially from the physisorption of oxygen and nitrogen (which takes places in a timescale of minutes), and subsequently from absorption of water leading to degradation and breakdown (a slower process that takes several hours to days). During the preparation of this manuscript we became aware of a complementary work on the oxidation of BP [31].
