Superoxide reductase (SOR) is a newly discovered activity by which some anaerobic or microaerophilic organisms eliminate superoxide,  $O_2^{\cdot-}$ .<sup>1</sup> The SOR catalyzed reaction differs from that of well-known superoxide dismutases SOD in that it does not produce  $O_2$ , but instead reduces by one electron  $O_2^{\cdot-}$  to form  $H_2O_2$  exclusively:  $O_2^{\cdot-} + 1 e^- + 2H^+ \rightarrow H_2O_2$ .

The active site of SOR consists of a  $Fe^{2+}$  center (center II) in an unusual [ $His_4 Cys_1$ ] square pyramidal pentacoordination.<sup>2</sup> It reacts specifically at a nearly diffusion-controlled rate with  $O_2^{\cdot-}$ , generating  $H_2O_2$  and the oxidized form of the enzyme, the ferric iron center II. The SORs (originally called desulfoferrodoxin) found in some sulfate reducing bacteria, e.g. *Desulfoarculus baarsii*<sup>1b</sup> and *Desulfovibrio desulfuricans*,<sup>2a,3</sup> contain an additional mononuclear  $Fe^{3+}$  center, called center I, coordinated by four cysteines with a distorted rubredoxin-type structure. However, center I is not required for the reaction and, up to now, its function remains unknown.<sup>1b-c</sup>

Recent pulse radiolysis studies of the reaction of center II with  $O_2^{\cdot-}$  have allowed the observation, in the micro and millisecond time scale, of intermediates characterized by absorption bands in the 550-650 nm range.<sup>4</sup> These transient species were proposed to be  $Fe^{3+}$  peroxo complexes, from which  $H_2O_2$  is liberated, on the assumption of an inner sphere mechanism for  $O_2^{\cdot-}$  reduction and on the basis that the corresponding absorption bands were slightly different from those of the final ferric iron center II.<sup>4</sup>

On the basis of the crystal structure<sup>2b</sup> and spectroscopic studies<sup>5</sup> of the SOR from *Pyrococcus furiosus*, it has been proposed that upon oxidation the iron active site becomes six-coordinated, as the consequence of a local protein domain movement which places a strictly conserved glutamate (Glu47 in the SOR from *D. baarsii*) in the free coordination site. We have mutated the Glu47 to alanine (E47A) in the SOR from *D. baarsii* and found that this mutation did not affect the kinetics of formation of the above mentioned intermediates detected by pulse radiolysis.<sup>4a-b</sup> However, because this Glu residue becomes a ligand for the oxidized iron, a likely hypothesis could be that it serves to release  $H_2O_2$  from the  $Fe^{3+}$  peroxo intermediate by substitution in the iron coordination sphere.

Here, we have reacted SOR E47A from *D. baarsii* directly with  $H_2O_2$  and have found that the active site of the mutant can indeed transiently stabilize a  $Fe^{3+}$  peroxo species, that could be spectroscopically characterized.

When we rapidly manually mixed SOR E47A from *D. baarsii* with 6 equivalents of  $H_2O_2$ , a UV-visible absorption feature with a maximum at 560 nm, characteristic for the oxidation of the iron center II,<sup>6a</sup> was immediately observed (Fig.1A).<sup>6b</sup> The

4.2 K EPR spectrum,<sup>7</sup> after subtraction of signals from center I, recorded just after addition of 6 equivalents of  $H_2O_2$  was complex, with a major feature at  $g = 4.3$  and a minor one at  $g = 4.15$  (Fig.1Bi). The former one is comparable to that of an EPR spectrum of SOR E47A oxidized with hexachloroiridate (IV) (Fig.1Bii). It is characteristic for a high-spin  $Fe^{3+}$  in a rhombic ligand field.<sup>1b,3</sup> No other signals in the  $g = 2$  and  $g = 8-10$  regions were observed. At longer incubation time (10 min) with  $H_2O_2$ , the feature at  $g = 4.15$  completely disappeared (data not shown).

Resonance Raman (RR) spectra at 15 K,<sup>8</sup> taken from the SOR E47A frozen immediately after addition of  $H_2O_2$  indicated the presence of two new bands at 850 and 438  $cm^{-1}$  (Fig.2b), which were not present when SOR was oxidized with hexachloroiridate (IV) (Fig.2a). The RR spectra also exhibit a band at 742  $cm^{-1}$  which has been attributed to an internal C-S stretching mode of the  $CysS-Fe^{3+}$  active site.<sup>3</sup> When the same Raman measurements were made after mixing with  $H_2^{18}O_2$ , the 850 and 438  $cm^{-1}$  bands were observed to down shift to 802 and 415  $cm^{-1}$ , respectively (Fig.2c). RR measurements in  $D_2O$  buffer indicated no significant shifts of the 850 and 438  $cm^{-1}$  bands to within 1  $cm^{-1}$  (cf. Supporting Information).

When the reaction was carried out with the wild-type SOR and  $H_2O_2$ , under the same conditions that we described above for the mutant, an intense RR band at 743  $cm^{-1}$  was observed (Fig. 2d). This band can be used as a marker of the amount of  $Fe^{3+}$  formed in these conditions. The bands at 850 and 438  $cm^{-1}$  observed in the case of the mutant with a similar amplitude as that of the 743  $cm^{-1}$  band (Fig. 2b) were now in the case of the wild-type found to be very weak compared to the 743  $cm^{-1}$  band (Fig. 2d). However, they exhibited the same shift upon  $^{18}O$  substitution than reported in the case of the mutant (data not shown). The 4.2 K EPR spectra of the SOR wild-type, after subtraction of signal of center I, and recorded immediately after addition of  $H_2O_2$ , exhibited the rhombic signal at  $g = 4.3$ ,<sup>1b,3</sup> whereas the feature at  $g = 4.15$  was very weak and completely vanished within a few min (data not shown).

The observed RR frequencies at 850 and 438  $cm^{-1}$  and their  $^{18}O$  isotopic shifts (-48 and -23  $cm^{-1}$ ) are consistent with the  $\nu(O-O)$  and  $\nu(Fe-O_2)$  stretching modes, respectively, of an  $Fe^{3+}$ -peroxo species.<sup>9</sup> The lack of deuterium isotopic shifts suggests that this peroxo species is not protonated. We thus conclude that  $H_2O_2$  can oxidize SOR and bind to the ferric center II to yield a transient high-spin  $Fe^{3+}$ -peroxo species, associated with the feature at  $g = 4.15$ , as observed from the 4.2 K EPR spectra. The absorption band at 560 nm resulted probably mainly from the  $Cys$ -to- $Fe^{3+}$  charge transfer band,<sup>3,5</sup> but also

contains a contribution of the peroxo-to-iron  $\text{Fe}^{3+}$  charge transfer band.<sup>9</sup> The resolution of these two charge transfer bands could be achieved by a RR excitation profile, but this is complicated because of the strong interference of center I when excitations are made below 647 nm.<sup>3</sup>

The observed Raman frequencies are comparable to those described for the end-on high-spin  $\text{Fe}^{3+}$ -OOH species in oxyhemerythrin which showed deuterium isotope shifts.<sup>10</sup> However, for SOR reported here, the unusually low  $\text{Fe-O}_2$  frequency ( $438\text{ cm}^{-1}$ ) strongly suggests a side-on  $\eta^2\text{Fe}^{3+}$ -peroxo species<sup>11</sup> as found in the high-spin Fe complexes such as  $[(\text{EDTA})\text{Fe}(\eta^2\text{-O}_2)]^{3+}$ , for example.<sup>9</sup> In addition, the lack of deuterium shift, suggesting a non-protonated peroxo species, is also consistent with a side-on  $\eta^2\text{Fe}^{3+}$ -peroxo species since it is expected to be more stable in the unprotonated form. Such a coordination in the SOR active site would thus imply either a heptacoordination for the iron or a loss of one of the imidazole ligands, but up to now there is no evidence for such possible coordination changes.<sup>5</sup> Clearly, relevant model Fe-peroxo species with sulfur ligands, not yet available, would support our proposal of a side-on peroxo coordination in SOR.

In conclusion, the data presented here first show that SOR active site can accommodate a  $\text{Fe}^{3+}$ -peroxo species and thus support the hypothesis that reduction of  $\text{O}_2^{\cdot-}$  proceeds through such intermediates. To our knowledge, this is the first  $\text{Fe}^{3+}$ -(hydro)peroxo species that has been identified in a mononuclear non-heme iron protein, with such an unusual active site. Current RR experiments in the laboratory are directed in order to identify  $\text{Fe}^{3+}$ -peroxo species formed immediately after reaction with  $\text{O}_2^{\cdot-}$ .

Second, the results suggest that the conserved Glu47 might serve to help  $\text{H}_2\text{O}_2$  release, as illustrated in Scheme 1, since mutation of that residue to alanine results in stabilization of the  $\text{Fe}^{3+}$  peroxide. It should be noted that the presence of the cysteinate trans to the peroxide may also be crucial in promoting  $\text{H}_2\text{O}_2$  dissociation from the  $\text{Fe}^{3+}$ -peroxo intermediate, by pushing electron density on the iron. As a matter of fact, the  $\text{Fe-O}_2$  bond observed here, with  $\nu = 438\text{ cm}^{-1}$ , is particularly weak and the  $\text{O-O}$  bond with  $\nu = 850\text{ cm}^{-1}$  strong, when compared to the corresponding values reported for model complexes that promote  $\text{O-O}$  cleavage and formation of high valent Fe-O species.<sup>9</sup>

ABSTRACT FOR WEB PUBLICATION.

The active site of superoxide reductase SOR consists of a  $\text{Fe}^{2+}$  center in an unusual  $[\text{His}_4 \text{Cys}_1]$  square pyramidal geometry. It specifically reduces superoxide to produce  $\text{H}_2\text{O}_2$ . Here, we have reacted the SOR from *Desulfoarculus baarsii* directly with  $\text{H}_2\text{O}_2$ . We have found that its active site can transiently stabilize a  $\text{Fe}^{3+}$ -peroxo species that we have spectroscopically characterized by resonance Raman. The mutation of the strictly conserved Glu47 into alanine results in a stabilization of this  $\text{Fe}^{3+}$ -peroxo species, when compared to the wild-type form. These data support the hypothesis that the reaction of SOR proceeds through such  $\text{Fe}^{3+}$ -peroxo intermediate. This also suggests that Glu47 might serve to  $\text{H}_2\text{O}_2$  released during the reaction with superoxide.

**Figure S1.** Deuterium isotopic effects on the resonance Raman spectra for the  $\nu(\text{Fe-O}_2)$  (left panel) and  $\nu(\text{O-O})$  (right panel) regions of SOR E47A mutant from *D. baarsii* (1 mM in 50 mM Tris/HCl pH 7.6, or pD 8.0) excited at 647.1 nm (50 mW) at 15 K, treated with 6 equivalents of  $\text{H}_2\text{O}_2$ , rapidly mixed and immediately frozen (less than 5 s). Upper spectra in  $\text{D}_2\text{O}$  solution. Lower spectra in  $\text{H}_2\text{O}$  solution.
