

Identifiability for Blind Source Separation of Multiple Finite Alphabet Linear Mixtures

Merle Behr, Axel Munk

Abstract—We give under weak assumptions a complete combinatorial characterization of identifiability for linear mixtures of finite alphabet sources, with unknown mixing weights and unknown source signals, but known alphabet. This is based on a detailed treatment of the case of a single linear mixture. Notably, our identifiability analysis applies also to the case of unknown number of sources. We provide sufficient and necessary conditions for identifiability and give a simple sufficient criterion together with an explicit construction to determine the weights and the source signals for deterministic data by taking advantage of the hierarchical structure within the possible mixture values. We show that the probability of identifiability is related to the distribution of a hitting time and converges exponentially fast to one when the underlying sources come from a discrete Markov process. Finally, we explore our theoretical results in a simulation study. Our work extends and clarifies the scope of scenarios for which blind source separation becomes meaningful.

Index Terms—Blind source separation; BSS; finite alphabet signals; single mixture; instantaneous mixtures; Markov processes, stopping time

I. INTRODUCTION

A. Problem description

In this work we are concerned with identifiability in a particular kind of blind source separation (BSS) motivated by different applications in digital communication (see e.g., [1]–[3]), but also in cancer genetics (see e.g., [4]–[7]). A prominent example is the separation of a mixture of audio or speech signals, which has been picked up by several microphones, simultaneously (see e.g., [8]). In this case the different speech signals correspond to the sources and the recordings of the microphones to the mixture of signals with unknown mixture weights. From this mixture the individual signals have to be separated.

More generally, in BSS problems one observes P mixtures of N sources and aims to recover the original sources from the available observations. In this paper we focus on the linear case (for the non-linear case see e.g., [9], [10]), where the blindness refers to the fact that neither the sources nor the mixing weights are known. We also treat the case of unknown number of sources.

A minimal requirement underlying any recovery algorithm for sources and mixture weights (in a deterministic or noisy setting) to be valid is identifiability, i.e., the unique decomposition of the mixture into sources and mixing weights.

M. Behr is with the Institute for Mathematical Stochastics and the Felix Bernstein Institute for Mathematical Statistics in the Bioscience, University of Goettingen, 37077 Göttingen, Germany (e-mail: behr@math.uni-goettingen.de). A. Munk is with the Institute for Mathematical Stochastics, the Felix Bernstein Institute for Mathematical Statistics in the Bioscience, University of Goettingen and the Max Planck Institute for Biophysical Chemistry, 37077 Göttingen, Germany (e-mail: munk@math.uni-goettingen.de).

Without any additional information on the source signals S identifiability cannot hold, of course, as from a linear system $X = AS$ the matrices A and S are not uniquely determined, in general. In particular this applies to single linear mixtures ($P = 1$). However, if we assume that the values of the sources are attained in a known finite set of real numbers (finite alphabet), then BSS identifiability holds under certain conditions, which is necessary for any recovery algorithm to be valid.

Therefore, the aim of this work is to give a comprehensive discussion of such conditions. We are able to give (under weak assumptions) a complete combinatorial characterization of identifiability. From this we derive sufficient conditions, which are easy to verify. Moreover, these conditions yield an explicit construction to recover sources and weights in the noiseless case from the deterministic mixture. More specifically, using the notation

$$v = (v_i)_{1 \leq i \leq n} = (v_1, \dots, v_n)^\top, \quad V = (V_{ij})_{\substack{1 \leq i \leq n \\ 1 \leq j \leq m}}$$

for a vector $v \in \mathbb{R}^n$ and a matrix $V \in \mathbb{R}^{n \times m}$ with n rows and m columns and $V_{i \cdot}, V_{\cdot j}$ for the corresponding row and column vectors, respectively, we assume from now on that the observed signal is linked to the sources via

$$X = AS \tag{1}$$

where X is the deterministic mixture, $A = (A_{pn})_{1 \leq p \leq P, 1 \leq n \leq N}$ are the unknown mixing weights, $S = (S_1, \dots, S_N)^\top \in \Omega^{N \times T}$ are the unknown source signals, and $\Omega := \{\omega_1, \dots, \omega_k\} \subset \mathbb{R}$ is a known alphabet, i.e., the set of possible values the sources can attain. The row vectors S_n with $1 \leq n \leq N$ denote the single source signals (of length T) and the row vectors A_p with $1 \leq p \leq P$ denote the mixing vectors (of length N) of the different mixtures.

In an observational model we often have $Y = X + \epsilon$ where ϵ is some random noise term with zero mean. All identifiability results for (1) transfer to this situation as well, of course. However, we stress that the primary aim of this paper is not to provide a method which reconstructs the mixing weights A and the sources S from the (possibly) noisy observations Y , but rather to clarify the scope of scenarios under which this is possible. To this end, we will analyze necessary and sufficient conditions under which the decomposition in (1) is unique.

For the moment, we assume that the number of sources N is known. However, we point out that most of our results remain true even when N is unknown (see Section VIII), a case which has never been treated before to best of our knowledge.

B. Related Work

As far as we are aware of, identifiability of model (1) has not yet been considered in the literature in this general form, although various special cases and variations of this BSS problem have been addressed. The particular case of a binary alphabet, i.e., when $k = 2$ and $\{\omega_1, \omega_2\} = \{-1, 1\}$, has been considered in [11]–[15]. Diamantaras and Papadimitriou [16] and Rostami et al. [17] assume the alphabet to be equally spaced, i.e., $\{\omega_1, \dots, \omega_k\} = \{\omega_0, \omega_0 + T, \omega_0 + 2T, \dots, \omega_0 + kT\}$. We consider arbitrary finite alphabets $\{\omega_1, \dots, \omega_k\} \subset \mathbb{R}$. Moreover, several authors (e.g., [12], [16], [17]) assume a specific distribution on the alphabet, e.g., uniform. Our results show that it is already sufficient to observe some specific combinations of alphabet values (which are minimal conditions in a sense), hence we do not need to assume such a specific distribution. Diamantaras [18] works with a general finite alphabet as well but considers a mixture of two sources, $N = 2$. Li et al. [19] gave necessary and sufficient identifiability criteria for sparse signals, i.e., signals having many zero entries, in contrast to our work. Although they consider underdetermined mixtures, their results require at least two sensors ($P > 1$) and do not hold for single linear mixture ($P = 1$). Bofill and Zibulevsky [20] suggest for $P = 2$ a method for estimating the mixing weights for sparse signals as well, although without giving any explicit identifiability criteria. Diamantaras [14] considers a general finite alphabet but assumes the mixing weights to be complex. Thus, he works with a 2-dimensional signal. Combing the results from [14] and [21] yields a sufficient identifiability criterion for finite alphabet sources with complex mixing weights. However, this result does not hold when the mixing weights are real as considered here.

There are further variations of the BSS problem. Some of them are associated with Independent Component Analysis (ICA) (see e.g., [22]), which is based on the stochastic independence of the different sources (assumed to be random). ICA can be a powerful tool for (over)determined models ($P \geq N$) [22] and there are approaches for underdetermined multiple linear mixture models ($1 < N < P$) as well [23]. However, ICA is not applicable for single linear mixtures ($P = 1$), as the error terms of the single sources sum up to a single error term such that stochastic independence of the sources becomes irrelevant.

Also conceptually related is blind deconvolution (see e.g., [24], [25]), however, the convolution model makes analysis and identifiability severely different [26].

Another related problem is non-negative matrix factorization (see e.g., [27]–[29]), where one assumes (1), but instead of $S \in \Omega^{N \times T}$, both S and A are non-negative. Indeed, the identifiability conditions derived in [28], [29] are quite related in nature to ours in Section IV, where their simpliciality condition on A corresponds to our condition (6) and their separability condition on S corresponds to our assumption A3. However, whereas their assumptions necessarily imply $P > 1$, ours yield identifiability for single linear mixtures ($P = 1$), explicitly exploring the finite alphabet.

For the non-blind scenario, i.e., when A in model (1) is

known, [30] considers identifiability in a probabilistic framework.

To the best of our knowledge, a comprehensive characterization and unifying treatment of identifiability of the mixing weights and the sources for model (1) has been elusive. This issue is, however, fundamental for identifying the scope of possible scenarios where recovery algorithms for S and A in (1) are applicable (see, e.g., [12], [14], [15], [17]). In this sense our work provides an almost "minimal" set of conditions under which any recovery algorithm for the BSS problem only can be expected to be valid; in the noiseless case as well as for the case with random error.

C. Organisation of the paper

We will start our analysis by making two simplifications, which lead to a better interpretation of the corresponding identifiability conditions.

First, we will assume that $P = 1$, i.e., that we observe a single linear mixture in (1). Clearly, when P increases the identification problem becomes easier, as more mixtures of the same sources are observed. Thus, the case $P = 1$ corresponds to the most difficult scenario and therefore we treat this case in detail. Generalizations to arbitrary P will then follow easily from this case and are given in Section VI.

Second, we start with considering probability mixing weights, i.e., $A_{pn} > 0$ and $\sum_{n=1}^N A_{pn} = 1$ for all $p = 1, \dots, P$. This is because the corresponding identifiability conditions have an easier interpretation when the mixing weights are positive. When we allow for negative mixing weights, the identifiability issue becomes slightly more difficult and the corresponding conditions become more complicated. Generalizations to negative mixing weights are given in Section VII.

The paper is organized as follows. After introducing a rigorous formulation of the problem and model (Section II), we will give a necessary and sufficient identifiability criterion for the mixing weights and the sources (Section III). To this end, we will first characterize the identifiability issue as a purely combinatorial problem. In Sections IV we will then generalize a result from Diamantaras and Chassiotti [13] in order to derive a simple sufficient identifiability criterion. This characterizes those source signal combinations which make the variation of the mixture rich enough in order to become identifiable. This condition also provides an explicit construction (see the algorithm in Figure 2) for recovery of the weights A and the sources S from the mixture X in (1).

In Section V we will shortly discuss how likely it is for the identification criterion of Section IV to be satisfied when the underlying sources S_1, \dots, S_N are discrete Markov processes. To this end, we will bound the probability of identification from below by a phase-type distribution. Using a stopping time argument, we will show that the mixture becomes identifiable exponentially fast, which reveals identifiability as less a critical issue in many practical situations as one might expect.

Although, we assume the number of source components N to be known, in Section VIII we show that most of our results remain true even when N is unknown.

In Section IX we simulate source signals from a two-state Markov chain to illustrate how far our derived sufficient identifiability conditions (Section IV) are from being necessary in this setting. To this end, our results from Section III are fundamental as they give an explicit way to decide whether a given mixture is identifiable or not. Our simulation results reveal the simple sufficient condition in Section IV as quite sharp as we find that the number of observations needed for this to hold is quite close to the actual number of observations required for identifiability. This establishes the exponential bound in Section V as a useful tool to estimate the required number of observations guaranteeing identifiability with high probability.

We conclude in Section X.

II. PROBLEM STATEMENT

As mentioned above, for ease of presentation, we start with analyzing identifiability in (1) for single linear mixtures, i.e., $P = 1$ (for arbitrary P see Section VI) and probability mixing weights (for arbitrary mixing weights see Section VII). To this end, let $\mathcal{A} := \{a \in \mathbb{R}^N : 0 < a_1 < \dots < a_N < 1 \text{ and } \sum_{n=1}^N a_n = 1\}$ denote the set of positive (probability) mixing vectors. Note that $a_n \neq a_m$ for $n \neq m$ is always necessary to ensure identifiability of different sources S_n, S_m . (if $a_n = a_m$ interchanging of S_n, S_m results in the same mixture x). For given finite alphabet $\Omega = \{\omega_1, \dots, \omega_k\} \subset \mathbb{R}$, with $\omega_1 < \dots < \omega_k$, number of sources $N \in \mathbb{N}$, and number of observations $T \in \mathbb{N}$ let the sources $S = (S_1, \dots, S_N)^\top \in \Omega^{N \times T}$ and the mixing weights $a = (a_1, \dots, a_N) \in \mathcal{A}$. Then the observed values are given by $x = aS$, i.e.,

$$x_t = \sum_{n=1}^N a_n S_{nt}, \quad t = 1, \dots, T. \quad (2)$$

Definition II.1.

Let $x = aS$; $(a, S) \in \mathcal{A} \times \Omega^{N \times T}$ as in (2). Then we denote the vector a and the matrix S as (jointly) identifiable from the observational vector x when there exists exactly one $(\tilde{a}, \tilde{S}) \in \mathcal{A} \times \Omega^{N \times T}$ such that $x = \tilde{a}\tilde{S}$.

In other words, identifiability means that $x = \tilde{x}$ in (2) implies that $a = \tilde{a}$ and $S = \tilde{S}$. For simplicity, we refer to a and S being identifiable from x just by saying that (a, S) is identifiable. The aim of this paper is to study under which conditions (a, S) is identifiable from x .

Even though we assume N to be known, most of our results remain true when N is unknown, i.e., $x = aS$ with $(a, S) \in \bigcup_{N \geq 2} (\mathcal{A} \times \Omega^{N \times T})$ (see Section VIII).

Example II.2.

To illustrate the problem and notation, let us start with a simple example of model (2), where $N = 2$ and the alphabet is binary with $\Omega = \{0, 1\}$. This means that we consider mixing vectors of the form $a = (a_1, a_2)$ with $a_1, a_2 > 0$, $a_1 + a_2 = 1$ and two different sources $S_1 = (S_{11}, \dots, S_{1T})$, $S_2 = (S_{21}, \dots, S_{2T})$ with $S_{nt} \in \{0, 1\}$ for $n = 1, 2$ and $t = 1, \dots, T$. The question we would like to answer is, under which conditions on a and S is (a, S) uniquely determined via $x = aS$.

For a given observation x_t the underlying source vector $S_{\cdot t} = (S_{1t}, S_{2t})^\top$ equals one of the four different values

$$(0, 0)^\top, (1, 0)^\top, (0, 1)^\top, (1, 1)^\top \quad (3)$$

and hence,

$$x_t \in \{0, a_1, a_2, 1\}. \quad (4)$$

Clearly, if any two of the four values in the set on the r.h.s. of (4) coincide, then two different source values in (3) lead to the same mixture value for x_t and hence the sources are not identifiable, i.e., they cannot be distinguished. Consequently, a necessary condition for identifiability is that all values in the r.h.s. of (4) are different, which is equivalent to

$$a_1 \neq a_2. \quad (5)$$

In other words, it is necessary that the alphabet values in Ω^N are well separated via the mixing weights $a \in \mathcal{A}$. A generalization of this argument to arbitrary alphabets and number of sources is done later in (6). Further, we may assume w.l.o.g. $a_1 < a_2$, i.e., we denote that source as S_1 which comes with the smaller weight.

(5) alone, however, is necessary but not sufficient for identifiability. For instance, if $S_{1t} = S_{2t}$ for all $t = 1, \dots, T$ then $x_t \in \{0, 1\}$ and hence, a is not identifiable from x . Thus, a certain variability of the two sources S_1 and S_2 is necessary to guarantee identifiability of a . In this simple example, it is easy to check that a necessary and sufficient variability of S_1 and S_2 is that S either takes the value $(1, 0)$ (i.e., $x_t = a_1$ for some t) or $(0, 1)$ (i.e., $x_t = a_2$ for some t) as by (5) and $a_1 + a_2 = 1$ it follows that $0 < a_1 < 1/2 < a_2 < 1$. In other words, it is necessary that the mixing weight a_1 (or a_2 respectively) is seen somewhere in the mixture x on its own, without the influence of the other mixing weight. A generalization of these assumptions and this argument to general systems (1) is done later in Theorem IV.1 and Theorem VII.1, respectively.

III. A COMBINATORIAL CHARACTERISATION OF IDENTIFIABILITY: GENERAL THEORY

In model (2) every observation x_t , for $t = 1, \dots, T$, is given by a linear combination of $a \in \mathcal{A}$ (unknown) with one of the finitely many vectors in Ω^N . So in order to identify $S_{\cdot t}$, we have to determine the corresponding vector in Ω^N . Note that multiple observed values leave this identification problem invariant, i.e., do not contribute further to identifiability. Hence, w.l.o.g. we assume all observations x_1, \dots, x_T to be pairwise different. Note, that this implies $T \leq k^N = |\Omega^N|$.

Of course, when for a given mixing vector $a \in \mathcal{A}$ there exist $w' \neq w'' \in \Omega^N$ with $aw' = aw''$ and one observes this value, it is not possible to identify the underlying sources S_1, \dots, S_N uniquely. Consequently, a necessary condition for identifiability is that those values are not observed, i.e., $x_t \notin \{aw : \exists w' \neq w \in \Omega^N \text{ s.t. } aw = aw'\}$ for all $t = 1, \dots, T$. For arbitrary sources this is comprised in the condition of a positive alphabet separation boundary, i.e.,

$$ASB(a) := \min_{w' \neq w \in \Omega^N} |aw - aw'| > 0. \quad (6)$$

Let S_N^T be the collection of injective maps from $\{1, \dots, N\}$ to $\{1, \dots, T\}$, i.e., for $\rho \in S_N^T$ the vector $(x_{\rho(1)}, \dots, x_{\rho(N)})$ corresponds to a selection of elements from (x_1, \dots, x_T) .

Theorem III.1.

Assume model (2) with $x = (x_1, \dots, x_T) = aS$; $(a, S) \in \mathcal{A} \times \Omega^{N \times T}$. Let $E \in \Omega^{N \times N}$ be an arbitrary but fixed invertible $N \times N$ matrix with elements in Ω . Assume that $ASB(a) > 0$ and

A 1.

there exists $\rho \in S_N^T$ such that $(S_{1\rho(r)}, \dots, S_{N\rho(r)})_{1 \leq r \leq N}^\top = E$. Then (a, S) is identifiable if and only if

A 2.

there exists exactly one $\sigma \in S_N^T$ such that for $\tilde{a} := (x_{\sigma(1)}, \dots, x_{\sigma(N)})E^{-1}$

$$\tilde{a} \in \mathcal{A} \quad \text{and} \quad \{x_1, \dots, x_T\} \in \{\tilde{a}w : w \in \Omega^N\}, \quad (7)$$

i.e., \tilde{a} is a valid mixing weight and can reproduce all observations.

For a proof see Appendix A-A.

Theorem III.1 is fundamental for the following as A2 provides a necessary and sufficient condition for identifiability of (a, S) , given A1 holds. In Section IV, it will serve to derive a simple sufficient identifiability condition which is easy to check.

Theorem III.1 is formulated for a fixed (but arbitrary) invertible matrix E and the two identifiability conditions A1 and A2 depend on this matrix E in the following way: For a given E imposing the conditions A1 and A2 restricts the set of all possible mixtures $\mathcal{A} \times \Omega^{N \times T}$ to a smaller set that depends on E in which all elements are identifiable. Thus, different choices of E lead to different instances of Theorem III.1, i.e., to different identifiable submodels. In the following, we will discuss the role of E and conditions A1 and A2 more detailed.

First, we consider A1. Assumption A1 says that the columns of the fixed matrix E must appear somewhere in the columns of the sources S . However, knowledge of where these columns of E occur is not assumed, ρ can be an arbitrary map in S_N^T . Thus, A1 restricts the set of all sources to those where a given set of alphabet combinations, namely the columns of E , appears somewhere in the signal. Hence, in practice, it requires pre-knowledge that certain combinations of values in Ω^N are present *somewhere* in the sources.

Without further restrictions on the matrix E , A1 simplifies to $\text{rank}(S) = N$ (in particular implying $T \geq N$), which is, indeed, an almost minimal condition. By simple linear algebra, it is easy to check that $\text{rank}(S) < \dim(\text{span}(\mathcal{A})) = N - 1$ implies that for any $a \in \mathcal{A}$ exists an $\tilde{a} \neq a \in \mathcal{A}$ such that $aS = \tilde{a}S$, i.e., (a, S) is not identifiable. When we allow for arbitrary mixing weights (see Section VII), i.e., not necessarily summing up to one, then by the same argument $\text{rank}(S) = N$ becomes even a necessary condition. Intuitively, A1 ensures that the sources S_1, \dots, S_N differ sufficiently such that one can identify a from their mixture. For instance, if $S_1 = \dots = S_N$, it follows that $x = S_1$, irrespective of a . Note that if k^N different values x_1, \dots, x_t are observed, i.e., $T = k^N$ (recall that w.l.o.g. in this section T equals

the number of pairwise different x_t 's), then it must hold true that $\{x_1, \dots, x_t\} = \{aw : w \in \Omega^N\}$. Thus, A1 follows trivially for any invertible $N \times N$ matrix E with elements in Ω . However, A1 is a much weaker assumption than $T = k^N$.

Second, we comment on assumption A2. Given A1, assumption A2 reveals a as identifiable as soon as we can assign a collection of observations to rows in E in a unique way. If for some $\sigma \neq \rho \in S_N^T$ \tilde{a} in A2 fulfills the conditions in (7), \tilde{a} is a different mixing weight which can produce the same mixture x with some sources fulfilling A1 and hence, (a, S) is not identifiable. However, if such a $\sigma \neq \rho \in S_N^T$ does not exist, a is uniquely determined from x and identifiability of S follows from $ASB(a) > 0$.

In Section IV we will show that for some specific choices of E A2 always holds, i.e., A1 already implies identifiability. The following example shows that this is not true in general, i.e., not for any choice of E .

Example III.2.

With the notation of (2) and Theorem III.1, let $T = N = 3$, $\Omega = \{0, 1, \frac{21}{6+\sqrt{15}}, 6\}$, $a = \left(\frac{6-\sqrt{15}}{30}, \frac{6+\sqrt{15}}{30}, 0.6\right)$, and

$$S = E = \begin{pmatrix} 6 & 0 & 0 \\ 0 & \frac{21}{6+\sqrt{15}} & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

i.e., ρ in A1 is the identity map and

$$x = aS = \left(\frac{6-\sqrt{15}}{5}, 0.7, 0.6\right).$$

For $\sigma : (1, 2, 3) \mapsto (3, 1, 2)$ we find that

$$(x_{\sigma(1)}, x_{\sigma(2)}, x_{\sigma(3)})E^{-1} = (0.1, 0.2, 0.7) =: \tilde{a},$$

which is a valid mixing weight. Hence, (a, S) is not identifiable.

As mentioned before, in Section IV we will show that some specific choices of E already lead to uniqueness of the selection σ in A2, and thus ensure identifiability. The following remark illustrates how specific choices of rows in E fix some subdomain of σ in A2.

Remark III.3.

If $T = k^N$ with $x_1 < \dots < x_{k^N}$, then x_1 , the smallest observed value, corresponds to the situation when all sources S_{1t}, \dots, S_{Nt} take the smallest value of the alphabet (denoted with ω_1), i.e., if $E_{1\cdot} = (\omega_1, \dots, \omega_1)$, then for all σ satisfying A2 $\sigma(1) = 1$. The second smallest observed value, x_2 , corresponds to the situation when all sources S_{2t}, \dots, S_{Nt} take the smallest value ω_1 , but the source S_{1t} with the smallest weight a_1 takes the second smallest value ω_2 , i.e., if $E_{2\cdot} = (\omega_2, \omega_1, \dots, \omega_1)$, then for all σ satisfying A2 $\sigma(2) = 2$. Analogous holds for the largest observed value and the second largest observed value.

IV. A SIMPLE SUFFICIENT IDENTIFIABILITY CRITERION

We have seen in Theorem III.1 that the problem of identifying a and S from the observations x_1, \dots, x_T reduces to find the corresponding observations x_t for N linear independent

rows of an invertible $N \times N$ matrix E with elements in Ω . Remark III.3 points out that some observations x_t can always be uniquely assigned to source vectors $(S_{1t}, \dots, S_{Nt})^\top \in \Omega^N$ and thus, limit the possible maps σ in A2. The next theorem shows that there is even more structure in the observations x_1, \dots, x_T and that certain variations in the sources, i.e., certain choices of E in A1, already ensure identifiability. Moreover, the proof of the following theorem gives an explicit construction of the unique (a, S) from x .

Theorem IV.1.

Assume model (2) with $x = (x_1, \dots, x_T) = aS$; $(a, S) \in \mathcal{A} \times \Omega^{N \times T}$. Furthermore, assume that $ASB(a) > 0$ and

A 3. there exists $\rho \in S_N^T$ such that

$$(S_{1\rho(r)}, \dots, S_{N\rho(r)})^\top = \mathfrak{s}^r, \quad r = 1, \dots, N,$$

with $(\mathfrak{s}^r)_{1 \leq n \leq N} := (\omega_1 \mathbb{1}_{n \neq r} + \omega_2 \mathbb{1}_{n=r})_{1 \leq n \leq N}$.

Then (a, S) is identifiable.

Before we give a proof (which is based on an explicit algorithm to compute a from x_1, \dots, x_T) we will discuss relationships and differences between the previous results and their assumptions A1 - A3.

Assumption A3 of Theorem IV.1 has a simple interpretation. It means that each of the mixing weights a_n appears somewhere in the mixture on its own (without the influence of any other mixing weight $a_m \neq a_n$) via the mixture value $x_{\rho(n)} = a\mathfrak{s}^n = (\omega_2 - \omega_1)a_n + \omega_1$. For instance, if the alphabet is of the form $\Omega = \{0, 1, \omega_3, \dots, \omega_k\}$ A3 simplifies to the condition that the mixing weights appear somewhere in the mixture, i.e., $a_n \in \{x_1, \dots, x_T\}$ for all $n = 1, \dots, N$. Intuitively, A3 means that for each $n = 1, \dots, N$ there exists one mixture observation x_t such that only S_{nt} is active (taking the value ω_2) and all other sources S_{mt} with $m \neq n$ are silent (taking the value ω_1). It is easy to check that the choice of alphabet values ω_1 and ω_2 (the smallest and second smallest alphabet value) in Theorem IV.1 can be replaced by ω_k and ω_{k-1} (the largest and second largest alphabet value).

Obviously, assumption A3 arises from assumption A1 for a specific choice of E in Theorem III.1, namely with

$$E = \begin{pmatrix} \mathfrak{s}^1 \\ \vdots \\ \mathfrak{s}^m \end{pmatrix} = \begin{pmatrix} \omega_2 & \omega_1 & \dots & \omega_1 & \omega_1 \\ \omega_1 & \omega_2 & \dots & \omega_1 & \omega_1 \\ \omega_1 & \omega_1 & \ddots & \omega_1 & \omega_1 \\ \omega_1 & \omega_1 & \dots & \omega_2 & \omega_1 \\ \omega_1 & \omega_1 & \dots & \omega_1 & \omega_2 \end{pmatrix}. \quad (8)$$

Consequently, if the matrix in (8) is invertible, A3 implies A1. The following Lemma shows that this holds under mild conditions on Ω and N .

Lemma IV.2.

For model (2) let A3 be as in Theorem IV.1 and A1 as in Theorem III.1.

If $\omega_2 \neq \omega_1(1 - N)$, then A3 implies A1.

For a proof see Appendix A-B.

Figure 1 summarizes all relations between A1 - A3 in a diagram.

Figure 1. Relation between A1, A2, and A3

Now we turn to the proof of Theorem IV.1, which is proven by explicit recovery of (a, S) . This generalizes an algorithm of Diamantaras and Chassiot [13] for the binary alphabet $\Omega = \{-1, 1\}$ to a general finite alphabet.

Proof of Theorem IV.1: Assumption A3 implies that

$$x_{\rho(r)} = a\mathfrak{s}^r, \quad r = 1, \dots, N, \quad (9)$$

and hence,

$$a_r = \frac{x_{\rho(r)} - \omega_1}{\omega_2 - \omega_1}. \quad (10)$$

Thus, it suffices to determine the map ρ and the values $x_{\rho(1)}, \dots, x_{\rho(N)}$, respectively, in order to determine a . When a is determined, identifiability of S follows from $ASB(a) > 0$.

Recall Remark III.3 and note that

$$x_{\rho(1)} = \min(\{x_1, \dots, x_T\} \setminus \{\omega_1\}), \quad (11)$$

which determines a_1 as in (10). The following two lemmas show that successively all the other $\rho(r)$ (and hence a_r) for $r = 2, \dots, N$ can be determined as well, which finishes the proof.

Let $B = B(N, \Omega)$ be the $N \times k^N$ -matrix, where the j th column of B is the number $j - 1$ written in the positional notation based on the number k , identifying 0 with ω_1 , 1 with ω_2 , and so on, i.e.,

$$B_{ij} = \sum_{r=1}^k \omega_r \mathbb{1}_{\lfloor \frac{(j-1) \bmod k^i}{k^{i-1}} \rfloor = r-1}, \quad (12)$$

and $d := aB$ the k^N dimensional vector of all possible values that x can take.

Lemma IV.3.

From a_1, \dots, a_r one can determine d_1, \dots, d_{k^r} uniquely.

Lemma IV.4.

It holds that $x_{\rho(r)} = \min(\{x_1, \dots, x_T\} \setminus \{d_1, \dots, d_{k^{r-1}}\})$.

For proofs see Appendix A-C and A-D, respectively. ■

The proof of Theorem IV.1 gives an explicit recovery construction for (a, S) which is summarized in Figure 2. For noisy data one may use algorithm 2 to proceed similar as Diamantaras and Chassiot [13] who suggest a clustering approach for estimating a and S from noisy observations of x . However, as the purpose of this paper is not to propose a practical method for recovery from noisy data, but rather to analyze the scope of scenarios under which this is possible

Input: x_1, \dots, x_T
 $r = 1$
 $\mathfrak{G} \leftarrow \{x_1, \dots, x_T\} \setminus \{\omega_1\}$
 $c_1 \leftarrow \min \mathfrak{G}$
 $a_1 \leftarrow \frac{c_1 - \omega_1}{\omega_2 - \omega_1}$
Determine d_1, \dots, d_k with Lemma IV.3 (using a_1).
 $\mathfrak{G} \leftarrow \mathfrak{G} \setminus \{d_1, \dots, d_k\}$
while $\mathfrak{G} \neq \emptyset$ **do**
 $r = r + 1$
 $c_r \leftarrow \min \mathfrak{G}$
 $a_r \leftarrow \frac{c_r - \omega_1}{\omega_2 - \omega_1}$
Determine d_1, \dots, d_{kr} with Lemma IV.3 (using a_1, \dots, a_r).
 $\mathfrak{G} \leftarrow \mathfrak{G} \setminus \{d_1, \dots, d_{kr}\}$
end while
 $N \leftarrow r$
return N and a_1, \dots, a_N

in principle, we are not going to follow this approach here further.

V. IDENTIFIABILITY FOR MIXTURES OF STOCHASTIC PROCESSES

In this subsection we will shortly discuss how likely it is for the identifiability condition of Theorem IV.1 to be satisfied when $(S_{1t}, \dots, S_{Nt})_t^\top$ is a stochastic process. Therefore, let \mathfrak{s}^r be as in Theorem IV.1, and define the hitting times

$$\mathfrak{T}^r := \min\{t \in \mathbb{N} : (S_{1t}, \dots, S_{Nt}) = \mathfrak{s}^r\}, \quad (13)$$

for $r = 1, \dots, N$, and the stopping time

$$\mathfrak{T} := \max_{r=1, \dots, N} \mathfrak{T}^r.$$

Then it follows from Theorem IV.1 that

$$\begin{aligned} & \mathbf{P}((a, S) \text{ is identifiable}) \\ & \geq \mathbf{P}(\exists \rho \in S_N^T : (S_{1\rho(r)}, \dots, S_{N\rho(r)})^\top = \mathfrak{s}^r) \\ & = \mathbf{P}(\mathfrak{T} \leq T) \geq 1 - \sum_{r=1}^N \mathbf{P}(\mathfrak{T}^r > T). \end{aligned} \quad (14)$$

Note that this bound only depends on the distributions of the hitting times \mathfrak{T}^r , which are often explicitly known or good estimates exist. A prominent class of examples for modeling the distribution of the source signals are Markov processes including iid sequences (see e.g., [4], [16], [17]).

Theorem V.1.

Assume that the source signals $(S_{1t}, \dots, S_{Nt})_t^\top$ in (2) constitute an irreducible Markov process on the finite state space Ω^N , with transition matrix $P = (p_{ij})_{1 \leq i, j \leq k^N}$, where we identify the first N states of Ω^N with $\mathfrak{s}^1, \dots, \mathfrak{s}^N$ from Theorem IV.1. Let $M \in \mathbb{N}$ be such that $P^M > 0$ and

$$\begin{aligned} Q_r & := (p_{ij})_{1 \leq i, j \neq r \leq k^N}, \quad r = 1, \dots, N, \\ c & := \max_{1 \leq r \leq N} \|Q_r^M \mathbf{1}\|_\infty. \end{aligned}$$

Then $c < 1$ and, if $ASB(a) > 0$,

$$1 - \mathbf{P}((a, S) \text{ is identifiable}) \leq Nc^{\lfloor \frac{T}{M} \rfloor} \leq Nc^{\frac{T-M}{M}}. \quad (15)$$

For a proof see Appendix A-E.

Example V.2 (Bernoulli Model).

Let us consider (2) for the simple case where we have two sources S_1 and S_2 that can take two different values, i.e., $\Omega = \{\omega_1, \omega_2\}$. For instance, the source signals could come from a binary antipodal alphabet ($\Omega = \{-1, 1\}$) as they appear in many digital modulated schemes.

If we assume that S_{1t} and S_{2t} are independent and identically distributed (i.i.d.) for all $t = 1, \dots, T$ with $\mathbf{P}(S_{nt} = \omega_1) = p \in (0, 1)$ and $\mathbf{P}(S_{nt} = \omega_2) = 1 - p =: q$ for $n = 1, 2$ and $t = 1, \dots, T$, then $(S_{1t}, S_{2t})_t^\top$ constitutes an irreducible Markov process on the state space $\{(\omega_2, \omega_1)^\top, (\omega_1, \omega_2)^\top, (\omega_1, \omega_1)^\top, (\omega_2, \omega_2)^\top\}$ with transition matrix

$$P = \begin{pmatrix} pq & pq & p^2 & q^2 \\ pq & pq & p^2 & q^2 \\ pq & pq & p^2 & q^2 \\ pq & pq & p^2 & q^2 \end{pmatrix} > 0.$$

Hence, $M = 1$,

$$Q_1 = Q_2 = \begin{pmatrix} pq & p^2 & q^2 \\ pq & p^2 & q^2 \\ pq & p^2 & q^2 \end{pmatrix},$$

and $c = qp + p^2 + q^2 = 1 - pq$. Thus, Theorem V.1 yields

$$1 - \mathbf{P}((a, S) \text{ is identifiable}) \leq 2(1 - pq)^T.$$

In this simple setting we can even calculate the probability of identifiability exactly. Note that (a, S) is identifiable if and only if $c_1 = a_1\omega_2 + a_2\omega_1$ or $c_2 = a_1\omega_1 + a_2\omega_2$ is observed as $\omega_1 < c_1 < \omega_1 + (\omega_2 - \omega_1)/2 < c_2 < \omega_2$ and

$$\begin{aligned} (a_1, a_2) & = \left(\frac{c_1 - \omega_1}{\omega_2 - \omega_1}, \frac{\omega_2 - c_1}{\omega_2 - \omega_1} \right) \\ & = \left(\frac{\omega_2 - c_2}{\omega_2 - \omega_1}, \frac{c_2 - \omega_1}{\omega_2 - \omega_1} \right). \end{aligned}$$

Therefore,

$$1 - \mathbf{P}((a, S) \text{ is identifiable}) = \mathbf{P}(S_{11} = S_{21})^T = (1 - 2pq)^T.$$

Example V.2 shows that the bound in Theorem V.1 does not need to be sharp in general but captures the exponential decay (in T) well. This is mainly because in Theorem V.1 the probability of (a, S) being identifiable is bounded using the sufficient (and not necessary) identifiability condition A3 from Theorem IV.1. In Section IX the gap between this bound and the true probability $\mathbf{P}((a, S) \text{ is identifiable})$ in (15) is further explored in a simulation study.

VI. MULTIPLE LINEAR MIXTURES

After analyzing the most difficult scenario of a single linear mixture with $P = 1$ in (1), generalizations to arbitrary number of mixtures P now follow easily. To this end, for a vector v

let $\|v\|_1 := \sum_{i=1}^n |v_i|$ denote the l_1 -norm and define the set of P -mixtures as

$$\mathcal{A}_P := \{A \in \mathbb{R}_+^{P \times N} : \|A_{\cdot 1}\|_1 < \dots < \|A_{\cdot P}\|_1, \\ \|A_{\cdot 1}\|_1 = \dots = \|A_{\cdot P}\|_1 = 1\}.$$

Again, note that $\|A_{\cdot n}\|_1 \neq \|A_{\cdot m}\|_1$ for $n \neq m$ is necessary to ensure identifiability of different sources. Then for $S \in \Omega^{N \times T}$ and $A \in \mathcal{A}_P$ the observed values are given by $X = AS$, i.e.,

$$X_{pt} = \sum_{n=1}^N A_{pn} S_{nt}, \quad t = 1, \dots, T, p = 1, \dots, P.$$

Identifiability means to decompose the matrix $X \in \mathbb{R}^{P \times T}$ uniquely into matrices $A \in \mathcal{A}_P$ and $S \in \Omega^{N \times T}$ for given finite alphabet $\Omega = \{\omega_1, \dots, \omega_k\}$ with $\omega_1 < \dots < \omega_k$ and given $T, N, P \in \mathbb{N}$. Analog to before we define the alphabet separation boundary of a mixture matrix $A \in \mathcal{A}_P$ as

$$ASB(A) := \min_{w' \neq w \in \Omega^N} \|Aw - Aw'\|_1.$$

Clearly, $ASB(A) > 0$ is a necessary condition on A for (S, A) to be identifiable. Theorem III.1, Theorem IV.1, and Theorem V.1 assume that $P = 1$. It is straight forward to check that Theorem III.1 holds unchanged when $P > 1$ with \mathcal{A} replaced by \mathcal{A}_P . The same is true for Theorem IV.1, where in the proof the minimum of a set of observations $X_{\cdot t}$ must be replaced by the minimum defined in terms of the ordering of $\sum_{p=1}^P X_{pt}$. Thus, clearly Theorem V.1 also holds unchanged when $P > 1$.

VII. ARBITRARY MIXING WEIGHTS

So far, we assumed the mixing weights to be positive and to sum up to one. However, in some applications this assumption is not satisfied (e.g., in digital communications [2]) and in the following we discuss such generalizations. Let $\tilde{\mathcal{A}} \subseteq \mathcal{A}_0 := \{a \in \mathbb{R}^N : a_1 < \dots < a_N\}$ be an arbitrary subset of mixing weights $a_n \in \mathbb{R}$. Note that w.l.o.g. $a_1 < \dots < a_N$ in order to assign the mixing weight to a source.

It is easy to check that Theorem III.1 holds unchanged with \mathcal{A} replaced by $\tilde{\mathcal{A}}$. Note, however, that if $\tilde{\mathcal{A}} \supsetneq \mathcal{A}$ condition A2 becomes more restrictive, i.e., a mixture (a, S) which is identifiable with respect to \mathcal{A} might not be identifiable with respect to $\tilde{\mathcal{A}}$.

Analogously, Theorem IV.1 can be generalized for $\tilde{\mathcal{A}} \supsetneq \mathcal{A}$, where now the corresponding identifiability assumption A3 becomes more restrictive.

The following theorem considers the most general case of arbitrary mixing weights in \mathcal{A}_0 .

Theorem VII.1.

Assume model (2) $x = aS$ with $(a, S) \in \mathcal{A}_0 \times \Omega^{N \times T}$. Furthermore, assume that $ASB(a) > 0$ and there exists $\rho, \mu \in S_{N+1}^T$ such that

$$\begin{aligned} (S_{1\rho(r)}, \dots, S_{N\rho(r)})^\top &= \mathfrak{s}^{r-1}, \quad r = 1, \dots, N+1, \\ (S_{1\mu(r)}, \dots, S_{N\mu(r)})^\top &= \mathfrak{r}^{r-1}, \quad r = 1, \dots, N+1, \end{aligned} \quad (16)$$

with $\mathfrak{s}^r, \mathfrak{r}^r \in \Omega^N$ for $r = 0, \dots, N$ defined as

$$\begin{aligned} (\mathfrak{s}^r)_i &:= \omega_2 \mathbb{1}_{i=r} + \omega_k \mathbb{1}_{a_i * a_r < 0} + \omega_1 \mathbb{1}_{\substack{a_i * a_r > 0, \\ i \neq r}}, \\ (\mathfrak{r}^r)_i &:= \omega_{k-1} \mathbb{1}_{i=r} + \omega_1 \mathbb{1}_{a_i * a_r < 0} + \omega_k \mathbb{1}_{\substack{a_i * a_r > 0, \\ i \neq r}}, \end{aligned}$$

for $i = 1, \dots, N$ and $a_0 := 1$. Then (a, S) is identifiable.

The proof of Theorem VII.1 is given in Appendix A-F.

Recall that for positive mixing weights the identifiability condition A3 in Theorem IV.1 had a very simple interpretation, namely that each of the single mixing weights a_n appears somewhere in the mixture x on its own, without the influence of any of the other mixing weights a_m for $m \neq n$. The interpretation of (16) is somewhat more difficult, but similar. In the case of probability mixing weights $a \in \mathcal{A}$ as in Theorem IV.1 both, the sum and the absolute sum of the mixing weights were fixed via $\sum_{n=1}^N a_n = \sum_{n=1}^N |a_n| = 1$ and this determined the scaling in which the mixing weights appear in the mixture x . Now for general mixing weights $a \in \mathcal{A}_0$ as in Theorem VII.1 both, the sum and the absolute sum (or equivalently the sum of the negative mixing weights and the sum of the positive mixing weights) are unknown and thus, additional conditions to determined these unknown scaling parameters are needed. These correspond to \mathfrak{s}^0 and \mathfrak{r}^0 . They ensure that the smallest possible mixture value (which corresponds to \mathfrak{s}^0) and the largest possible mixture value (which corresponds to \mathfrak{r}^0) are observed and thus determine the scaling parameters. Now analog to \mathfrak{s}^n in A3 of Theorem IV.1, \mathfrak{s}^n and \mathfrak{r}^n in (16) of Theorem VII.1 ensure that a_n appears somewhere in the mixture x on its own and can thus be determined. However, as the sign of a_n is now unknown, too, we get the additional unambiguity that a mixture value can be increased either by increasing a source which corresponds to a positive mixing weight or by decreasing a source which corresponds to a negative mixing weight.

From Theorem VII.1 it follows directly that Theorem V.1 holds with N replaced by $2N+2$, when we allow for arbitrary mixing weights in \mathcal{A}_0 .

VIII. UNKNOWN NUMBER OF SOURCE COMPONENTS

So far, we assumed that the number of sources N is fixed and known. Now we consider the case where N is unknown, i.e. $x = aS$ with

$$(a, S) \in \bigcup_{N \geq 2} (\mathcal{A} \times \Omega^{N \times T}). \quad (17)$$

While it is not clear how to generalize Theorem III.1 for (a, S) as in (17), condition A3 in Theorem IV.1 is still sufficient for identifiability when N is unknown.

To see this, note that the proof of Theorem IV.1 (in particular Lemma IV.3) does not require the number of sources N to be known, where N is determined via

$$N = \min(r \in \mathbb{N}_{\geq 2} \text{ s.t. } \{x_1, \dots, x_T\} \subset \{d_1, \dots, d_{kr}\}),$$

and thus, we obtain the following theorem.

Theorem VIII.1.

Assume model (2) with $x = (x_1, \dots, x_T) = aS$; $(a, S) \in$

$\bigcup_{N \geq 2} (\mathcal{A} \times \Omega^{N \times T})$. Furthermore, assume that $ASB(a) > 0$ and $A3$ holds. Then (a, S) (and thus N) is identifiable.

Analogously, Theorem V.1 and Theorem VII.1 do not require N to be known.

IX. SIMULATIONS

Finally, we explore in a simulation study how far assumption $A3$ from Theorem IV.1 is from being necessary when the sources come from an irreducible Markov process; which corresponds to exploring the tightness of the bound in Theorem V.1. To this end, Theorem III.1 is fundamental as it enables us to explicitly examine identifiability of (a, S) . We consider an example with a binary alphabet $\Omega = \{-2, 1\}$ and a mixture of $N = 3$ sources. The matrix E in Theorem III.1 was chosen randomly over the set of invertible $N \times N$ matrices with elements in Ω . Simulation runs were always 1,000.

First, we assume the mixing weights $a = (0.2, 0.35, 0.45)$. Note that $a\omega \neq a\omega'$ for all $\omega \neq \omega' \in \{-2, 1\}^3$, i.e., $ASB(a) > 0$.

A. Bernoulli Model

Assuming the sources to be i.i.d. for all $n = 1, 2, 3$ and $t = 1, \dots, T$, with $\mathbf{P}(S_{nt} = -2) = \mathbf{P}(S_{nt} = 1) = 0.5$ we find that (a, S) is already identifiable on average for $t \geq 4.39$ observations. For the sufficient identifiability condition from Theorem IV.1 to hold we find an average value of $t \geq 14.79$ observations. Figure 3 shows the corresponding histograms and cumulative distribution functions. The results indicate that the number of observations needed for the sufficient identifiability condition $A3$ from Theorem IV.1 to be satisfied is not considerably higher than the actual number of observations until (a, S) is identifiable and thus the bound in Theorem V.1 is quite sharp in this example.

Figure 3. Top row: histograms of number of observations until (a, S) is identifiable (left) and until the sufficient identifiability condition from Theorem IV.1 is fulfilled (right), bottom row: corresponding empirical cumulative distribution function, with $N = 3$, $\Omega = \{-2, 1\}$, $a = (0.2, 0.35, 0.45)$ and S_{nt} i.i.d. on Ω .

B. Markov Model

We consider a more general Markov model for generating the sources, i.e., we assume the sources to be independent Markov processes on the state space $\Omega = \{-2, 1\}$ with transition matrix

$$P = \begin{pmatrix} p_1 & 1 - p_1 \\ 1 - p_2 & p_2 \end{pmatrix}. \quad (18)$$

In Figure 4 we display the average numbers of observations until (a, S) is identifiable and until the sufficient identifiability condition $A3$ from Theorem IV.1 is fulfilled, respectively, for each $(p_1, p_2) \in \{0.1, 0.15, 0.2, \dots, 0.8, 0.85, 0.9\}^2$. Note that $p_1 = 1 - p_2$ corresponds to i.i.d. observations, with $1 - \mathbf{P}(S_{nt} = 1) = \mathbf{P}(S_{nt} = -2) = p_1$.

Figure 4. Heat-maps of average number of observations until (a, S) is identifiable (left) and until the sufficient identifiability condition from Theorem IV.1 is fulfilled (right) in dependence of p_1 and p_2 from (18).

From Figure 4 we draw that identifiability is achieved faster when p_1 and p_2 are close to 0.5, which corresponds to the i.i.d. Bernoulli model from Section IX-A. This is explained by condition $A2$ in Theorem III.1, where a richer variation in the sources, i.e., many different observations x_1, \dots, x_T , reduces the set of possible valid mixing weights and thus favor identifiability. The sufficient identifiability condition $A3$ from Theorem IV.1, however, requires repeated occurrence of the smallest alphabet values ω_1 . Consequently, small p_1 and large p_2 discriminate against those variations.

C. Multiple Linear Mixtures

Now, we consider multiple linear mixtures, i.e., $P > 1$. Therefore, for each run, we draw P mixing weights, each of length $N = 3$, independently from the uniform distribution on \mathcal{A} (implying $ASB(a) > 0$). For the sources, we consider a Bernoulli model as in Section IX-A.

We find that (a, S) is identifiable on average after $t \geq 4.17, 4.07, 4.01, 3.99$ for $P = 1, 2, 3, 4$ observations, revealing that identifiability (condition $A2$ in Theorem III.1) depends much more on the variability of the sources than on the specific mixing weights. This is confirmed in Figure 5, which shows the corresponding histograms and cumulative distribution functions. The histograms and cumulative distribution functions for $P = 1$ and $P = 4$ differ only slightly and for $P = 1$ they look almost the same as in Figure 3, although in Figure 3 a is fixed, whereas in Figure 5 it is random. For the sufficient identifiability condition from Theorem IV.1 to hold we find an average value of $t \geq 15.13$ observations. Note that this condition depends on the sources only and, thus, is the same for all P .

D. Arbitrary Mixing Weights

Finally, we consider arbitrary mixing weights in \mathcal{A}_0 . Therefore, for each run, we draw mixing weights ($P = 1$,

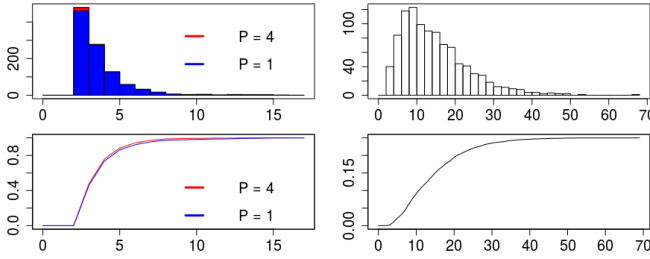

Figure 5. Top row: histograms of number of observations required until (a, S) is identifiable (left) and until the sufficient identifiability condition A3 from Theorem IV.1 is fulfilled (right), bottom row: corresponding empirical cumulative distribution function, with $N = 3$, $\Omega = \{-2, 1\}$, a uniformly distributed on \mathcal{A} and S_{nt} i.i.d. on Ω .

Figure 6. Top row: histograms of number of observations until (a, S) is identifiable (left) and until the sufficient identifiability condition from Theorem IV.1 is fulfilled (right), bottom row: corresponding empirical cumulative distribution function, with $N = 3$, $\Omega = \{-2, 1\}$, a uniformly distributed on $\{a \in [-10, 10]^N : a_1 < \dots < a_N\}$ and S_{nt} i.i.d. on Ω .

$N = 3$) independently from the uniform distribution on $\{a \in [-10, 10]^N : a_1 < \dots < a_N\}$ and for the sources we consider a Bernoulli model as in Section IX-A.

We find that (a, S) is identifiable on average after $t \geq 6.09$ observations. Confirming, that identifiability, i.e., condition A2 in Theorem III.1, is achieved slower, when we allow for larger sets of possible mixing weights. For the sufficient identifiability condition from Theorem VII.1 to hold we find an average value of $t \geq 20.82$ observations. Figure 6 shows the corresponding histograms and cumulative distribution functions.

In summary, our simulations show that the number of observations needed for our simple sufficient identifiability condition A3 to hold is relatively close to the actual number of observations until (a, S) is identifiable and thus, serves as a good benchmark criterion for identifiability. This can be used as a simple proxy for validating the applicability of any recovery procedure in practice.

X. CONCLUSIONS

In this paper we have established identifiability criteria for single linear mixtures of finite alphabet sources as well as its matrix analogue. We gave not only sufficient but also necessary criteria for identifiability. Our work reveals the identification problem as a combinatorial problem utilizing the one to one correspondence between the mixture values and the mixing weights. We generalized the method of Diamantaras and Chassiotti [13] to an arbitrary finite alphabet in order to derive a simple sufficient identifiability criterion. The proof

uses the specific hierarchical structure of possible mixture values leading to successive identification of the weights. Thus, our results characterize and extend the range of settings under which recovery algorithms (for statistical data) are applicable.

Notably, we showed that our identifiability conditions extend to unknown number of sources N . This lays the foundation to design algorithms to recover the number of active sources from a mixture and sketches a road map to pursue this in future research.

Finally, we showed that the probability of identifiability converges exponentially fast to 1 when the underlying sources come from a discrete Markov process. This provides a useful and simple tool to pre-determine the required number of observations in order to guarantee identifiability at a given probability.

The derived sufficient identifiability conditions were briefly investigated in a simulation study and the required sample size for their validity was found to be quite close to the minimal sample size for identifiability.

This work is intended to give a solid theoretical background for a model that is used in a variety of applications in digital communications, but also in bioinformatics.

APPENDIX A PROOFS

A. Proof of Theorem III.1

Proof:

For $\sigma \in S_N^T$ we define $x^\sigma = (x_{\sigma(1)}, \dots, x_{\sigma(N)})$.

“ \Leftarrow ”

By assumption A1 $x^\rho = aE$, i.e., $x^\rho E^{-1} = a$ and, consequently,

$$x^\rho E^{-1} \in \mathcal{A} \text{ and } \{x_1, \dots, x_T\} \in \{(x^\rho E^{-1})\omega : \omega \in \Omega^N\},$$

which, by assumption A2, is not fulfilled for any other $\sigma \in S_N^T$. Thus, a is uniquely determined. Moreover, as $ASB(a) > 0$, S is uniquely determined as well.

“ \Rightarrow ”

Assume A2 does not hold, i.e., there exists $\sigma \neq \rho \in S_N^T$ such that $\tilde{a} := x^\sigma E^{-1}$ fulfills

$$\tilde{a} \in \mathcal{A} \text{ and } \{x_1, \dots, x_T\} \in \{\tilde{a}\omega : \omega \in \Omega^N\}.$$

As we assume all observations to be pairwise different, $\tilde{a} \neq a$ and \tilde{a} with the corresponding \tilde{S} lead to the same observations x_1, \dots, x_T . Therefore, (a, S) is not identifiable. ■

B. Proof of Lemma IV.2

Proof: Obviously, A3 arises from A1 when we choose the matrix E in Theorem III.1 as in (8). Hence, A3 implies A1 if the matrix in (8) is invertible. (8) can be written as

$$\begin{pmatrix} \omega_1 & \dots & \omega_1 \\ \vdots & & \vdots \\ \omega_1 & \dots & \omega_1 \end{pmatrix} - (\omega_1 - \omega_2) \begin{pmatrix} 1 & \dots & 0 \\ \vdots & & \vdots \\ 0 & \dots & 1 \end{pmatrix}$$

and consequently, the matrix in (8) has zero determinant if and only if $\omega_1 - \omega_2$ is an eigenvalue of

$$\begin{pmatrix} \omega_1 & \cdots & \omega_1 \\ & \ddots & \\ \omega_1 & \cdots & \omega_1 \end{pmatrix},$$

i.e., $\omega_1 - \omega_2 = 0$ or $\omega_1 - \omega_2 = N \cdot \omega_1$. As $\omega_1 < \omega_2$ the assertion follows. ■

C. Proof of Lemma IV.3

Proof: For $r = N$ the assertion is obvious. So let $r < N$. Then for $i \in \{1, \dots, k^r\}$ we have that

$$\begin{aligned} d_i &= \sum_{j=1}^r a_j B_{ji} + \sum_{j=r+1}^N a_j \omega_1 = \\ &= \sum_{j=1}^r a_j B_{ji} + \omega_1 (1 - \sum_{j=1}^r a_j), \end{aligned}$$

where B_{ji} are the entries of the matrix B in (12). ■

D. Proof of Lemma IV.4

Proof: By definition $x_{\rho(r)} = d_{k^{r-1}+1}$. Therefore, $x_{\rho(r)} \geq \min(\{x_1, \dots, x_T\} \setminus \{d_1, \dots, d_{k^{r-1}}\})$ and for $i \in \{k^{r-1} + 1, \dots, k^N\}$

$$\begin{aligned} d_i - x_{\rho(r)} &= \sum_{l=1}^{r-1} a_l (B_{li} - \omega_1) + a_r (B_{ri} - \omega_2) \\ &\quad + \sum_{l=r+1}^N a_l (B_{li} - \omega_1). \end{aligned}$$

If $B_{ri} \in \{\omega_2, \dots, \omega_k\}$, then obviously $d_i - x_{\rho(r)} \geq 0$. If $B_{ri} = \omega_1$, then by definition of B there exists an $s \in \{r+1, \dots, N\}$ such that $B_{si} \in \{\omega_2, \dots, \omega_k\}$, and therefore,

$$\begin{aligned} d_i - x_{\rho(r)} &= \sum_{l=1}^{r-1} a_l (B_{li} - \omega_1) + a_r (\omega_1 - \omega_2) \\ &\quad + a_s \underbrace{(B_{si} - \omega_1)}_{\geq (\omega_2 - \omega_1)} + \sum_{l=r+1, l \neq s}^N a_l (B_{li} - \omega_1) \\ &\geq \sum_{l=1}^{r-1} a_l (B_{li} - \omega_1) + \underbrace{(a_s - a_r)}_{>0} \underbrace{(\omega_2 - \omega_1)}_{>0} \\ &\quad + \sum_{l=r+1, l \neq s}^N a_l (B_{li} - \omega_1) \geq 0. \end{aligned}$$

Consequently, $x_{\rho(r)} \leq \min(\{x_1, \dots, x_T\} \setminus \{d_1, \dots, d_{k^{r-1}}\})$. ■

E. Proof of Theorem V.1

Proof: Let \mathfrak{T}^r be as in (13) and let p_0 be the initial distribution of $(S_{1t}, \dots, S_{Nt})_t^\top$. Define the stopped process

$$\tilde{s}_t^r := \begin{cases} (S_{1t}, \dots, S_{Nt})^\top & \text{if } t < \mathfrak{T}^r \\ \mathfrak{s}^r & \text{otherwise,} \end{cases}$$

for $r = 1, \dots, N$, which is a Markov process as well (see e.g., [31, Proposition 4.11.1.]). It is obvious that for the Markov process $(\tilde{S}_t^r)_t$ the state \mathfrak{s}^r is absorbing and all other states are transient. Moreover, when we reorder the states in Ω^N such that \mathfrak{s}^r is the first state, the transition matrix of $(\tilde{S}_t^r)_t$ is given by

$$\tilde{P}_r = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ p_{2r} & & & \\ & Q_r & & \\ p_{Nr} & & & \end{pmatrix}.$$

The distribution of \mathfrak{T}^r is a discrete phase type distribution (see e.g., [32, Section 2.2.]), i.e.,

$$\mathbf{P}(\mathfrak{T}^r > T) = p_0 Q_r^T \mathbf{1} \leq \|Q_r^T \mathbf{1}\|_\infty. \quad (19)$$

As $P^M > 0$

$$\tilde{P}_r^M = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ s_{2r} & & & \\ \vdots & & & \\ s_{Nr} & & & Q^M \end{pmatrix}$$

with $s_{2r}, \dots, s_{Nr} > 0$ for $r = 1, \dots, N$. Consequently, all row sums of Q_r^M are smaller than 1, i.e.,

$$c_r := \|Q_r^M \mathbf{1}\|_\infty < 1 \quad (20)$$

and hence $c = \max_{1 \leq r \leq N} c_r < 1$.

Next, we show by induction that $\|Q_r^T \mathbf{1}\|_\infty \leq c_r^{\lfloor T/M \rfloor}$ for all $T \geq M$. For $T = M$ this holds by definition. So assume that $\|Q_r^l \mathbf{1}\|_\infty \leq c_r^{\lfloor l/M \rfloor}$ for all $M \leq l \leq T$ and define $A = (a_{ij})_{ij} := Q_r^T$, i.e.,

$$\max_i \sum_j a_{ij} \leq c_r^{\lfloor T/M \rfloor}.$$

If $\lfloor \frac{T}{M} \rfloor = \lfloor \frac{T+1}{M} \rfloor$, then

$$\begin{aligned} \|Q_r^{T+1} \mathbf{1}\|_\infty &= \|A Q_r \mathbf{1}\|_\infty = \max_i \sum_j \sum_k a_{ik} q_{kj} \\ &= \max_i \sum_k a_{ik} \sum_j q_{kj} \leq c_r^{\lfloor \frac{T}{M} \rfloor} = c_r^{\lfloor \frac{T+1}{M} \rfloor}, \end{aligned}$$

as $\max_i \sum_k a_{ik} \leq c_r^{\lfloor \frac{T}{M} \rfloor}$ and $\sum_j q_{kj} \leq 1$.

If $\lfloor \frac{T}{M} \rfloor \neq \lfloor \frac{T+1}{M} \rfloor$, then $\lfloor \frac{T}{M} \rfloor + 1 = \lfloor \frac{T+1}{M} \rfloor$ and $T+1 = M \lfloor \frac{T}{M} \rfloor + M$, with $M \lfloor \frac{T}{M} \rfloor =: l \in \{M, \dots, T\}$. Therefore,

$$\|Q_r^{T+1} \mathbf{1}\|_\infty = \|Q_r^l Q_r^M \mathbf{1}\|_\infty \leq c_r^{\lfloor \frac{l}{M} \rfloor + 1} = c_r^{\lfloor \frac{T+1}{M} \rfloor}.$$

With (19) and (14) it follows that

$$1 - \mathbf{P}((a, S) \text{ is identifiable}) \leq N c^{\lfloor \frac{T}{M} \rfloor}$$

and as

$$\frac{N c^{\lfloor \frac{T}{M} \rfloor}}{c^{\frac{T}{M}}} \leq \frac{N}{c} < \infty$$

the assertion follows. ■

F. Proof of Theorem VII.1

Proof: Assume that $\frac{\omega_2 - \omega_1}{\omega_k - \omega_{k-1}} \leq 1$. Otherwise, we can multiply all observations by -1 , such that the new alphabet becomes $-\omega_k < \dots < -\omega_1$, which then fulfills $\frac{\omega_2 - \omega_1}{\omega_k - \omega_{k-1}} \leq 1$. Further, note that $ASB(a) > 0$ implies that $a_n \neq 0$ for all $n = 1, \dots, N$. Let $\mathfrak{G} := \{x_1, \dots, x_T\}$ be the set of the pairwise different observations. (16) implies that there exist $i_0, \dots, i_N, j_0, \dots, j_N \in \{1, \dots, T\}$ such that $x_{i_r} = a\mathbf{s}^r$ and $x_{j_r} = a\mathbf{r}^r$ for $r = 0, \dots, N$.

First, note that

$$\begin{aligned} \min \mathfrak{G} &= x_{i_0} = \omega_k \sum_{\substack{n=1 \\ a_n < 0}}^N a_n + \omega_1 \sum_{\substack{n=1 \\ a_n > 0}}^N a_n, \\ \max \mathfrak{G} &= x_{j_0} = \omega_1 \sum_{\substack{n=1 \\ a_n < 0}}^N a_n + \omega_k \sum_{\substack{n=1 \\ a_n > 0}}^N a_n \end{aligned}$$

and thus

$$\begin{aligned} \mathfrak{o}_+ &:= \sum_{\substack{n=1 \\ a_n > 0}}^N a_n = \frac{\omega_k \max \mathfrak{G} - \omega_1 \min \mathfrak{G}}{\omega_k^2 - \omega_1^2}, \\ \mathfrak{o}_- &:= \sum_{\substack{n=1 \\ a_n < 0}}^N a_n = \frac{\omega_k \min \mathfrak{G} - \omega_1 \max \mathfrak{G}}{\omega_k^2 - \omega_1^2}. \end{aligned}$$

If $\mathfrak{o}_- = 0$, all weights are positive and, as \mathfrak{o}_+ is identified and thus w.l.o.g equal to one, Theorem IV.1 applies. Thus, assume that $\mathfrak{o}_- < 0$ and define $\mathfrak{G}_0 := \mathfrak{G} \setminus \{\min \mathfrak{G}, \max \mathfrak{G}\}$ and

$$\begin{aligned} \tilde{N}_0 &:= \max\{n = 1, \dots, N \text{ s.t. } a_n < 0\}, \\ \tilde{N}_0^+ &:= \tilde{N}_0 + 1, \end{aligned}$$

i.e., $a_1 < \dots < a_{\tilde{N}_0} < 0 < a_{\tilde{N}_0^+} < \dots < a_N$. Second, note that analog to (11)

$$\min \mathfrak{G}_0 = \min(x_{i_{\tilde{N}_0^+}}, x_{j_{\tilde{N}_0}}), \quad \max \mathfrak{G}_0 = \max(x_{j_{\tilde{N}_0^+}}, x_{i_{\tilde{N}_0}})$$

and thus

$$\begin{aligned} \frac{\min \mathfrak{G}_0 - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_k - \omega_{k-1}} &= \min \left(\frac{\omega_2 - \omega_1}{\omega_k - \omega_{k-1}} a_{\tilde{N}_0^+}, -a_{\tilde{N}_0} \right) \\ \frac{\omega_k \mathfrak{o}_+ + \omega_1 \mathfrak{o}_- - \max \mathfrak{G}_0}{\omega_2 - \omega_1} &= \min \left(-a_{\tilde{N}_0}, \frac{\omega_k - \omega_{k-1}}{\omega_2 - \omega_1} a_{\tilde{N}_0^+} \right). \end{aligned}$$

Hence, if $\frac{\min \mathfrak{G}_0 - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_k - \omega_{k-1}} < \frac{\omega_k \mathfrak{o}_+ + \omega_1 \mathfrak{o}_- - \max \mathfrak{G}_0}{\omega_2 - \omega_1}$ we find that

$$a_{\tilde{N}_0^+} = \frac{\min \mathfrak{G}_0 - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_2 - \omega_1}$$

and if $\frac{\min \mathfrak{G}_0 - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_k - \omega_{k-1}} = \frac{\omega_k \mathfrak{o}_+ + \omega_1 \mathfrak{o}_- - \max \mathfrak{G}_0}{\omega_2 - \omega_1}$ that

$$a_{\tilde{N}_0} = \frac{\max \mathfrak{G}_0 - \omega_k \mathfrak{o}_+ - \omega_1 \mathfrak{o}_-}{\omega_2 - \omega_1}.$$

Thus, we have identified the first weight, namely

$$a_1^* := \begin{cases} a_{\tilde{N}_0^+} & \text{if } \frac{\min \mathfrak{G}_0 - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_k \mathfrak{o}_+ + \omega_1 \mathfrak{o}_- - \max \mathfrak{G}_0} < \frac{\omega_k - \omega_{k-1}}{\omega_2 - \omega_1} \\ a_{\tilde{N}_0} & \text{otherwise.} \end{cases}$$

Now assume that we have identified l different weights, a_1^*, \dots, a_l^* . If $\mathfrak{o}_- = \sum_{\substack{n=1 \\ a_n^* < 0}}^l a_n^*$, all the remaining weights

are positive and Theorem IV.1 applies. Thus assume that $\mathfrak{o}_- < \sum_{\substack{n=1 \\ a_n^* < 0}}^l a_n^*$ and define $\mathfrak{G}_l := \mathfrak{G}_{l-1} \setminus \mathfrak{R}_{l-1}$, with

$$\begin{aligned} \mathfrak{R}_{l-1} &:= \bigcup_{\substack{\omega', \omega'' \in \Omega \\ \omega \in \Omega^l}} \left\{ \omega' \left(\mathfrak{o}_- - \sum_{\substack{n=1 \\ a_n^* < 0}}^l a_n^* \right) + \omega'' \left(\mathfrak{o}_+ - \sum_{\substack{n=1 \\ a_n^* > 0}}^l a_n^* \right) \right. \\ &\quad \left. + (a_1^*, \dots, a_l^*) \omega \right\} \end{aligned}$$

and

$$\begin{aligned} \tilde{N}_l &:= \max\{i = 1, \dots, N \text{ s.t. } a_n < 0 \text{ and } a_n \notin \{a_1^*, \dots, a_l^*\}\}, \\ \tilde{N}_l^+ &:= \min\{n = 1, \dots, N \text{ s.t. } a_n > a_{\tilde{N}_l} \text{ and } a_n \notin \{a_1^*, \dots, a_l^*\}\}. \end{aligned}$$

Note that analog to Lemma IV.4

$$\min \mathfrak{G}_l = \min(x_{i_{\tilde{N}_l^+}}, x_{j_{\tilde{N}_l}}), \quad \max \mathfrak{G}_l = \max(x_{j_{\tilde{N}_l^+}}, x_{i_{\tilde{N}_l}})$$

and thus

$$\begin{aligned} \frac{\min \mathfrak{G}_l - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_k - \omega_{k-1}} &= \min \left(\frac{\omega_2 - \omega_1}{\omega_k - \omega_{k-1}} a_{\tilde{N}_l^+}, -a_{\tilde{N}_l} \right) \\ \frac{\omega_k \mathfrak{o}_+ + \omega_1 \mathfrak{o}_- - \max \mathfrak{G}_l}{\omega_2 - \omega_1} &= \min \left(-a_{\tilde{N}_l}, \frac{\omega_k - \omega_{k-1}}{\omega_2 - \omega_1} a_{\tilde{N}_l^+} \right). \end{aligned}$$

Hence, if $\frac{\min \mathfrak{G}_l - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_k - \omega_{k-1}} < \frac{\omega_k \mathfrak{o}_+ + \omega_1 \mathfrak{o}_- - \max \mathfrak{G}_l}{\omega_2 - \omega_1}$ we find that

$$a_{\tilde{N}_l^+} = \frac{\min \mathfrak{G}_l - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_2 - \omega_1}$$

and if $\frac{\min \mathfrak{G}_l - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_k - \omega_{k-1}} = \frac{\omega_k \mathfrak{o}_+ + \omega_1 \mathfrak{o}_- - \max \mathfrak{G}_l}{\omega_2 - \omega_1}$ that

$$a_{\tilde{N}_l} = \frac{\max \mathfrak{G}_l - \omega_k \mathfrak{o}_+ - \omega_1 \mathfrak{o}_-}{\omega_2 - \omega_1}.$$

Thus, we have identified the $(l+1)$ -th weight as

$$a_{l+1}^* := \begin{cases} a_{\tilde{N}_l^+} & \text{if } \frac{\min \mathfrak{G}_l - \omega_k \mathfrak{o}_- - \omega_1 \mathfrak{o}_+}{\omega_k \mathfrak{o}_+ + \omega_1 \mathfrak{o}_- - \max \mathfrak{G}_l} < \frac{\omega_k - \omega_{k-1}}{\omega_2 - \omega_1} \\ a_{\tilde{N}_l} & \text{otherwise.} \end{cases}$$

By induction, we can identify all weights and thus, by $ASB(a) > 0$ the assertion follows. \blacksquare
