Abstract

The recent explosion of genomic data has underscored the need for interpretable and comprehensive analyses that can capture complex phylogenetic relations within and across species. Recombination, reassortment, horizontal gene transfer, and species hybridization constitute examples of pervasive biological phenomena that cannot be captured by tree-like representations. Starting from tens or hundreds of genomes, we are interested in the reconstruction of potential evolutionary histories leading to the observed data. Ancestral recombination graphs (ARGs) represent potential histories that explicitly accommodate recombination and mutation events across orthologous genomes. However, ARGs are computationally costly to reconstruct and usually become infeasible for more than few tens of genomes. Recently, Topological Data Analysis (TDA) methods have been proposed as robust and scalable methods that can capture the genetic scale and frequency of recombination. We build on previous TDA developments for detecting and quantifying recombination, and present a novel framework that can be applied to hundreds of genomes and can be interpreted in terms of minimal histories of mutation and recombination events, quantifying the scales and identifying the genomic locations of recombinations. For that aim, we extend the notion of barcodes in persistent homology, largely increasing their sensitivity to recombination, and present a new type of summary graph (topological ARG, or tARG), analogous to ARGs, that capture ensembles of minimal recombination histories. We implement this framework in a software package, called TARGet, and apply it to several examples, including small migration between different populations and horizontal evolution in finches inhabiting the Galápagos Islands.

1 Introduction

Since the publication of the first draft of the human genome in 2001 [1,2], there has been an explosion in genomic data. The genomes of thousands of different human individuals across the globe have been sequenced [3], cancer patients are getting their genome routinely studied [4–7], several hundreds of eukaryotic genomes have been characterized, and new viral, bacterial and archaeal species are being sequenced on an almost daily basis [8,9]. The rapid progression of single cell sequencing [10] permits genomic analysis of many uncultivated bacterial species, providing a glimpse into what has been denoted as microbial dark matter [11]. Even before Darwin [12], taxonomists have been classifying organisms into different taxa, from species to domains. But it was Darwin who provided a historical dimension to the taxonomical enterprise, proposing that closely related species in the hierarchical taxonomy share ancestors. Since then, tree-like structures have been proposed to represent the evolutionary/historical relationship between organisms. In the last few years, however, the richer and more comprehensive genomic characterization of many organisms have underscored the need of representations that are not strictly tree-like. Phenomena such as horizontal gene transfer in bacteria [13], the ability of viruses to borrow and lend genes across species,

the exchange of genomic material by archea and bacteria [14], and hybridization in metazoa (in plants, in particular [15,16]) are exposing some of the limitations imposed by tree-like phylogenetic structures. The definition of species itself becomes cumbersome in bacteria and viruses [17]. Needless to say that within many species, including humans, genetic recombination is so pervasive that tree-like representations are useless. It is then natural to wonder what other frameworks could be used to capture phylogenetic relations without losing the interpretability and simplicity of trees [18–20]. Of particular interest are representations that reduce to trees when evolution is tree-like; that capture genetic relations (genetic scales) between ancestors, and identify genomic regions originating from different ancestral lineages; and, more generally, that allow for an interpretation of the observed data in terms of a chronological sequence of events.

Several such frameworks have been proposed in the last two decades. The study of phylogenetic networks has been an area particularly active [21-23]. Phylogenetic networks provide representations that extend trees to graphs (networks), generating loops when the data does not fit into a tree. Some of those methods can easily be applied to more than one hundred genomes [24–29] providing the opportunity for large-scale representations. However, the biological interpretation of these representations is limited. as loops represent inconsistencies with trees, but it is unclear how these inconsistencies arose historically, what genomic regions were involved, or how frequently an exchange happened. Other types of representations, sometimes named *explicit networks* [21,30], do aim to provide a historical account in terms of a chronology of events. Ancestral recombination graphs, or ARGs, provide potential explanations of the observed data in terms of a progression of recombination and mutation events. As in trees, mutations are represented as events along the branches. Recombinations, however, appear as the fusion of two parental branches into one offspring branch. ARGs provide simple histories that can be used in association mapping [31–33], SNP genotyping [34] or statistical inference of the frequency and scale of recombination [35]. However, these applications are hindered by the computational infeasibility of constructing ARGs that explain hundreds of sequences. The construction of minimal ARGs, containing the minimum number of recombination events required to explain the sample in absence of convergent evolution and back-mutation, is known to be an NP-hard problem [36–38]. Several approximations have been developed in the last few years, including galled trees [39,40], branch and bound [41], heuristic [31] and sequentially Markov coalescent (SMC) approaches [42].

Recently, a new framework to study genomic relations has been proposed [43–45],

based on Topological Data Analysis [46–48]. Topology is the area of mathematics that aims to characterize properties of spaces up to continuous deformations. TDA extends the concepts and tools of topology to finite metric spaces, that is, finite sets of points and distances between them. Stability results [43, 49, 50] guarantee that small fluctuations in the data only create small changes in the inferred topological features, providing robust characterizations of the data. In this framework, genomes can be viewed as points in a high dimensional space, and relations between these genomes are characterized by distances. Recombination events appear as loops in these spaces, and their frequency and scale is summarized in a set of open intervals, named *barcodes*. These provide a basic structure on which statistics of genomic exchange can be built.

TDA methods are particularly well suited for large datasets. In the context of molecular phylogenetics and evolution, they have been applied to the study of viral recombination and reassortment [43], bacterial species [44] and point estimators in population genetics [45]. However, these implementations have limitations. Specifically, they only use information about genetic distances between sequences, and so they discard the full structure of segregating characters, missing numerous recombination events that are required to explain the data. Relatedly, it is unclear which specific evolutionary histories explaining the data TDA informs about, and what is the precise relation between barcodes and these histories.

Here we address these two important aspects, improving on the scalable capabilities of persistent homology to extract robust information on the possible evolutionary histories of a sample of genetic sequences. In particular, we show that by systematically sampling subsets of segregating sites and performing TDA, we are able to identify most of the necessary recombination events identified by bound methods [41, 51, 52], providing a significant improvement of past methods [43] in terms of interpretation and sensitivity. Moreover, we introduce a novel type of graph, closely related to minimal ARGs, that we name *topological ARG (tARG)*; and show that barcodes inform about the topological features and genetic scales of these graphs.

Like minimal ARGs [30,31], tARGs can be considered as explicit, parsimonious, interpretable phylogenetic representations. The main advantage of tARGs and barcodes versus minimal ARGs is, however, the possibility of obtaining such phylogenetic information in polynomial time, which allows us to deal with hundreds of sequences. We have implemented this method in a software, called **TARGet**, and have illustrated it with several examples, including horizontal evolution of finches inhabiting the Galápagos archipelago. The software, instructions and example files used in the manuscript can be obtained from https://github.com/RabadanLab/TARGet.

2 Topological aspects of minimal ARGs

An ARG is an explicit phylogenetic network representing a possible evolutionary history of a sample of genetic sequences, where only mutation and recombination events are present and convergent evolution is not considered and so never occurs [30, 53, 54]. ARGs are very useful constructs in population genetics and phylogenetics. However, the problem of building a minimal ARG from a set of genetic sequences is known to be NP-hard [36–38]. The use of ARGs has therefore been traditionally limited to small samples, consisting of a handful of sequences.

In this section, we introduce a particular class of minimal ARGs and a set of related graphs. Then, using computational algebraic topology, in the next section we show that it is possible to extract, in polynomial time, phylogenetic information from this class of minimal ARGs, without having to explicitly construct them. Thus, by restricting to this specific class of graphs, we are able to extend the realm of ARGs to large samples of sequences.

To be specific, we consider a sample S consisting of n distinct genetic sequences with m binary segregating characters. The latter can be single nucleotide polymorphisms (SNPs), indels, gene duplications or any other genetic trait that takes one of two possible states, 0 or 1, in each sequence. An ARG is then formally defined as a directed acyclic graph \mathcal{N} with n leaf nodes and a unique root node, where every node other than the root has in-degree one (tree node) or two (recombination node) and every character or sequence in S labels respectively a unique edge or leaf in \mathcal{N} . Moreover, each node in \mathcal{N} is labelled by a m-length binary sequence, such that 1) the sequence labelling a tree node differs from the sequence of the parent node only at the character labelling the edge that connects the two nodes; and 2) the sequence labelling the two parent nodes.

There is an infinite number of ARGs that can explain a particular sample S. An stochastic model, such as the coalescent model with recombination [53,55], would assign probabilities to each possible ARG. Here, however, we adopt a parsimony approach and consider ARGs that are minimal (in a sense defined below), without assuming an underlying probabilistic model. Such an approach has proven useful in summarizing all the information contained in the sequences into evolutionary histories where all events are required.

Figure 1: Minimal ARGs and condensed graphs. Two examples of minimal ARGs and the condensed graphs that result from collapsing their unlabelled edges. The root node is marked red whereas sampled nodes are marked green. Mutations in the r-th character are indicated by m_r . Edges pointing to a recombination node are labelled with the letter P or S, depending on whether they contribute to the prefix or suffix of the recombinant sequence. Recombinant nodes are marked with the position of the recombination breakpoint. All nodes are labelled by their sequence of characters. Condensed graphs of ARGs can be embedded into m-dimensional hypercubes and their diagonals.

Specifically, we consider ARGs that contain exactly the minimum number R_{\min} of single-crossover recombinations required to explain the sample, and that minimize the function

$$D(\mathcal{N}) = \sum_{r=0}^{R_{\min}} d_r \tag{2.1}$$

where the sum runs over all recombination events in \mathcal{N} , and d_r is the genetic distance between the two parental sequences involved in the *r*-th recombination. This is a slightly more restricted definition of minimal ARG than the one that usually appears in population genetics literature [30], where the condition on $D(\mathcal{N})$ is generally not required. By construction, a minimal ARG explaining any given sample always exists. Examples of minimal ARGs are given in figs. 1 and 2.

An ARG can be condensed by collapsing all unlabelled edges, so that the resulting graph can be embedded into an *m*-dimensional hypercube and its diagonals, except for the axial ones (fig. 1). The number of edges and vertices of such a condensed representation is $m + 2R_{\min}$ and $m + R_{\min} + 1$, respectively, whereas the number of independent loops is R_{\min} .

Figure 2: Minimal ARGs and eq. (2.1). Two examples of ARGs containing the minimum number of recombination events, $R_{\min} = 3$, required to explain the sample. The ARG in a) minimizes eq. (2.1). It is therefore a minimal ARG according to the restricted definition used here. The ARG in b), on the contrary, does not minimize eq. (2.1).

The general question that we want to address is, given a set S of sampled sequences, what information can we obtain about the structure of minimal ARGs that explain S, without having to explicitly construct them? To address this question, we consider the union graph of all undirected condensed minimal ARGs explaining S and sharing the same set of vertices (fig. 3). We call this construction topological ARG, or tARG, for reasons that will become clear in next section. Note that, contrary to ARGs, a tARG is uniquely specified in terms of its vertices. Denoting by \overline{R}_{\min} the number of loops of a tARG, by construction it follows that $\overline{R}_{\min} \geq R_{\min}$. In particular, $\overline{R}_{\min} > R_{\min}$ when some recombination node in a minimal ARG explaining the sample can be alternatively obtained from another pair of nodes in the ARG, without affecting (2.1). In terms of the sample, $\overline{R}_{\min} > R_{\min}$ when there are three characters for which all eight possible allele combinations are present in S. In models like the coalescent with recombination, this only happens at very large recombination rates (see fig. 5 below). In the most extreme case, where the sample consists of all possible 2^m sequences with m segregating characters, $R_{\min} = 2^m - m - 1$ and $\overline{R}_{\min} = 2^{m-1}m - 2^m + 1$.

3 Persistent homology and the extended barcode of a sample

Topological data analysis (TDA) has emerged during the last decade as a branch of applied topology that attempts to infer topological features of spaces from sets of sampled points [46]. Topological invariants are algebraic structures (groups, modules, etc) of the space preserved under continuous deformations. One example of such invariants are homology groups. Generators of the zero-th homology group correspond to connected components of the space; generators of the first homology group correspond to noncontractible loops; and in general, generators of the *n*-th homology group correspond to non-contractible *n*-dimensional voids. In the case where only a finite set of points of the space is known, there is still a well-defined notion of homology, known as persistent homology [47,48]. At each scale ϵ , a simplicial complex (a finite set representation of the topology of the space) can be constructed by taking balls of radius ϵ centred at the sampled points, and considering their intersections (fig. 4). Two points are connected by an edge in the simplicial complex if the corresponding balls intersect. This process produces a filtration of simplicial complexes parametrized by ϵ , from which homology groups can be computed. Remarkably, the computation time of persistent homology is polynomial in the number of points [48].

In our current context, we exploit the use of persistent homology to infer topological features of an unknown tARG from the known set of sampled nodes. A distance function between pairs of nodes of the tARG can be defined by taking the hamming

Figure 3: **Topological ARGs**. Examples of condensed minimal ARGs (left) and their corresponding tARGs (right). In a tARG the edges are completely determined by the vertices. In these two examples the topology of the resulting tARG differs from that of the original condensed minimal ARGs. In example a) the minimal ARG has $R_{\min} = 4$, whereas the corresponding tARG has $\overline{R}_{\min} = 5$. In example b) the minimal ARG has $R_{\min} = 11$, whereas the corresponding tARG has $\overline{R}_{\min} = 17$.

distance between the corresponding sequences of characters that label the nodes. This is the simplest possible notion of genetic distance.

Figure 4: **Persistent homology of a sample of genetic sequences**. Barcode and simplicial complexes at several values of the filtration parameter ϵ , for the sample of sequences $S = \{000, 010, 101, 111\}$. Only the zero-th (H_0) and first (H_1) homology groups are shown. At small ϵ the four sampled points are disconnected and H_0 consists of 4 elements. Increasing ϵ leads to a loop, that appears as a single element of H_1 . Further increasing ϵ fills in the loop, leading to a single connected surface, that is represented by a single element of H_0 . A minimal ARG explaining S and the corresponding tARG were presented in figure 1b. The barcode only captures one of the $R_{\min} = \overline{R}_{\min} = 2$ recombination events. The generators of the loop in this case are the four sequences present in S, that form a loop enclosing the two recombination loops present in the minimal ARG.

Barcodes are a useful representation of persistent homology [56]. These are graphical representations where each element of a homology group is represented by a segment spanning the interval $[\epsilon_b, \epsilon_d]$, where ϵ_b and ϵ_d are the values of the parameter ϵ at which the corresponding feature is formed and destroyed, respectively. Hence, the barcode of a sample contains information about the topology and scales of the tARG underlying the sample (fig. 4). Specifically, elements of the first homology group correspond to recombination loops in the tARG, whereas ϵ_b and ϵ_d provide information about the genetic scales involved in the recombination events. The number of generators of the first homology group or *persistent first Betti number*, b_1 , is thus a lower bound of \overline{R}_{\min} . First homology generators permit to identify a set of sequences in S that enclose the corresponding recombination loop in the tARG, and can be used to partially reconstruct the underlying tARG.

Whereas tARGs provide an interpretation of persistent homology barcodes in terms of minimal evolutionary histories and ARGs, the sensitivity of persistent homology to recombination is in general low, and b_1 is a loose lower bound of \overline{R}_{\min} . To address a similar problem, Myers and Griffiths showed in ref. [52] that, given a lower bound coming from a sample of aligned sequences, it is possible to build a more stringent bound by suitably combining the local bounds that result from intervals within the alignment. In this way, information about the ordering of characters is incorporated, and the location of crossover breakpoints in the sequence is constrained. This general idea was applied in [52] to the haplotype bound to built a stronger lower bound, $n - m - 1 \leq R_{\text{MG}} \leq R_{\text{min}}$.

A similar idea can be applied in the context of persistent homology barcodes to build an *extended first-homology barcode*, given by the disjoint union of the first-homology barcodes of a set of optimally chosen, non-overlapping intervals within the sequence alignment. From a geometric perspective, this corresponds to projecting the original space on a optimal set of mutually orthogonal hyperplanes in the ambient hypercube, and computing persistent homology in each of those projections. The extended barcode incorporates information about the full structure of characters in the sample, largely increasing the sensitivity of persistent homology and providing information on the location of the recombination breakpoints in the sequence.

To extend the construction of ref. [52] to persistent homology barcodes, we need to establish an ordering relation on barcodes. Being sets of intervals, it is natural to take the maximum of two barcodes to be given by the one with largest L^0 -norm, namely largest b_1 . If both barcodes have the same L^0 -norm, we may successively compare other norms (e.g. other L^p -norms), until the tie is broken. The algorithm of [52] is then generalized to persistent homology barcodes as follows:

- 1. Let \mathcal{B}_{ik} be the first-homology barcode of the sequences that result from the *i*-th to *k*-th characters in \mathcal{S} . Set $\mathcal{R}_{ij} = 0$ and k = 2.
- 2. For j = 1, ..., k 1, set $\mathcal{R}_{jk} = \max\{\mathcal{R}_{ji} \cup \mathcal{B}_{ik} : i = j, ..., k 1\}$

3. If k < m, increment k by 1 and go to step 2.

The extended first-homology barcode of S is the union barcode \mathcal{R}_{1m} that results from this algorithm.

Figure 5: Comparison between lower bounds $\bar{b}_1 \leq \bar{R}_{\min}$ and $R_{\text{MG}} \leq R_{\min}$ in coalescent simulations. Values of \bar{b}_1 and R_{MG} for simulated samples of 40 sequences with 12 segregating sites, sampled from a population under the coalescent model with recombination. 4000 samples were simulated in total. The colored band represents the interdecile range, whereas the central line represents the mean. The values of \bar{b}_1 and R_{MG} are highly correlated (Pearson's r = 0.98). At very high recombination rates, \bar{b}_1 tends to be bigger than R_{MG} , as cases like those of fig. 3 occur more frequently.

The number of bars in the extended barcode, \bar{b}_1 , is a optimized lower bound of \overline{R}_{\min} , in the same way as R_{MG} is a optimized lower bound of R_{\min} ,

tARG
$$\longrightarrow \overline{R}_{\min} \ge \overline{b}_1 \ge b_1$$

$$\uparrow$$
minimal ARG $\longrightarrow R_{\min} \ge R_{MG} \ge n - m - 1$

In biological data, \bar{b}_1 and $R_{\rm MG}$ are in general very close to each other (fig. 5), as the probability of generating minimal ARGs that produce tARGs with a different topology (e.g. those of fig. 3) is low. However, as opposed to $R_{\rm MG}$, the extended first-homology barcode provides additional phylogenetic information about the sample, such as the genetic scales and sequences involved in the recombination events. These features put extended first-homology barcodes at the very interesting interface between the fast, but phylogenetically limited, existing lower bounds to $R_{\rm min}$; and the slow, but phylogenetically rich methods for reconstructing minimal ARGs. We have implemented the computation of extended first-homology barcodes of genetic samples in publicly available software, called TARGet, that also attempts to partially reconstruct the tARG using persistent homology generators. Although TARGet makes use of the above algorithm inspired in that of ref. [52], more efficient integer linear programming algorithms, like that of ref. [41], can in principle be also generalized to the computation of extended first-homology barcodes.

4 Examples

We consider three examples that illustrate how the formal developments presented in previous sections can be used to extract useful phylogenetic information from samples of genetic sequences. The first example is a simple toy model where an explicit minimal ARG can be easily constructed. It displays how the information contained in the extended first-homology barcode of the sample directly maps to features of minimal ARGs. The second example, based on simulated data of two sexually reproducing populations exchanging genetic material at low rate, shows the applicability of persistent homology to large datasets, consisting of several hundreds of sequences. It also demonstrates the use of phylogenetic information contained in the extended first-homology barcode to distinguish among various biological settings with similar recombination rates. The last example consists of a 9 megabase scaffold in the genome of 112 Darwin's finches [57]. This example illustrates the applicability of the extended first-homology barcode to real datasets.

4.1 A simple example

We illustrate the use and interpretation of extended barcodes with a simple example, consisting of a sample of 4 genetic sequences with 7 binary characters: 1111001, 1111111, 0000110 and 0000000. Minimal ARGs explaining this sample require two single-crossover recombination events. One such minimal ARG is presented in fig. 6a. The most ancestral recombination event involves genetically distant parental gametes, leading to a large recombination loop. On the contrary, the most recent recombination event involves genetically close parental gametes, leading to a small recombination loop in the ARG. These features are captured by the extended first-homology barcode of the 4 sequences (fig. 6b), which consists of two bars, corresponding to the two recombination events. The length and position of the bars represent the genetic scales associated to the recombination events, with the high (low) genetic scale bar corresponding respectively to the large (small) recombination loop. The position of the crossover breakpoints associated to these recombination events is also correctly reproduced. Hence, taking as input the 4 sequences, the extended first-homology barcode extracts phylogenetic information from minimal ARGs that explain the sample, without requiring complete reconstruction of the ARGs.

Figure 6: Minimal ARG, extended first-homology barcode and reconstructed tARG of a sample of 4 sequences. The four sampled sequences are represented by green leaf nodes in the minimal ARG depicted in a). The minimal ARG involves two single-crossover recombination loops. Both recombination loops and their genetic scales are correctly captured by the extended first-homology barcode of the samples, shown in b). Intervals containing the location of recombination breakpoints are indicated over each bar. Persistent first-homology generators can be used to reconstruct the topology of the tARG, as depicted in c). Without adding any extra sequences to the sample, the two bars are associated to the same four generators, allowing only to reconstruct the large envelope of the two recombination loops. Adding sequences E and F to the sample (represented by blue leaf nodes in (a)) disentangles the generators of the two recombination loops, fully reconstructing the topology of the tARG. The persistent first-homology generators, and hence the reconstructed tARG, strongly depend on the specific sampled nodes.

We note here the importance of using the extended barcode instead of the ordi-

nary barcode, used in previous applications of persistent homology [43]. In this simple example $b_1 = 1$, and only one of the two recombination events would have been detected if the ordinary barcode had been used. The extended barcode, implementing a composite bound algorithm similar to that of Myers and Griffiths, largely increases the sensitivity to recombination events.

Finally, we can attempt to reconstruct the tARG of the sample by using persistent homology generators (fig. 6c). Whereas there are theorems ensuring the stability of barcodes against small perturbations [49, 50], the generators of persistent homology identified by TDA strongly depend on the sample, and many different choices of basis are possible. In this simple example, both bars in the extended first-homology barcode are generated by the four sampled sequences. Therefore, the reconstructed loop enclosing each recombination event is the same in both cases and corresponds to the large enveloping loop in the minimal ARG (fig. 6a). Adding the internal nodes 1111000 and 111110 to the sample permits disentangling the generators of the two recombination loops (fig. 6c), fully reconstructing the topology of the underlying tARG. Hence, if sampling frequency is high, this method also allows to approximate the tARG of the sample with some accuracy.

4.2 Genetic exchange between two divergent populations

We now consider a more involved example consisting of two sexually-reproducing populations, simulated under the coalescent with recombination. The two populations diverged 24N generations before present. Their effective population sizes are taken to be constant and given by N and N/5. We consider two different cases, depicted in fig. 7. In the first case (fig. 7a), the two populations are completely isolated from each other. In the second case (fig. 7b), on the contrary, there is a small migration rate between the two populations, with a migration event occurring every 2N generations on average. The recombination rate is the same in both cases. Alternatively, in a phylogenetic context, this setting describes the incomplete lineage sorting of two species, with or without the presence of gene flow.

We randomly sample 250 sequences from the large population and 50 sequences from the small population. The full sample consists of 300 sequences with 300 segregating sites. We present in fig. 7 the extended first-homology barcode for simulated samples in each of the above two cases. Whereas the number of detected recombination events in the tARG, counted by the number bars, is similar in both cases, their genetic scales are very different. In particular, in presence of migration the scale of some of the

Figure 7: Extended first-homology barcode of two divergent sexuallyreproducing populations. The case in a) assumes the two populations are completely isolated. All recombination events present in the extended first-homology barcode involve genetically close parental gametes. The case in b) considers a small migration rate between the two populations. Some of the recombination events present in the extended first-homology barcode involve genetically distant parental strains. The total number of detected recombination events is similar in both cases and uniform across the entire genome. Intervals with the location of the recombination breakpoints are indicated for each recombination event, where positions refer to segregating sites.

recombination loops is large, corresponding to migration events that are followed by a recombination event (fig. 7b).

Note that in this example the extended first-homology barcode provides rich phylogenetic information that can be hardly obtained by other methods. Methods that attempt to construct a minimal (or nearly-minimal) ARG are computationally inefficient for such large sample sizes [41, 58]. Fast bound methods [41, 51, 52], on the other hand, do not provide enough phylogenetic information to distinguish between the cases with and without migration, as the total recombination rate is the same in both situations. Sequentially Markov coalescent (SMC) approaches [42] produce an ARG that is far from being minimal but is a good approximation to the maximum likelihood. However, these methods require an underlying coalescent model, whose mutation, recombination and population structure parameters are not given with the sample. Finally, algorithms for constructing phylogenetic split networks [29] are fast and provide very different outputs in each of the above two cases. However, the interpretation of their output in terms of recombination and migration events is obscure.

4.3 Darwin's finches

The previous examples served to illustrate the relation between features of the extended first-homology barcode of a genetic sample and those of the minimal ARGs explaining the sample. However, both examples were based on simulated data. We now consider a more realistic example, consisting of the genetic sequences of 112 Darwin's finches, belonging to 15 different species inhabiting the Galápagos archipielago and Cocos Island [57]. We aligned and genotyped a 9 megabase scaffold of their genome and, after filtering for high-quality variants, we focussed on a set of 140 SNPs that were homozygous across the 112 samples, thus avoiding potential phasing artefacts. By considering this set, we mostly restrict to very ancestral recombination/gene flow events, close to the origin of radiation from a common ancestor 1.5 million years ago [59]. We used **TARGet** to obtain the extended first-homology barcode of the sample, as well as the partially reconstructed tARG.

The extended first-homology barcode (fig. 8a) contains 13 recombination events, mostly involving samples from multiple species and usually including samples from the genus *Certhidea* (fig. 8b), the most ancestral lineage among the genera present in the sample [57]. These results add support to the evidence for genetic introgression found in [57]. Our analysis also reveals that the crossover breakpoints of these events localize at four different genomic regions within the 9 megabase scaffold that we have considered in this example (fig. 8c).

5 Discussion

As the famous title of the essay by Dobzhansky "Nothing in Biology Makes Sense Except in the Light of Evolution" underscores, evolutionary processes are central orches-

Figure 8: Extended first-homology barcode and partially reconstructed tARG of a sample of 112 Darwin's finches. The extended first-homology barcode is shown in a), based on 140 homozygous SNPs present in a 9 megabase scaffold. In total, 13 recombination/gene flow events are captured in the extended barcode, with different genetic scales. Bars are colored according to the position of the corresponding recombination breakpoint in the genome, as depicted in c). We also indicate the number of recombination events detected at each genomic interval, as well as some of the orthologous genes present at regions where recombination events are detected. The reconstructed tARG is presented in b). Recombination loops in the reconstructed tARG are outlined using the same code of colors. We have also included leaf nodes that do not participate in any recombination event, using a nearest neighbour algorithm based on genetic distance. Edge lengths are arbitrary.

trating themes in biology. Mutations, recombinations and other evolutionary processes get imprinted into genomes through selection, reflecting the accumulated history giving rise to an organism. Phylogenetics try to reconstruct the evolutionary history through the comparison of genomes of related organisms. In addition to reporting relationships and elucidating particular histories, one would like to understand and quantify how different evolutionary processes have occurred. The identification and quantification of evolutionary processes can be challenging due to the lack of a well-established universal framework to capture evolutionary relationships beyond trees. In addition, robust statistical inference needs to exploit the large number of genomes that are now becoming available, aggravating the computational burden and obscuring interpretations. Ideally, we would like to have a biologically interpretable framework able to quantify different evolutionary processes by analyzing large numbers of genomes.

In this paper we have proposed a few steps in this direction. We have extended the notion of barcodes in persistent homology to identify the genetic scale and number of recombination events. We have shown that, by correctly studying persistent homology in subsets of segregating sites, it is possible to characterize the genomic regions where recombination takes place and identify the gametes involved in particular recombination events. The persistent homology barcodes derived from each of these sets can be structured as an "extended barcode" where each bar captures a recombination event. Extended barcodes can be interpreted as counting and quantifying the scale of recombination events in a variation of Ancestral Recombination fraces that can explain the data. The method proposed, TARGet, is scalable to hundreds of genomes. As an alternative to some phylogenetic networks, extended barcodes provide robust quantification of events, the distribution of genetic scales, computational scalability and interpretative graphs.

6 Methods

6.1 Algorithm implementation

We implemented the algorithm for the computation of the extended first-homology barcode and tARG reconstruction in publicly available multi-threaded software, TARGet, which is distributed under the GNU General Public License (GPL v3). The application is fully written in Python 2.7, and relies on Dionysus C++ library for persistent homology computations (http://www.mrzv.org/software/dionysus).

6.2 Population genetics simulations

We performed 4000 simulations of a sample of 40 sequences with 12 segregating sites, using the software ARGweaver [42]. The population was simulated using a coalescent infinite sites model with recombination. Population-scaled recombination rate, ρ , was randomly generated in each simulation, taking values from a uniform distribution between 0 and 110. For each simulated sample, Myers and Griffiths lower bound $R_{\rm MG} \leq R_{\rm min}$ was computed using the software RecMin [52], with parameters -s 12 -w 12. Lower bounds $\bar{b}_1 \leq \overline{R}_{\rm min}$ were computed using our application TARGet, with parameters -s 12 -w 12.

Samples of genetic exchange between two divergent populations were simulated using the software ms [60], using the commands,

ms 300 1 -s 300 -r 40 10000 -I 2 250 50 -ej 6.0 1 2 -n 2 0.2 -m 1 2 0.5 and,

ms 300 1 -s 300 -r 40 10000 -I 2 250 50 -ej 6.0 1 2 -n 2 0.2 respectively for the cases with and without migration. The extended first-homology barcode of each sample was computed using TARGet with parameters -s 12 -w 14 -e.

6.3 Darwin's finches genotyping

Raw paired-end reads from 112 Darwin finches [57] were obtained from SRA archive (accession number PRJNA263122) and aligned against the consensus sequence of *Geospiza Fortis*, version GeoFor_1.0/geoFor1, scaffold JH739904. We followed essentially the same procedure than that of ref. [57] for the alignment, SNP calling, genotyping and filtering. In short, the alignment was performed with Burrows-Wheeler aligner (BWA) [61], version 0.7.5, using BWA-MEM algorithm and default parameters. PCR duplicates were marked using Picard tools (http://picard.sourceforge.net/). Indel realignment, SNP discovery and simultaneous genotyping across the 112 samples was performed using Genome Analysis Toolkit (GATK) [62], following GATK best practice recommendations [63]. SNP calls were filtered by keeping variants with SNP quality > 100, total depth of coverage > 117 and < 1750, ratio between SNP quality and depth of coverage > 2, Fisher strand bias < 60, mapping quality > 50, mapping quality rank > -4 and read position rank sum > -2. To avoid phasing errors, we only considered SNPs that were homozygous across the 120 samples. The resulting genotypes were processed with TARGet for extended first-homology barcode computation and tARG reconstruction, using the options -s 14 -w 14.

Acknowledgments: We thank D. S. Rosenbloom, K. Emmett, M. Lesnick, S. Zairis and V. Aleksandrov for useful discussions and comments. The work of the authors is supported by NIH grant 1 U54 CA121852-05.
