**Abstract.** We review the so-called spin Hall magnetoresistance (SMR) in bilayers of a magnetic insulator and a metal, in which spin currents are generated in the normal metal by the spin Hall effect. The associated angular momentum transfer to the ferromagnetic layer and thereby the electrical resistance is modulated by the angle between the applied current and the magnetization direction. The SMR provides a convenient tool to non-invasively measure the magnetization direction and spin-transfer torque to an insulator. We introduce the minimal theoretical instruments to calculate the SMR, i.e. spin diffusion theory and quantum mechanical boundary conditions. This leads to a small set of parameters that can be fitted to experiments. We discuss the limitations of the theory as well as alternative mechanisms such as the ferromagnetic proximity effect and Rashba spin-orbit torques, and point out new developments.

*Keywords:* spintronics, spin currents, spin Hall effect

## 1. Introduction and motivation

Spintronics invokes the spin degree of freedom of the electron to improve the efficiency of and add functionalities to electronic devices [1, 2]. Here the generation, propagation, processing, and detection of spin currents form central themes [3]. The spin-orbit coupling (SOC) provides a mechanism to couple the charge and spin of electrons. A prominent example is the spin Hall effect (SHE), i.e. the SOC-induced pure spin current transverse to an applied charge current [4, 5, 6]. In bilayers of a normal metal (N: a non-magnetically ordered metal) and a ferromagnet (F, which includes “ferrimagnet” in the present context), the magnetization dynamics is affected by the SHE spin current via the spin-transfer torque [7] that can be strong enough to switch the magnetization [8, 9]. On the other hand, the inverse of the SHE (ISHE), i.e., the pure spin current-driven transverse charge current, is a convenient tool to detect spin currents generated by spin pumping (SP) [10, 11, 12, 13] and the spin Seebeck effect (SSE) [14, 15, 16, 17, 18]. Quite some attention has been recently focused on ferromagnetic insulators (FI) such as yttrium iron garnet (YIG:  $\text{Y}_3\text{Fe}_5\text{O}_{12}$ ) that can be activated electrically and thermally by attached normal metal contacts. YIG’s very low magnetization damping makes it an attractive material for low-power spin-wave based interconnects and heat-harvesting devices [19].

The magnetoresistance (MR) is the ratio of the electrical resistance of a material with and without an applied magnetic field [20]. In ferromagnetic conductors the MR is often dominated by effects that are not caused directly by the applied magnetic field, but rather by the magnetization orientation as controlled by the applied field. The anisotropic magnetoresistance (AMR), for example, refers to the phenomenon that the electrical resistance of ferromagnets depends on the angle between the current and magnetization directions [21, 22, 23]. For applications in magnetic field sensors and data storage devices, the AMR has been superseded by the giant magnetoresistance (GMR) [24] and tunneling magnetoresistance [25, 26].

This review addresses a new type of MR discovered in a bilayer made of a metal N with strong SOC (usually platinum) and an FI (usually YIG), where the electrical resistance was found to depend on the magnetization of the FI [17, 27, 28, 29, 30, 31]. Since it can be explained by the simultaneous action of the SHE and ISHE [32], it has been dubbed spin Hall magnetoresistance (SMR). This mechanism is similar to that of the predicted magnetoresistance of the two-dimensional electron gas induced by magnetic field-induced decoherence of an edge spin accumulation [33] (the related “Hanle effect” was observed recently in Pt films under large magnetic fields [34]). The SMR can be used to electrically measure the magnetization direction of an insulator [35] and helps to non-invasively access fundamental transport parameters such as the spin Hall angle, spin diffusion length, and spin-transfer torque (spin-mixing conductance) at an N|FI interface [36].

The SMR originates from the simultaneous action of two effects, viz. the SHE and ISHE, that both made an impact on modern spintronics. The SHE causes current-induced spin-transfer torques without a polarizing ferromagnet (“spin-orbit torques”) while the ISHE has become a standard method of detecting spin currents. However, controversial issues remain, such as the magnetic proximity effect and the Rashba SOC at the N|FI interface, challenging the applications mentioned above, but also our understanding of phenomena such as the spin Seebeck effect. The SMR in N|FI bilayers is arguably the most simple observable to detect SOCs: It exists in bilayers of well-studied and characterized materials, and is a strictly linear response effect. Hence, it is essential to understand the SMR before more complicated ones that involve complex devices, difficult materials, magnetization dynamics, noise or non-linearity. Many groups have theoretically and experimentally studied the SMR since its discovery. Hence we believe that the time has come to consolidate the existing knowledge.

This review is organized as follows: In section 2, we introduce the basic concepts and prevalent materials necessary to understand and observe the SMR. In section 3, we describe the diffusion theory for the (I)SHE with quantum mechanical boundary conditions at interfaces. Experiments by various groups are discussed in section 4 as well as the parameters obtained by fitting the theory. In section 5, we address controversial issues such as magnetic proximity and Rashba SOC at interfaces. SMR-related new developments are reviewed in section 6. We present conclusions and an outlook in section 7.

## 2. Materials and devices

In this chapter we review briefly pertinent basic notions in spintronics and magnetism that are used in the subsequent discussions. It starts with metallic ferromagnets that have been subject of transport studies for almost two centuries. Phenomena driven by the SOC in metallic ferromagnets such as the anisotropic magnetoresistance (AMR) and the anomalous Hall effect (AHE) are still not fully understood. The spin Hall effect, i.e. the analogue of the AHE in nonmagnetic metals, has a much shorter history. Its potential to convert the flows of charge and spin has inspired the whole spintronics community. Multilayers made of metallic ferromagnets and nonmagnetic metals are known to display the GMR and TMR as well as spin-transfer torques mediated by the exchange interaction. More recently, SOC induced spin-transfer torques have been the center of interest. Here we introduce a few of these notions as background to the system and phenomenon of interest, i.e. the SMR in N|FI bilayers.

### 2.1. Metallic ferromagnets, AMR and AHE

Metallic ferromagnets, especially the 3d transition metals and their alloys, are important in magnetoelectronics due to their high conductivities and Curie temperatures. Their magnetization is therefore ideal for non-volatile information storage

and electrical readout. The band structure in a ferromagnet is spin-dependent, as are its transport properties that are well described by a two parallel current model for majority and minority spins. Introducing the spin-dependent conductivity  $\sigma_{\zeta F}$  ( $\zeta = \uparrow / \downarrow$ ), an electric field induces the charge current

$$\vec{j}_{cF} = \vec{j}_{\uparrow F} + \vec{j}_{\downarrow F} = (\sigma_{\uparrow F} + \sigma_{\downarrow F}) \vec{E} \equiv \sigma_F \vec{E}, \quad (1)$$

where  $\sigma_F = \sigma_{\uparrow F} + \sigma_{\downarrow F}$  is the total conductivity. An applied charge current is accompanied by a spin current [37]

$$\vec{j}_{sF} = \vec{j}_{\uparrow F} - \vec{j}_{\downarrow F} = (\sigma_{\uparrow F} - \sigma_{\downarrow F}) \vec{E} \equiv P \sigma_F \vec{E}, \quad (2)$$

with conductance spin polarization

$$P \equiv \frac{\sigma_{\uparrow F} - \sigma_{\downarrow F}}{\sigma_{\uparrow F} + \sigma_{\downarrow F}}. \quad (3)$$

The spin dependence of transport is not easily observed in bulk ferromagnets directly. The ‘‘ordinary’’ magnetoresistance, i.e. the dependence of the electrical resistance on an applied magnetic field exists even for normal metals without SOC through the Lorentz force [20]. The AMR, i.e. the phenomenon that the electric resistance depends on the angle between the electric current and the magnetization vectors, is observed in metallic ferromagnets [21, 22]. When current and magnetization direction are given by unit vectors  $\hat{m}$  and  $\hat{j}_c$ , the electric resistance in an isotropic (or cubic) material reads

$$\rho_{\text{long}} = \rho_0 + \Delta\rho_b (\hat{m} \cdot \hat{j}_c)^2, \quad (4)$$

where  $\Delta\rho_b = \rho_{\parallel} - \rho_{\perp}$  with  $\rho_{\parallel}$  ( $\rho_{\perp}$ ) the resistivity for magnetization parallel (transverse) to the applied current, and  $\rho_0$  is an averaged value over all directions for which different definitions can be found in the literature, for example, as  $\rho_0 \equiv (\rho_{\parallel} + 2\rho_{\perp})/3$  [22]. A corollary of the AMR is the transverse resistivity  $\rho_{\text{trans}}$  also referred to as planar Hall effect. With current direction along  $\hat{x}$

$$\rho_{\text{long}} = \rho_0 + \Delta\rho_b m_x^2, \quad (5)$$

$$\rho_{\text{trans}} = \Delta\rho_b m_x m_y, \quad (6)$$

where  $m_i$  is the Cartesian  $\hat{i}$ -component of the magnetization direction unit vector. Higher order contributions to the AMR are found in single-crystalline thin films [39]. From the theoretical point of view,  $\Delta\rho_b$  can be derived microscopically from the  $s$ - $d$  model with a free  $s$ -electron conduction band and localized  $d$ -electrons with a strong exchange interaction and weak SOC. In this model, transport is carried by the conduction electrons with a contribution to the resistivity from scattering into localized  $d$ -states by impurities that depends on the magnetization direction owing to the SOC. The AMR has been of considerable interest as a tool to measure the magnetization direction electrically, thereby serving as a magnetic field sensor [22]. It still attracts scientific attention nowadays [40], and new regimes are being opened by studies in ultrathin films [41, 42, 43].

The ‘‘ordinary’’ Hall effect refers to the transverse charge current normal to both an applied current and external magnetic field and is named after its discoverer [44]. The

AHE, found by Hall two years later [38], depends neither on the external magnetic field nor on the internal dipolar field, but is caused by the SOC or magnetic orientational disorder (which is generated by SOC) [45]. Phenomenologically,

$$\vec{j}_c^{\text{AHE}} = \theta_{\text{AH}} \hat{m} \times \vec{j}_c, \quad (7)$$

where  $\vec{j}_c$  is the applied charge current density and  $\theta_{\text{AH}}$  is the anomalous Hall angle, i.e. the ratio between the transverse and longitudinal conductivities or the slope in plots of the anomalous Hall conductivity as a function of the longitudinal one. Controversies about the microscopic mechanism of the AHE, e.g. whether it is intrinsic or extrinsic, linger, but it appears to be generally accepted that the extrinsic skew scattering process dominates in the clean regime, while intrinsic band structure effects and/or extrinsic side jump scattering explain results for moderately good metals [45, 46, 47]. The anomalous Hall effect can be interpreted in terms of the spin Hall effect discussed hereafter: In ferromagnets a spin polarized current is converted into a transverse charge current or voltage by the spin-dependent conductances as parameterized by the polarization  $P$ .

## 2.2. Spin Hall effect and its inverse in normal metals

In normal metals without magnetic order, electrons with spin up and spin down are degenerate and contribute to transport as two channels in parallel. Nevertheless, significant SOC causes an analogue of the AHE known as the spin Hall effect (SHE), by which a charge current generates a pure transverse spin current, i.e., a current of spin angular momentum [4, 6]. While a spin accumulation can be detected by optical methods at least in some systems [48], we are not aware of experiments that can measure a spin current directly. However, Onsager reciprocity demands that an inverse SHE (ISHE) exists, implying that a spin current drives an easily detectable transverse charge current or voltage [49, 50].

The SHE and ISHE can be described by

$$\vec{j}_{st}^{\text{SHE}} = \theta_{\text{SH}} \hat{i} \times \vec{j}_c, \quad (8)$$

$$\vec{j}_c^{\text{ISHE}} = \theta_{\text{SH}} \hat{i} \times \vec{j}_{st}. \quad (9)$$

Here  $\vec{j}_{st}^{\text{SHE}} / |\vec{j}_{st}^{\text{SHE}}|$  is the direction vector of an SHE spin current density polarized along  $\hat{i}$  with modulus  $|\vec{j}_{st}^{\text{SHE}}|$ . It is driven by the applied charge current density  $\vec{j}_c$  and proportional to the spin Hall angle  $\theta_{\text{SH}}$ .  $\vec{j}_c^{\text{ISHE}}$  is the charge current driven by an  $\hat{i}$ -polarized spin current in  $\vec{j}_{st} / |\vec{j}_{st}|$  direction. Note that we define spin currents in units of Ampere; they can be converted to angular momentum currents by the factor  $\hbar/(2e)$ .

## 2.3. Metallic multilayers and spin-transfer torques

Modern crystal growth techniques allow controlled fabrication of multilayers from various materials with individual film thicknesses of only a few monolayers. This led to the discovery of the giant magnetoresistance (GMR) in the current-in-plane (CIP)

configuration, i.e., the difference of electric conductivity between parallel and anti-parallel (magnetic) configurations in the layered structures [51, 52]. This effect has been explained by the spin-dependent scattering of electrons at N|F interfaces: in the anti-parallel configuration both spin species are scattered strongly at opposite interfaces. When an applied magnetic field forces a parallel configuration one spin channel is short-circuited, leading to a reduced resistance [53].

The GMR in the current perpendicular to plane (CPP) configuration is often larger [54, 55, 56] and easy to model by one-dimensional spin diffusion theory [57]. The essential quantity is here the distributed difference between the effective chemical potentials of electrons with opposite spins or “spin accumulation”. The transfer of spin angular momentum between magnetic layers by an applied current, i.e., the spin-transfer torque, was predicted [58, 59] and observed [60, 61, 62, 63] in CPP spin valve structures. Magnetoelectronic circuit theory for magnetic heterostructures with non-collinear magnetizations provides a theoretical basis to understand the material dependence of these effects [64]. By scattering theory, the spin current  $\vec{j}_s^{(N|F)}$  through an N|F interface (on the N side, flowing into F) can be expressed in terms of the F magnetization  $\hat{m}$  and the (vector) spin accumulation  $\vec{\mu}_{sN}$  in N:

$$e\vec{j}_s^{(N|F)}(\hat{m}) = e(j_\uparrow - j_\downarrow)\hat{m} - G_r\hat{m} \times (\hat{m} \times \vec{\mu}_{sN}) - G_i(\hat{m} \times \vec{\mu}_{sN}), \quad (10)$$

where  $e = -|e|$  is the charge of an electron, and

$$ej_\uparrow = G_\uparrow [(\mu_{cN} - \mu_{cF}) + (\hat{m} \cdot \vec{\mu}_{sN} - \mu_{sF})/2], \quad (11)$$

$$ej_\downarrow = G_\downarrow [(\mu_{cN} - \mu_{cF}) - (\hat{m} \cdot \vec{\mu}_{sN} - \mu_{sF})/2]. \quad (12)$$

are the flows of electrons with spin-up and down electrons along  $\hat{m}$  driven by the difference between effective charge chemical potentials in N and F ( $\mu_{cN} - \mu_{cF}$ ) and the difference between spin accumulations at both sides of the interface ( $\hat{m} \cdot \vec{\mu}_{sN} - \mu_{sF}$ ). The charge and spin chemical potentials are related to each other as discussed in section 3.1, while the spin-dependent conductances at the interface read

$$\frac{G_\uparrow}{G_0} = \sum_{nm} [\delta_{nm} - |r_{nm}^\uparrow|^2], \quad (13)$$

$$\frac{G_\downarrow}{G_0} = \sum_{nm} [\delta_{nm} - |r_{nm}^\downarrow|^2], \quad (14)$$

where  $r_{nm}^{\uparrow(\downarrow)}$  is the spin up (down) reflection coefficient of an electron at the N|F interface from transport channel  $n$  to channel  $m$  in N. Here  $G_0 = e^2/h$  is the (single-spin) conductance quantum.

The last two terms in (10) are spin currents transverse to the magnetization and parameterized by the spin-mixing conductance at the interface defined by the elements of the spin-dependent scattering matrix

$$\frac{G_{\uparrow\downarrow}}{G_0} = \frac{G_r + iG_i}{G_0} = \sum_{nm} [\delta_{nm} - r_{nm}^\uparrow (r_{nm}^\downarrow)^*]. \quad (15)$$

Figure 1 illustrates the spin current polarizations at the interface expressed in (10). The part of the spin current with spin polarization along the magnetization orientation

**Figure 1.** The spin current at the N side of an N|F interface in (10) is the sum of the contributions from the longitudinal conduction electron current  $(j_{\uparrow} - j_{\downarrow}) \hat{m}$  (that vanishes when F is an insulator) and the transverse spin current absorbed at the interface as a spin-transfer torque. The latter is parametrized by the real and imaginary parts of the spin-mixing conductance (15). The vectors indicate spin current polarizations, while the flow direction is normal to the interface (from N to F).

in F component  $[(j_{\uparrow} - j_{\downarrow}) \hat{m}]$  can flow in a metallic F, while the transverse components  $[G_r \hat{m} \times (\hat{m} \times \vec{\mu}_{sN}) / e$  and  $G_i (\hat{m} \times \vec{\mu}_{sN}) / e]$  are absorbed at the interface on an (for strong ferromagnets) atomic length scale and therefore acts as a torque on the magnetization. The spin-transfer torque at the interface is obtained from  $\vec{j}_s^{(N|F)}$  by projection

$$\vec{\tau}_{\text{STT}} = \frac{\hbar}{2e} \hat{m} \times \left( \hat{m} \times \vec{j}_s^{(N|F)} \right). \quad (16)$$

(10) can be used stand-alone for tunnel junctions or point contacts, or serve as a boundary condition between bulk materials described by diffusion theory.

#### 2.4. Spin-orbit torques

Electron and spin transport in N|F bilayers in the current-in-plane (CIP) configuration attracted attention recently because of the observed large current-induced spin-transfer torques generated by the SOC [65]. Those spin-orbit torques can result from the spin currents generated by the SHE in the N layer [4, 5, 6], and converted to a magnetization torque by the conventional exchange interaction at the interface. This contributes a so-called “damping-like” torque proportional to  $G_r$  with symmetry identical to the exchange-mediated term. The magnetic (Gilbert) damping in N|F bilayers subject to an in-plane electric current is modulated by the spin-transfer torque in (16) generated by the direct SHE [7]. While the SHE generates spin currents, the ISHE in a normal metal is an efficient detector of spin currents generated, e.g., by spin pumping [10, 11, 12, 13] or the spin Seebeck effect [16]. On the other hand, a Rashba-Edelstein effect at the

interface may generate a spin accumulation that acts directly on the magnetization to exert a “field-like” torque, corresponding to a finite  $G_i$  [66, 67, 68, 65]. The torque on the magnetization induced by the SOC can be strong enough to switch the magnetization [8, 9], with potential applications in magnetic storage technology. (10) may still be used for the boundary condition of SOC-generated spin currents at N|F(I) interface [69], but the parameters might differ from their exchange-only values.

### 2.5. Magnetic insulators

In conventional spintronic devices such as spin valves, metallic ferromagnets serve as spin emitter (detector) to inject (absorb) spin current into (from) an adjacent normal metal. The spin transport in this CPP configuration requires charge flow through the ferromagnet that therefore has to be a metal. Recently, ferromagnetic insulators such as yttrium iron garnet (YIG) attracted attention of spintronics researchers [19]. Insulators can obviously not be used for voltage induced CPP charge flow, but importantly simplify interpretation in the CIP configuration because parallel charge transport channels through the magnet do not exist. Ferromagnetic insulators can have a much better magnetic quality than metals. YIG in particular features ultralow magnetization damping, which makes it attractive for various applications [19].

N|F bilayers with an insulating ferromagnet F can be activated electrically by means of the SHE [70, 71], while the ISHE can be used to detect magnetization dynamics [10, 70, 72]. While electrical charge transport is suppressed in the CPP configuration, the thermal activation by a temperature gradient normal to the interface is possible. A temperature difference at the N|F interface generates a spin current that can be detected by the ISHE in N without complications of parallel transport in the ferromagnet driven by e.g. the anomalous Nernst effect. This phenomenon is called (longitudinal) spin Seebeck effect [16] and its reciprocal is the spin Peltier effect [73]. The theory of the spin Seebeck effect is based on the concepts of thermal spin pumping and spin-transfer torques in which the spin-mixing conductance and spin Hall angle are essential parameters [74, 75].

## 3. Theory

In the following we derive in some detail the minimum model for the SMR, closely following Chen *et al.* [32].

### 3.1. Diffusion theory with spin-flip relaxation but without (I)SHE

Our theory of the SMR is based on a spin diffusion theory in the limit of weak SOC. We address the diffusion theories for both ferromagnetic and normal metals, in which the charge and spin currents are expressed in terms of gradients of charge and spin accumulations (or spin-dependent electrochemical potentials and densities). The charge current density is the expectation value of the current operator  $\vec{j} = e(n\vec{v} + \vec{v}n)/2$  in

terms of electron charge  $e = -|e|$ , the electrons density  $n$ , and the velocity operator  $\vec{v}$ . For a normal metal with constant density  $n_N$  and drift velocity  $\vec{v}_N$ ,

$$\vec{j}_{cN} = en_N \vec{v}_N. \quad (17)$$

The spin current in the non-relativistic limit

$$\overleftrightarrow{\mathbf{j}}_{sN} = e \langle \vec{j} \otimes \vec{\sigma} + \vec{\sigma} \otimes \vec{j} \rangle / 2 = \left( \vec{j}_{sx}, \vec{j}_{sy}, \vec{j}_{sz} \right)^T = \left( \vec{j}_s^x, \vec{j}_s^y, \vec{j}_s^z \right), \quad (18)$$

is a second-order tensor, where  $\vec{\sigma}$  is the vector of Pauli spin matrices, and  $\langle \dots \rangle$  denotes an expectation value. The row vectors  $\vec{j}_{si} = en \langle \vec{v} \sigma_i + \sigma_i \vec{v} \rangle / 2$  in (18) are the spin current densities polarized in the  $\hat{i}$ -direction, while the column vectors  $\vec{j}_s^j = en \langle v_j \vec{\sigma} + \vec{\sigma} v_j \rangle / 2$  denote the spin current densities with polarization  $\vec{\sigma}$  flowing in the  $\hat{j}$ -direction. In metallic ferromagnets with homogenous texture, the average spin current is projected along the unit vector of the magnetization direction  $\hat{m}$ , so the charge current and spin current tensor read

$$\vec{j}_{cF} = e (n_{\uparrow F} \vec{v}_{\uparrow F} + n_{\downarrow F} \vec{v}_{\downarrow F}), \quad (19)$$

$$\overleftrightarrow{\mathbf{j}}_{sF} = \vec{j}_{sF} \otimes \hat{m} = \left( \vec{j}_{\uparrow F} - \vec{j}_{\downarrow F} \right) \otimes \hat{m} = e (n_{\uparrow F} \vec{v}_{\uparrow F} - n_{\downarrow F} \vec{v}_{\downarrow F}) \otimes \hat{m}, \quad (20)$$

where  $\vec{j}_{sF}$  is the spin current density direction vector, “ $\otimes$ ” denotes that the polarization is locked along  $\hat{m}$ , and  $n_{\uparrow/\downarrow}$  and  $\vec{v}_{\uparrow/\downarrow}$  are the spin-dependent electron density and drift velocity of majority/minority spins in the simple Stoner model. In contrast to the charge current, the (particle) spin current is not conserved in the presence of SOC and non-collinear magnetizations, leading to spin-transfer to the lattice or magnetization, respectively.

In heterostructures, it is useful to express currents in terms of (gradients of) local quasi-equilibrium thermodynamic parameters such as the (electro)chemical potential [76, 57, 77]. At temperatures well below the magnetic phase transition, transport in ferromagnetic metals is well described by the two-current model [37, 78]. The spin-dependent electrochemical potentials are denoted as  $\mu_{\varsigma F}$ :

$$\mu_{\varsigma F} = e\phi + \delta\mu_{\varsigma F}, \quad (21)$$

where  $\varsigma = \uparrow (\downarrow)$  represents the spin direction (anti-)parallel to the magnetization in the ferromagnet, and the gradient  $-\vec{\nabla}\phi \equiv \vec{E}$  is the external electric field. As discussed in section 2.1, the conductivity in ferromagnets is spin-dependent and denoted as  $\sigma_{\varsigma F}$ . Thus we expect that close to contacts,  $\mu_{\uparrow F} \neq \mu_{\downarrow F}$ , leading to spin-dependent diffusion currents

$$\vec{j}_{\varsigma F} = -\frac{\sigma_{\varsigma F}}{e} \vec{\nabla} \mu_{\varsigma F}. \quad (22)$$

The charge and spin currents now read

$$\vec{j}_{cF} = \vec{j}_{\uparrow F} + \vec{j}_{\downarrow F}, \quad (23)$$

$$\vec{j}_{sF} = \vec{j}_{\uparrow F} - \vec{j}_{\downarrow F}, \quad (24)$$

and polarization along  $\hat{m}$  is presumed. Correspondingly, the charge and spin electrochemical potentials are defined

$$\mu_{cF} = \frac{\mu_{\uparrow F} + \mu_{\downarrow F}}{2}, \quad (25)$$

$$\mu_{sF} = \mu_{\uparrow F} - \mu_{\downarrow F}. \quad (26)$$

With these conventions, we may write Ohm's law in the ferromagnetic metal

$$\begin{pmatrix} \vec{j}_{cF} \\ \vec{j}_{sF} \end{pmatrix} = \sigma_F \begin{pmatrix} 1 & P \\ P & 1 \end{pmatrix} \begin{pmatrix} -\vec{\nabla} \mu_{cF}/e \\ -\vec{\nabla} \mu_{sF}/(2e) \end{pmatrix}. \quad (27)$$

In a ferromagnet an applied electric field and/or a spin accumulation gradient generate a charge current as well as a spin current. The charge and spin electrochemical potentials can be obtained by solving the diffusion equations [57].

$$\nabla^2 \mu_{sF} = \frac{\mu_{sF}}{\lambda_F^2}, \quad (28)$$

$$\nabla^2 (\mu_{cF} + P\mu_{sF}/2) = 0, \quad (29)$$

where the spin-flip diffusion length  $\lambda_F = 1/\sqrt{\lambda_{\uparrow F}^{-2} + \lambda_{\downarrow F}^{-2}}$  is expressed in terms of the spin-diffusion length for each spin  $\lambda_{\zeta F} = \sqrt{D_{\zeta F} \tau_{\text{sf}, \zeta F}}$ . The spin-dependent charge diffusion constant  $D_{\zeta F} = \tau_{\zeta F} v_{\zeta F}^2/3$  depends on the spin-dependent relaxation time and Fermi velocity, and  $\tau_{\text{sf}, \zeta F}$  is the spin-dependent spin-flip time. With boundary conditions at contacts, interface and/or deep in the bulk materials, we may compute  $\mu_{cF}$  and  $\mu_{sF}$ , from which charge and spin currents are known by (27).

In normal metals, the electronic structure is spin-degenerate, but spin accumulations and spin currents can be injected by ferromagnetic contacts or generated via the SHE. The induced spin accumulations is represented by the (position dependent) vector

$$\vec{\mu}_{sN} = (\mu_{sx}, \mu_{sy}, \mu_{sz})^T - \mu_{cN} \hat{1}, \quad (30)$$

where  $\mu_{si}$  represents the  $\hat{i}$ -th Cartesian component. The charge and spin accumulations obey the diffusion equations

$$\nabla^2 \mu_{si} = \frac{\mu_{si}}{\lambda^2}, \quad (31)$$

$$\nabla^2 \mu_{cN} = 0. \quad (32)$$

In the absence of the SHE, charge and spin currents are governed by Fick's laws [20]

$$\vec{j}_{cN} = -\frac{\sigma_N}{e} \vec{\nabla} \mu_{cN}, \quad (33)$$

$$\vec{j}_{si} = -\frac{\sigma_N}{2e} \vec{\nabla} \mu_{si}. \quad (34)$$

The difference of the diffusion theory for normal metals with that of ferromagnets is the arbitrary direction of the spin polarization and the decoupling between spin and charge when  $P \rightarrow 0$ .

### 3.2. Interface boundary conditions

Solution of the diffusion equations requires boundary conditions for the currents at surfaces and/or interfaces. Here we disregard interfacial SOC and proximity effects. This approximation cannot be justified a priori, but first-principles calculations on N|Py|N sandwiches [Py: Permalloy ( $\text{Ni}_{80}\text{Fe}_{20}$ )] [79, 80] can be described by introducing effective spin-mixing conductances modified by the SOC.

In N|FI bilayers charge currents flow in the metal layer parallel to the applied electric field. The spin currents driven by the SHE generate a spin accumulation at the interface  $\vec{\mu}_s^I$  that in turn induces a spin current [64]

$$e\vec{j}_s^{(\text{N|F})}(\hat{m}) = -G_r \hat{m} \times (\hat{m} \times \vec{\mu}_{sN}^I) - G_i (\hat{m} \times \vec{\mu}_{sN}^I), \quad (35)$$

where  $G_r$  ( $G_i$ ) is the real (imaginary) part of the spin-mixing conductance  $G_{\uparrow\downarrow}$  defined by (15). At the N|FI interface, the reflection coefficients  $r_{nm}^{\uparrow(\downarrow)} = e^{i\delta_{nm}^{\uparrow(\downarrow)}}$  with modulus one and phase  $\delta_{nm}^{\uparrow(\downarrow)}$ , resulting in a non-zero value of  $G_{\uparrow\downarrow}$ :

$$\frac{G_{\uparrow\downarrow}}{G_0} = N_{\text{Sh}} - \sum_n r_{nm}^{\uparrow} (r_{nm}^{\downarrow})^* = N_{\text{Sh}} - \sum_{nm} e^{i(\delta_{nm}^{\downarrow} - \delta_{nm}^{\uparrow})}, \quad (36)$$

where  $N_{\text{Sh}}$  is the number of transport channels (per unit area) at the Fermi energy, *i.e.* the Sharvin conductance (for one spin) in N. Therefore,

$$\frac{G_r}{G_0} \leq 2N_{\text{Sh}}; \quad \frac{|G_i|}{G_0} \leq N_{\text{Sh}}. \quad (37)$$

The original circuit theory assumes that the nodes are in local equilibrium. In highly conductive systems, the interface conductances have to be corrected for the electron drift by subtracting spurious Sharvin conductance (Schep correction) [81, 82]. The corrected mixing conductance  $\tilde{G}_r$  reads

$$\frac{1}{\tilde{G}_r/G_0} = \frac{1}{G_r/G_0} - \frac{1}{2N_{\text{Sh}}}. \quad (38)$$

### 3.3. SMR

Here we derive an expression of the SMR for the bilayer in figure 2. We can generalize Ohm's law for metals with a weak SHE, *i.e.*, a small  $\theta_{\text{SH}}$ , as a relation between thermodynamic driving forces and currents that reflects Onsager's reciprocity by the symmetry of the response matrix [69]:

$$\begin{pmatrix} \vec{j}_{cN} \\ \vec{j}_{sx} \\ \vec{j}_{sy} \\ \vec{j}_{sz} \end{pmatrix} = \sigma_N \begin{pmatrix} 1 & \theta_{\text{SH}} \hat{x} \times & \theta_{\text{SH}} \hat{y} \times & \theta_{\text{SH}} \hat{z} \times \\ \theta_{\text{SH}} \hat{x} \times & 1 & 0 & 0 \\ \theta_{\text{SH}} \hat{y} \times & 0 & 1 & 0 \\ \theta_{\text{SH}} \hat{z} \times & 0 & 0 & 1 \end{pmatrix} \begin{pmatrix} -\vec{\nabla} \mu_{cN}/e \\ -\vec{\nabla} \mu_{sx}/(2e) \\ -\vec{\nabla} \mu_{sy}/(2e) \\ -\vec{\nabla} \mu_{sz}/(2e) \end{pmatrix}, \quad (39)$$

where  $\vec{\mu}_{sN} = (\mu_{sx}, \mu_{sy}, \mu_{sz})^T - \mu_{cN} \hat{1}$  is the spin accumulation, *i.e.* the spin-dependent chemical potential relative to the charge chemical potential  $\mu_{cN} = e\phi$ ,  $\sigma_N$  is the electric conductivity,  $\theta_{\text{SH}}$  is the spin Hall angle, and “ $\times$ ” denotes the vector cross product operating on the gradients of the spin-dependent chemical potentials. The SHE is

**Figure 2.** The N|FI bilayer system with FI a ferromagnetic insulator and N a normal metal.

represented by the “lower” non-diagonal elements that generate the spin currents in the presence of an applied electric field, in the following chosen to be in the  $\hat{x}$ -direction  $\vec{E} = E_x \hat{x} = -\hat{x} \partial_x \mu_{cN} / e$ . The ISHE is governed by elements “above” the diagonal that connect the gradients of the spin accumulations to the charge current density. (39) is valid for cubic lattices such as Pt.

For films with thickness  $d_N$  in the  $\hat{z}$ -direction as shown in figure 2, the general solution of the spin diffusion (31) reads

$$\vec{\mu}_{sN}(z) = \vec{A}e^{-z/\lambda} + \vec{B}e^{z/\lambda}, \quad (40)$$

where the constant column vectors  $\vec{A}$  and  $\vec{B}$  are determined by the boundary conditions at the interfaces. We do not have to consider the charge accumulation since YIG is an insulator and the SOC does not generate any transverse charge current (via the AHE) as long as N remains non-magnetic.

According to (39), the spin current in N consists of conventional diffusion and spin Hall drift contributions. Assuming translational invariance in the  $x$ - $y$  plane, we focus on the spin current density flowing in the  $\hat{z}$ -direction

$$\vec{j}_s^z(z) = -\frac{\sigma_N}{2e} \partial_z \vec{\mu}_{sN} - j_{s0}^{\text{SH}} \hat{y}, \quad (41)$$

where  $j_{s0}^{\text{SH}} = \theta_{\text{SH}} \sigma_N E_x$  is the bare spin Hall current, *i.e.*, the spin current generated directly by the SHE. The boundary conditions require that  $\vec{j}_s^z(z)$  is continuous at the interfaces  $z = d_N$  and  $z = 0$ . The spin current density at a vacuum interface ( $z = d_N$ ) vanishes,  $\vec{j}_s^z(d_N) = 0$  while at the magnetic interface ( $z = 0$ ), it is governed by the spin accumulation and spin-mixing conductance according to (35),  $\vec{j}_s^z(0) = -\vec{j}_s^{(\text{N|F})}$ , where the minus sign is due to that  $\vec{j}_s^{(\text{N|F})}$  is flowing from N to F, *i.e.*, in the  $-\hat{z}$ -direction.

With these boundary conditions we can determine the coefficients  $\vec{A}$  and  $\vec{B}$  for the bilayer, which leads to the spin accumulation

$$\vec{\mu}_{sN}(z) = -\hat{y} \mu_s^0 \frac{\sinh \frac{2z-d_N}{2\lambda}}{\sinh \frac{d_N}{2\lambda}} + \vec{j}_s^{(\text{N|F})}(\hat{m}) \frac{2e\lambda \cosh \frac{z-d_N}{\lambda}}{\sigma_N \sinh \frac{d_N}{\lambda}}, \quad (42)$$

**Table 1.** Normalized  $j_{sy}$ ,  $j_{sx}$ ,  $\mu_{sy}$ , and  $\mu_{sx}$  at the top ( $z = d_N$ ) and bottom ( $z = 0$ ) of N for magnetizations  $\hat{m} = \hat{y}$  (completely reflecting),  $\hat{m} = (\hat{x} + \hat{y})/\sqrt{2}$ , and  $\hat{m} = \hat{x}$  (maximally absorbing). At the top (contacted to vacuum), the values do not depend on the magnetization; while at the bottom (contacted to FI), the values are strongly affected by the orientation of magnetization. We adopt the parameters  $d_N = 12$  nm,  $\rho = 8.6 \times 10^{-7} \Omega \text{ m}$ ,  $\lambda = 1.5$  nm, and  $G_r = 5 \times 10^{14} \Omega^{-1} \text{ m}^{-2}$ .

	$j_{sy}(d_N)/j_{s0}^{\text{SH}}$	$j_{sx}(d_N)/j_{s0}^{\text{SH}}$	$\mu_{sy}(d_N)/\mu_s^0$	$\mu_{sx}(d_N)/\mu_s^0$
	0	0	-1	0
	$j_{sy}(0)/j_{s0}^{\text{SH}}$	$j_{sx}(0)/j_{s0}^{\text{SH}}$	$\mu_{sy}(0)/\mu_s^0$	$\mu_{sx}(0)/\mu_s^0$
$\hat{m} = \hat{y}$	0	0	1	0
$\hat{m} = (\hat{x} + \hat{y})/\sqrt{2}$	-0.28	0.28	0.72	0.28
$\hat{m} = \hat{x}$	-0.56	0	0.44	0

where  $\mu_s^0 \equiv \vec{\mu}_{sN}(0) = (2e\lambda/\sigma_N)j_{s0}^{\text{SH}} \tanh[d_N/(2\lambda)]$  is the spin accumulation at the interface in the absence of spin-transfer, *i.e.*, when  $G_{\uparrow\downarrow} = 0$ .

Using (35), we find the spin accumulation

$$\frac{\vec{\mu}_{sN}(z)}{\mu_s^0} = -\hat{y} \frac{\sinh \frac{2z-d_N}{2\lambda}}{\sinh \frac{d_N}{2\lambda}} + [\hat{m} \times (\hat{m} \times \hat{y}) \text{Re} + (\hat{m} \times \hat{y}) \text{Im}] \frac{2\lambda G_{\uparrow\downarrow}}{\sigma_N + 2\lambda G_{\uparrow\downarrow} \coth \frac{d_N}{\lambda}} \frac{\cosh \frac{z-d_N}{\lambda}}{\sinh \frac{d_N}{\lambda}}, \quad (43)$$

that leads to the distributed spin current in N

$$\frac{\vec{j}_s^z(z)}{j_{s0}^{\text{SH}}} = \hat{y} \frac{\cosh \frac{2z-d_N}{2\lambda} - \cosh \frac{d_N}{2\lambda}}{\cosh \frac{d_N}{2\lambda}} - [\hat{m} \times (\hat{m} \times \hat{y}) \text{Re} + (\hat{m} \times \hat{y}) \text{Im}] \frac{2\lambda G_{\uparrow\downarrow} \tanh \frac{d_N}{2\lambda}}{\sigma_N + 2\lambda G_{\uparrow\downarrow} \coth \frac{d_N}{\lambda}} \frac{\sinh \frac{z-d_N}{\lambda}}{\sinh \frac{d_N}{\lambda}}. \quad (44)$$

First we have a look at the spatial dependences of the spin current and spin accumulation. According to first principles calculations [83],  $|G_i|$  is at least one order of magnitude smaller than  $G_r$  for YIG, so  $G_i = 0$  appears to be a good first approximation. In this limit, the normalized components of spin current ( $j_{sx} = \vec{j}_s^z \cdot \hat{x}$  and  $j_{sy} = \vec{j}_s^z \cdot \hat{y}$ ) and spin accumulation ( $\mu_{sx}$  and  $\mu_{sy}$ ) at the top ( $z = d_N$ ) and bottom ( $z = 0$ ) of N for different magnetizations are shown in table 1. When the magnetization of F is along  $\hat{y}$ , the spin current at the N|F interface ( $z = 0$ ) vanishes just as for the vacuum interface. By rotating the magnetization from  $\hat{y}$  to  $\hat{x}$ , the spin current at the N|F interface and the torque on the magnetization is activated, while the spin accumulation is dissipated correspondingly. The  $x$ -components of both spin accumulation and spin current vanish when the magnetization is along  $\hat{x}$  and  $\hat{y}$ , and are largest at  $(\hat{x} + \hat{y})/\sqrt{2}$ . This behavior agrees with the relations between spin current and spin-transfer torque at a N|F interface discussed above.

The ISHE drives a charge current in the  $x$ - $y$  plane by the diffusion spin current component flowing along the  $\hat{z}$ -direction. The total longitudinal (along  $\hat{x}$ ) and transverse

or Hall (along  $\hat{y}$ ) charge currents become

$$\frac{j_{c,\text{long}}(z)}{j_c^0} = 1 + \theta_{\text{SH}}^2 \left[ \frac{\cosh \frac{2z-d_N}{2\lambda}}{\cosh \frac{d_N}{2\lambda}} + (1 - m_y^2) \operatorname{Re} \frac{2\lambda G_{\uparrow\downarrow} \tanh \frac{d_N}{2\lambda}}{\sigma_N + 2\lambda G_{\uparrow\downarrow} \coth \frac{d_N}{\lambda}} \frac{\sinh \frac{z-d_N}{\lambda}}{\sinh \frac{d_N}{\lambda}} \right], \quad (45)$$

$$\frac{j_{c,\text{trans}}(z)}{j_c^0} = \theta_{\text{SH}}^2 (m_x m_y \operatorname{Re} - m_z \operatorname{Im}) \frac{2\lambda G_{\uparrow\downarrow} \tanh \frac{d_N}{2\lambda}}{\sigma_N + 2\lambda G_{\uparrow\downarrow} \coth \frac{d_N}{\lambda}} \frac{\sinh \frac{z-d_N}{\lambda}}{\sinh \frac{d_N}{\lambda}}, \quad (46)$$

where  $j_c^0 = \sigma_N E_x$  is the charge current driven by the external electric field.

The charge current vector is usually expressed in terms of the longitudinal and transverse (Hall) resistivities. Averaging the electric currents over the film thickness  $z$  and expanding the longitudinal resistivity or current in the ( $x$ -)direction of the applied field to leading order in  $\theta_{\text{SH}}^2$ , we obtain

$$\rho_{\text{long}} = \sigma_{\text{long}}^{-1} = \left( \frac{j_{c,\text{long}}}{E_x} \right)^{-1} \approx \rho + \Delta\rho_0 + \Delta\rho_1 (1 - m_y^2), \quad (47)$$

$$\rho_{\text{trans}} = -\frac{\sigma_{\text{trans}}}{\sigma_{\text{long}}^2} \approx -\frac{j_{c,\text{trans}}/E_x}{\sigma_N^2} = \Delta\rho_1 m_x m_y + \Delta\rho_2 m_z, \quad (48)$$

where

$$\frac{\Delta\rho_0}{\rho} = -\theta_{\text{SH}}^2 \frac{2\lambda}{d_N} \tanh \frac{d_N}{2\lambda}, \quad (49)$$

$$\frac{\Delta\rho_1}{\rho} = \theta_{\text{SH}}^2 \frac{\lambda}{d_N} \operatorname{Re} \frac{2\lambda G_{\uparrow\downarrow} \tanh^2 \frac{d_N}{2\lambda}}{\sigma_N + 2\lambda G_{\uparrow\downarrow} \coth \frac{d_N}{\lambda}} \approx \theta_{\text{SH}}^2 \frac{\lambda}{d_N} \frac{2\lambda G_r \tanh^2 \frac{d_N}{2\lambda}}{\sigma_N + 2\lambda G_r \coth \frac{d_N}{\lambda}}, \quad (50)$$

$$\frac{\Delta\rho_2}{\rho} = -\theta_{\text{SH}}^2 \frac{\lambda}{d_N} \operatorname{Im} \frac{2\lambda G_{\uparrow\downarrow} \tanh^2 \frac{d_N}{2\lambda}}{\sigma_N + 2\lambda G_{\uparrow\downarrow} \coth \frac{d_N}{\lambda}} \approx -\theta_{\text{SH}}^2 \frac{\lambda}{d_N} \frac{2\lambda \sigma_N G_i \tanh^2 \frac{d_N}{2\lambda}}{(\sigma_N + 2\lambda G_r \coth \frac{d_N}{\lambda})^2}, \quad (51)$$

and  $\rho = \sigma_N^{-1}$  is the intrinsic electric resistivity of the bulk normal metal. The last approximations requires  $G_r \gg G_i$ . We may not conclude from  $\Delta\rho_0 < 0$  that SOC reduces the global resistivity, since the bulk  $\rho$  itself is increased by spin-flip scattering in the bulk that is not explicitly treated here. For general magnetization and current directions (with film in the  $x$ - $y$  plane) we can summarize the angle dependence as [6]

$$\rho_{\text{long}} = \rho + \Delta\rho_0 + \Delta\rho_1 - \Delta\rho_1 [\hat{m} \cdot (\hat{j}_c \times \hat{z})]^2, \quad (52)$$

$$\rho_{\text{trans}} = -\Delta\rho_1 (\hat{m} \cdot \hat{j}_c) [\hat{m} \cdot (\hat{j}_c \times \hat{z})] + \Delta\rho_2 (\hat{m} \cdot \hat{z}). \quad (53)$$

(47-51) are the main results of the SMR model that can be compared with and fitted to experiments. We also note that the magnetization orientation dependence of the resistivity derived here holds for an isotropic N. In the presence of crystalline anisotropy, the angle dependence may involve higher harmonics [39].

#### 4. Comparison with experiments

The SMR theory sketched above leads to simple analytic forms (47-51) that predict the magnetization dependence of the electric resistivity of the bilayers in terms of one sample parameter, i.e. the thickness  $d_N$ , and four material parameters: the conductivity  $\sigma_N$ ,

**Table 2.** Transport parameters ( $\theta_{\text{SH}}$ ,  $\lambda$ ,  $G_r$ ) in N|FI bilayers obtained from experiments: A=SMR, B=SSE, C1 =SP+FMR, and C2 =SP+ISHE. \* labeled fits employed parameters from other sources.

spin Hall angle  $\theta_{\text{SH}}$ , spin diffusion length  $\lambda$ , and spin-mixing conductance  $G_{\uparrow\downarrow} = G_r + iG_i$ , where  $G_i$  is believed small and treated *a posteriori* by perturbation theory. The parameters may be fitted to SMR observations and other independent experiments such as ferromagnetic resonance (FMR) on the same bilayers.

While the SMR was discovered and filed as a patent as a remote detector of the magnetization direction of a ferromagnetic insulator a few years ago [35], the effect was first published in the supplemental material of [17]. Initially only the in-plane magnetization dependence was measured in Pt|YIG, which is phenomenologically identical to the conventional AMR. Weiler *et al.* therefore suspected that a proximity-induced ferromagnetic Pt layer could play a role [17], which implied that the spin Seebeck effect in Pt|YIG could be caused by an anomalous Nernst effect [27].

Subsequent experimental efforts addressed the dependence of the SMR when the magnetization is forced out of the interface plane, which revealed that the SMR is not consistent with a conventional AMR in a polycrystalline bulk material [28, 31]. While the SMR is proportional to  $m_y^2$  according to (47) and (48), the conventional AMR depends on  $m_x^2$  according to (5) and (6). These conclusions were confirmed by other experiments [30, 86, 29, 84, 85] also for bilayers with other metals such as Ta [29] and Pd [84, 85]. The current level required for SMR experiments can be kept low, but Joule

heating artifacts can be excluded by using lock-in techniques or symmetry arguments [87, 88], as well.

Measurements on Pt|Cu|YIG and Pt|Au|YIG provide more tests for the plausibility of a proximity effect. Cu and Au are diamagnetic and not susceptible to a ferromagnetic proximity effect. The persistence of an MR in the above trilayers can then be interpreted in terms of the spin Hall effect in Pt [28, 31] when the parallel conductance channels of the high-mobility Cu and Au spacer layers are taken into account, as shown in the supplementary material of [28].

The essential material-dependent parameters ( $\theta_{\text{SH}}$ ,  $\lambda$ ,  $G_{\uparrow\downarrow}$ ) are assumed to be intensive, i.e. to not depend on the layer thicknesses, which is a debatable approximation (see section 5.2). They can then be determined by fitting (50) derived above to the experimental SMR for various  $d_N$ . The spin Hall angle and spin diffusion length both reflect the SOC and might be correlated with each other [89], but we treat them here as independent phenomenological parameters [32]. The extracted parameters by different groups for the N|FI [27, 28, 31], and those from earlier experiments e.g. FMR on metallic bilayers [36] are of the same order of magnitude. The transport parameters have been extracted from experiments of spin pumping detected by the ISHE in conjunction with SMR results on bilayers of Pt|YIG and Ta|YIG by Hahn *et al.* [29]: the thickness dependence of the ISHE voltage was used to fit the spin diffusion length  $\lambda$  using the expressions from [90]. The spin-mixing conductances can then be accurately fitted to the magnetoresistance because the ratio of the square of the spin pumping-ISHE voltage and the SMR does not depend on  $\theta_{\text{SH}}$ . They confirmed a different sign for Pt ( $\theta_{\text{SH}} > 0$ ) and Ta ( $\theta_{\text{SH}} < 0$ ) [91]. A systematic study including SSE, spin pumping (probed by the ISHE and FMR spectral broadening), and the SMR [92] led to a single set of parameters for these three effects, confirming the presumed identical physical origin. The real part of spin-mixing conductance appears to be in the interval  $0.5 \times 10^{19} \text{m}^{-2} \leq G_r \leq 1.5 \times 10^{19} \text{m}^{-2}$  for various samples [92]. The large value of the mixing conductance with YIG was predicted by first-principle calculations [83] and confirmed earlier by FMR experiments [116]. Parameters fitted from the SMR are listed in table 2 and compared with those obtained by other methods for N|FI heterostructures.

Besides the planar Hall effect (the transverse corollary of a longitudinal MR), a Hall voltage that scales linear with the  $z$ -component of the magnetization (normal to the film) has been observed, i.e. an anomalous Hall-like effect that can be explained by the SMR mechanism when the imaginary part of the spin-mixing conductance  $G_i$  in (51) is significant. Combining experiments on the magnetization direction and film thickness dependences, a value for  $G_i$  can be extracted [31, 86] that agrees with first principle calculations [83]. Alternative explanations in terms of a conventional AHE in a magnetized monolayer of Pt or surface roughness, however, cannot be excluded as discussed in section 5.

The SMR has been observed in bilayers made from other metals than Pt such as Ta, Pd, W, Nb, and Rh [29, 93, 84, 85, 94, 95, 96], and other magnetic insulators besides

YIG [31, 97, 99]. In Pt|CFO (CFO:  $\text{CoFe}_2\text{O}_4$ ) bilayers, the spin-mixing conductance was found to strongly depend on the crystallographic interface orientation, possibly due to different densities of magnetic moments [97], which should be confirmed by spin pumping and SSE experiments and first principle calculations. The dependence of the SMR on the magnetic ordering at the interface provides a convenient tool to probe the interface magnetization of the FI, which can be very different from the bulk magnetization [98]. The SMR with Pt on the antiferromagnet  $\text{SrMnO}_3$  was found to be finite only when a net magnetization was induced by an applied magnetic field [99]. Since a current-induced spin-transfer torque has been predicted for antiferromagnets [100, 101], we expect an SMR also for unpolarized, single-domain antiferromagnets.

The SMR has been observed for Pt| $\text{Fe}_3\text{O}_4$  bilayers at low [31] and room temperatures [102].  $\text{Fe}_3\text{O}_4$  is not an insulator, but a bad metal with resistivity about five orders of magnitude larger than that of Pt| $\text{Fe}_3\text{O}_4$  and a possible AMR in the ferrite is likely to be shunted [102]. The SMR is also observed in metallic layered systems, even though its interpretation is more difficult due to currents in the ferromagnet and possibly more serious proximity effects. MR measurements in Pt|Co|Pt and Pt|Py|Pt trilayers [103, 104] found a magnetization dependence that is a combination of the AMR and what we now call SMR phenomenology, revealing that the SMR could be present also in all-metallic samples. In Ta|Co, Pt|Co and W|Pt, a difference in the resistance by, respectively, two (Ta|Co) and three (Pt|Co and W|Pt) orders of magnitude smaller than AMR+SMR was found in N|FM bilayers for magnetizations parallel and antiparallel to  $\hat{j}_c \times \hat{z}$  [105, 106]. Indeed, in ferromagnetic metals (in contrast to insulators) the reflection of the spin Hall current at the interface is incomplete and differs when parallel and antiparallel to the magnetization [105]. To capture this contribution, one may have to extend the SMR model by including the diffusive transport in F and fitting the boundary condition with (10) rather than with (35). It was reported that in  $\text{Ga}_{0.91}\text{Mn}_{0.09}\text{As}|\text{Ga}_{0.97}\text{Mn}_{0.03}\text{As}$  (FM|NM), this difference in MR can be in the same order of the SMR+AMR [107]. An SMR in metallic bilayers W|CoFeB has been reported to be an order of magnitude larger than that in N|FI, which was interpreted in terms of a spin Hall angle  $\theta_{\text{SH}} \approx 0.2$  for  $\beta$ -tungsten [108, 109]. A complete model for the spin-orbit torques in bilayers should explain the observed correlation between the SMR amplitude and current-induced magnetization switching in these bilayers [109].

## 5. Issues

Here we address controversial and unsolved issues concerning the interpretation of experiments in terms of the SMR mechanism.

### 5.1. Magnetic proximity effects

As mentioned above, the observation of a magnetoresistance in Pt on a magnetic insulator could in principle be caused by the equilibrium magnetic proximity effect

(MPE). Pt and Pd have Stoner-enhanced magnetic susceptibilities and are therefore “almost” ferromagnetic [117]. For instance, magnetic impurities in these metals have a strongly enhanced magnetic moment. The MPE is well established in bilayers made of a normal metal and a ferromagnetic metal. X-ray magnetic circular dichroism (XMCD) [118] detected a large polarization at the interface of Pt on a magnetic metal [119, 120, 121, 122, 123] as compared to less-susceptible metals. For example, the MPE in Au|Co is about one order of magnitude smaller than that in Pt|Co [124]. XMCD studies on Pt|YIG led to conflicting results [125, 126]. Theoretically, spin-polarized density functional calculations for Pt|YIG and Au|YIG found the Pt spin polarization in Pt|YIG to be stronger than that of Au in Au|YIG [114]. However, since YIG is a ferrimagnet with a much smaller saturation magnetization, the MPE in Pt|YIG may be expected to be smaller than that for strongly ferromagnetic metals. Guo *et al.* [127] predicted a significant magnetotransport effect in slightly magnetized Pt. However, these calculations are for bulk materials and cannot be used to model a monolayer-scale proximity effect on a magnetic insulator. We are not aware of a realistic theoretical model for magnetotransport dominated by the MPE.

Kikkawa *et al.* [128] addressed the possible contribution of an MPE-induced anomalous Nernst effect (ANE) generated by an in-plane temperature gradient over a Pt|YIG bilayer with an out-of-plane magnetization. The observed Hall voltage was less than 5% of that for an in-plane magnetization and out-of-plane temperature gradient, i.e. the sum of the ANE and the SSE, leading to the conclusion that an MPE-induced ANE may be disregarded.

The reported temperature dependence of the SMR is not unequivocal. Some groups only find a decrease of the SMR amplitude at low temperatures (see section 6.2), others report an increasingly significant AMR contribution in Pd|YIG [85], Ta|YIG [93], IrMn|YIG [129], Pt|YIG [129], Pt|Co<sub>2</sub>FeAl [130], and Pt|LaCoO<sub>3</sub> [131] that might indicate a low temperature MPE. Puzzling is the sign change of the AHE-like SMR at temperatures between a few Kelvin and room temperature [94, 132, 129, 131], suggesting either a temperature-dependent  $G_i$  or a new low-temperature transport phenomenon, possibly caused by the MPE or interface disorder (discussed in section 5.2). An AHE-like signal at low temperatures and at magnetic fields higher than the saturation field of YIG [84, 133] is interpreted as evidence for a hard magnetization texture of unknown character at the interface. Further studies are required to shed light on the physical mechanisms that may affect the MR at low temperatures. At room temperature, the simple SMR model appears to be as yet unchallenged.

### 5.2. Interface roughness and AHE-like SMR

Surface roughness scattering disregarded here affects many in-plane transport properties of ultrathin metallic films. These effects can in principle be modeled by semiclassical Boltzmann or diffusion theories [134, 135]. When the metallic films become thinner, their resistivity increases by either reduced crystal quality or the increased importance

of surface roughness. Parameters such as the spin-flip diffusion length and spin Hall angle may become thickness dependent as well. The AMR of thin films of metallic ferromagnets is known to be affected by surface roughness [41, 42]. The spin-dependent scattering at rough interfaces is invoked to explain the current in-plane giant magnetoresistance [53]. The SHE and the SMR in N|FI should also be affected by roughness at the interface causing, for example, a spin-dependent mean-free path in the normal metal even without an equilibrium MPE. Interface roughness has minor effects on the spin-mixing conductance (when the SOC is small) [64]. Moreover, for out-of-plane magnetizations, spin-dependent roughness can drive a transverse charge current by the ISHE, competing with the contribution from the imaginary part of the spin-mixing conductance in (51). While (51) is a second-order contribution of the SOC, the contribution due to the spin-dependent roughness scales linearly to  $\theta_{\text{SH}}$  [136, 137]. The two mechanisms can therefore be distinguished by measurements on materials with opposite signs of spin Hall angle such as Pt and Ta [137].

Experimentally, the SMR in Pt|FM|MgO with (sub) monolayer (0.3 or 0.6 nm)  $\text{Co}_2\text{FeAl}$  was explained in terms of an interference of spin-dependent scattering at magnetic clusters and the SHE [130]. A quantitative analysis of the effects of roughness might be possible if induced by controlled ion bombardment [138, 139].

### 5.3. Interface spin-orbit couplings

The SMR model attributes the spin polarization to the SHE, which requires the SOC in the bulk layer, but disregards the SOC at the F|N interface. However, interface SOC can modulate transport parameters that can be separated from bulk effects experimentally only by tedious thickness-dependent studies. A material-dependent theory of spin transport through F|N interfaces is not available. However, an effective spin-mixing conductance can parameterize computed results for the spin pumping contribution to the Gilbert damping and interface spin flips [140] in N|Py|N sandwiches [79]. Such an effective spin-mixing conductance appears to be not very sensitive to the SOC for intermetallic interfaces such as Py|Pt [79]. A large spin-mixing conductance has been reported for Py|Cu|YIG [141]. Experiments with non-local spin valves on a YIG substrated were interpreted in terms of a finite Cu|YIG spin-mixing conductance; its relatively small value might be caused by interface contamination [142]. By a similar technique, i.e. using a non-local Py|Al spin valves on a YIG substrate, Dejene *et al.* [143] distill a large mixing conductance, but the modulation as a function of YIG magnetization direction is smaller than expected, which can be explained by thermal fluctuations [144, 73, 162] (see section 6.2).

The Edelstein effect refers to a current-induced spin accumulation with polarization normal to the current direction in the plane of the two-dimensional electron gas in which inversion symmetry is broken by a normal electric field that can be described by the Rashba Hamiltonian [145]. The Rashba Hamiltonian has been invoked also for thin metallic films, in which non-equivalent interfaces are the source of the inversion

symmetry-breaking [67, 68]. An MR was predicted for N|FI bilayers in the presence of a Rashba interaction at the interface (and without SHE in the bulk) that depends on the magnetization direction just like the SMR [146]. Other theoretical studies of the MR in ferromagnetic metallic thin films on a conventional insulating substrate with Rashba SOC based on the Boltzmann equation [147, 148] also predict a contribution to the magnetoresistance which has the same magnetization dependence as the SMR ( $m_y^2$ ) but a different thickness dependence [148]. Thus in principle, thickness-dependent studies could help distinguish these different mechanisms.

Recent positron annihilation experiments observed current-induced spin polarizations in normal metal films without proximity ferromagnets [149, 150]. The measured spin polarization is about one order of magnitude larger than that estimated by the diffusive SHE model defined as  $\mu_s^0$  in section 3.3. The authors attribute the observations to the Edelstein effect [66], i.e. a spin accumulation with an in-plane polarization normal to the applied current direction in a surface state, which may be interpreted as a two-dimensional limit of the SHE. Jellium model calculations suggest a universal current-induced spin polarization at metallic surfaces of  $|\vec{s}| = \Gamma j_c$  [151], where  $\Gamma$  is a material dependent constant that appears to be large for Pt and Ta, but small for Au and Cu [150].

## 6. Developments

We discuss in the following ongoing developments related to the SMR.

### 6.1. Dynamics

The SMR model took the magnetization in the FI to be static, which is not generally the case since spin currents absorbed by the FI generate spin-transfer torques which can amplify or attenuate [152] and even generate spin waves [70]. The threshold current for spin wave excitations in N|FI is higher than found in the experiments even when easy-axis magnetic surface anisotropy is taken into account [153, 154, 155]. Recent experiments show that current-induced auto-oscillation in YIG can be achieved by current densities as predicted, but only when reducing the lateral dimensions of the FI [71].

An ac SMR, or the spin Hall magnetoimpedance, was observed experimentally [156] to persist up to at least 4 GHz, allowing fast readouts of the magnetization in N|FI bilayers. The SMR also allows observation of spin torque induced FMR [157], i.e. the observation of a dc voltage by down conversion of an applied ac current by the oscillating resistance under resonance. Schreier *et al.* [158] and Sklenar *et al.* [159] separate the effects of the spin-transfer torque from that of Oersted fields generated by the applied ac current and spin pumping from the SMR rectification by comparing samples with different YIG and Pt thickness [158, 159]. This technique appears to be more sensitive than applying microwaves via a coplanar wave guide [160].

### 6.2. Temperature dependence

As a zero temperature theory, the SMR model described here assumes perfect reflection of a spin current with spin polarization collinear to the magnetization. At finite temperatures, the magnetization fluctuates and thereby allows for a finite spin current even for collinear configurations [144, 73, 161, 162]. The SMR model thereby overestimates the magnetoresistance. A larger than expected loss of spin accumulation in collinear configurations has been inferred from experiments for YIG|Al [143], which could imply that the spin-mixing conductances fitted to room temperature SMR experiments are underestimated.

In bilayers of Pt, Ta, and Pd with YIG [164, 163, 93, 84, 85]. SMR decrease with temperature when going from 300 K to 10 K. This contradicts the (above) notion of a spin current in the collinear configuration that is induced by thermal fluctuations, which should lead to a larger SMR at lower temperatures. The effect might be caused by a temperature dependence of the spin Hall angle [164]. A non-monotonic temperature dependence of the SMR in Pt|YIG and Pd|YIG with a maximum at 100 K was explained in terms of a spin diffusion length that is inversely proportional to the temperature, as expected from the Elliot-Yafet impurity scattering model [163, 85]. In the regime from ambient to the Curie temperature of YIG, the SMR decreases monotonically as expected [165]. The observation that the SMR decreases with temperature at a higher power than the magnetization could be caused by a temperature-dependent spin-mixing conductance [165].

Spin currents generated in a lateral F|N<sub>1</sub>|F spin valve can be absorbed by another contact (N<sub>2</sub>) placed between the magnetic electrodes on the path of the diffusive spin current in N<sub>1</sub>. This technique gives access to the spin diffusion length and spin Hall angle (via the ISHE) of N<sub>2</sub> [50, 166], and was used to measure their temperature dependence for Pt and Au [167, 168]. In Pt, both spin Hall angle and electric resistivity are found to increase linearly with temperature, implying an intrinsic mechanism for the spin Hall conductivity [6], while the SHE in Au appears to be dominated by extrinsic effects [167]. Such an analysis could be helpful to clarify the microscopic mechanism responsible for the temperature dependence of the SMR.

The spin Seebeck effect in gadolinium (Gd) iron garnet (Gd<sub>3</sub>Fe<sub>5</sub>O<sub>12</sub>) [169] changes sign twice when the temperature is lowered from 300 K to 35 K, and is explained in terms of different contributions from the magnetic sublattices. Experimental results for the temperature dependence of the SMR of rare earth iron garnets might help establishing the importance of interface vs. bulk effects to explain this intriguing phenomenon.

### 6.3. Spin valves and superlattices

The magnetizations in FI|N|FI spin valves can be coupled, in the ground states by dipolar and non-local exchange interactions. A dynamic exchange interaction is generated by spin current emission and absorption when magnetizations are moving [115]. The magnetic state can be detected by the SMR, which is enhanced when

the magnetizations are collinear and reduced when perpendicular to each other [32]. The SHE interferes when the charge current through the spacer becomes appreciable. Applied currents were found to modulate the damping of FI|N|FI spin valve and (FI|N|)<sub>n</sub> superlattice dynamics. The critical currents to excite magnetization dynamics (macrospin and spin waves) depend on the relative orientations of magnetizations [170]. The dynamic coupling between spin waves due to spin pumping and spin-transfer torques is in general mode-dependent [171].

#### 6.4. Bilayers of insulating and metallic magnets

Recent studies address bilayers made of a metallic ferromagnet such as permalloy and a ferromagnetic insulator such as YIG [104, 138, 172, 173, 141, 174, 175]. The MR in these systems [104, 138, 172] can be fully explained neither by the conventional AMR nor by the SMR theory that only holds for paramagnetic conductors. The MPE can induce a magnetic moment on a highly susceptible paramagnet, but should have minor effects on a strong ferromagnet, although Lu *et al.* [104] argue otherwise. The Hall voltages induced by thermal [138] and FMR [173] spin pumping have been interpreted in terms of the spin Hall angle of the ferromagnet, where Tsukahara *et al.* extracted a spin Hall angle of  $\theta_{\text{SH}} = 0.5\% - 1\%$  for Py. It was pointed out that dc Hall voltages can be generated as well by spin rectification caused by the dynamics and the AMR in Py [175]. Spin pumping as detected by Hall voltages in W|Py|YIG trilayers indicate opposite signs of the spin Hall angles in Py and W [141]. However, the mechanism of spin pumping into a metallic ferromagnet is not yet fully understood [174], so estimates of the spin Hall angle in magnetic metals should be taken with a grain of salt. By decoupling Py and YIG with a copper spacer layer [141], the problem becomes amenable to the conventional theory, however, a  $\theta_{\text{SH}} = 2\%$  for Py was deduced. First principles calculations predict extrinsic spin Hall angles in diluted ferromagnetic alloys of  $\theta_{\text{SH}} \geq 1\%$  [176].

## 7. Conclusions/outlook

The discovery of a magnetoresistance in nominally non-magnetic metals next to magnetic insulators has stimulated many subsequent studies. Experiments from different groups and sample growth techniques yield consistent results that are well reproduced by a few-parameter, simple and intuitive model called “spin Hall magnetoresistance (SMR)” that explains the observations by the concerted action of the direct and inverse spin Hall effects. While providing a convenient parametrization scheme, the detailed physics and material dependence is still a matter of discussion. By using an exchange-only theory of spin-transfer torque, the effect of interfacial spin-orbit coupling (SOC) is disregarded. This does not necessarily reduce the quality of the fits, but the parameters must then be considered to represent an effective average of interface and bulk contributions with the same symmetry. Fitting parameters that depend strongly on the thickness of the normal metal film have not been reported to

date. First-principles calculations including the SOC and disorder such as those by Liu *et al.* [79] should be able to shed more light on this issue. Measurements at low temperatures and high magnetic fields have been interpreted in terms of a magnetic proximity effect [84, 85, 93, 94, 129, 130, 131, 132, 133], although even a qualitative theory in support of this conjecture is lacking. XMCD experiments that in principle provide a definite answer lead to contradicting results [125, 126]. Also here first-principles calculation may importantly help to not only estimate the magnitude and penetration of the induced moments, but also its effects on transport and taking into account the magnetic fluctuations induced by finite temperatures [177].

The SMR has been employed to study spin-correlations in antiferromagnets [99] and multiferroic materials [178]. In these studies a magnetic field has to be applied in order to observe a finite SMR, which implies that an interface magnetic susceptibility is sampled, rather than a ground state spin texture. While the SMR is a sensitive detector for subtle spin correlations [178], more work is needed to better understand the implications. The spin Seebeck effect in paramagnets under strong magnetic fields [179] should be accompanied by an SMR. The SMR has been observed in the current-direction dependence of the Johnson-Nyquist noise of YIG|Pt bilayers, which can be understood in terms of the fluctuation dissipation theorem [180]. Another direction worth exploring are thermal analogies of the SMR [181]: we may, e.g., expect a dependence of the in-plane thermopower on the magnetization direction in N|FI bilayers as a fingerprint of the spin Nernst effect. Very recently, a non-local SMR (or magnon-drag effect [182]) was observed in Pt|YIG|Pt lateral heterostructures [183, 184], in which a current in one contact generates a voltage in the other contact that is maximal when both are normal to the magnetization direction.
