Origami and kirigami have emerged as potential tools for the design of mechanical metamaterials whose properties such as curvature, Poisson’s ratio, and existence of metastable states can be tuned using purely geometric criteria. A major obstacle to exploiting this property is the scarcity of tools to identify and program the flexibility of fold patterns. We exploit a recent connection between spring networks and quantum topological states to design origami with localized folding motions at boundaries and study them both experimentally and theoretically. These folding motions exist due to an underlying topological invariant rather than a local imbalance between constraints and degrees of freedom. We give a simple example of a quasi-1D folding pattern that realizes such topological states. We also demonstrate how to generalize these topological design principles to 2D. A striking consequence is that a domain wall between two topologically distinct, mechanically rigid structures is deformable even when constraints locally match the degrees of freedom.

Recent interest in origami mechanisms has been spurred by advances in fabrication and manufacturing [1–3], as well as a realization that folded structures can form the basis of mechanical metamaterials [4–8]. The ability to identify kinematic mechanisms – allowable folding motions of a crease pattern – is critical to the use of origami to design new deployable structures and mechanical metamaterials. For example, the mechanism in the celebrated Miura ori that allows it to furl and unfurl in a single motion [9, 10] is also the primary determinant of the fold pattern’s negative Poisson ratio [4, 5]. Identifying these mechanisms becomes more challenging when the number of apparent constraints matches the number of degrees of freedom (DOF).

When there is an exact balance between DOF and constraints in a periodic structure, the structure is marginally rigid [11, 12]. In such a case, new mechanical properties such as nonlinear response to small perturbations emerge [13–16]. A recent realization is that the flexibility of such solids may be influenced by nontrivial topology in the phonon band structure [17, 18]. Here, we show how to extend these topological ideas to origami and kirigami. We show that periodically-folded sheets may exhibit distinct mechanical “phases” characterized by a topological invariant called the *topological polarization*, recently introduced by Kane and Lubensky [17] using a mapping of mechanically marginal structures to topological insulators [19]. The importance of this invariant has emerged in the study of the soft modes of spring networks [18], and the nonlinear mechanics of linkages

[20] and buckling [21]. As in these examples, the phases in our origami and kirigami structures exhibit localized vibrational modes on certain boundaries, and transitions from between topological phases are characterized by the appearance of bulk modes that cost zero energy. These are the hallmarks of topologically protected behavior in classical mechanical systems [22–29]. Topology provides a new knob to tune how materials and, as we show here, origami and kirigami structures, respond to external perturbations.

We denote by *origami*, mechanical structures consisting of rigid flat polygonal plates joined by hinges. We will first discuss origami with no missing plates or “holes”, and then generalize to *kirigami*, defined to be origami where such holes are allowed. We will consider the mechanics of origami in the geometrical limit – folds will cost zero energy and faces do not stretch or bend.

To demonstrate the power of our approach, we introduce an example of a 1D strip of origami analogous to the Su-Schrieffer-Heeger polyacetylene model [17, 30]. It admits localized modes and stresses determined and protected by topology, which we realize and characterize in experiments. Additionally we show how to generalize this to 2D periodic origami sheets, where we have observed a striking property that causes origami without holes to have zero topological polarization. We give examples of hinged structures with holes (kirigami) that do admit distinct polarizations and thus can be used as building blocks for metasheets with programmable local flexibility.

Quasi-1D origami strip.— We start with a simple quasi-1D origami structure. Consider an origami strip of zig-zagging rigid quadrilateral plates, depicted in Fig. 1, consisting of a periodically-repeating unit cell of two four-fold vertices. Each vertex in a cell (labeled by $n = 1, 2$) has four creases (Fig. 1(a)), and one DOF [31] that we track with the dihedral angles of the bolded crease, $f_n(j)$, where j indexes the unit cell (Fig. 1(b)). Each adjacent

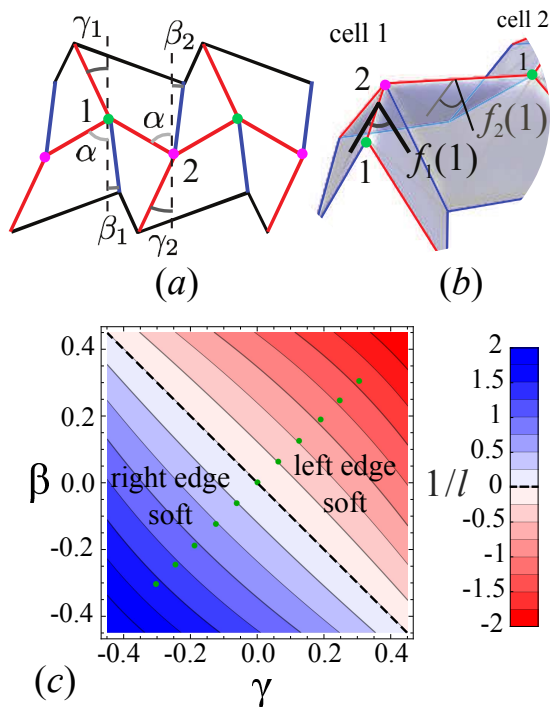

FIG. 1: A quasi-1D origami strip. (a) A unit cell of the fold pattern corresponding to the origami mechanism with planar angles labeled. Red (blue) creases are mountain (valley) folds, respectively. (b) A 3D depiction of a part of the strip with folding angles $f_i(n)$ labeled. (c) The phase diagram where $\alpha = \pi/3$, $\beta \equiv \beta_1 = \beta_2$ and $\gamma \equiv \gamma_1 = \gamma_2$. The colors indicate the phase (blue for right-localized, red for left-localized); the contours and intensity of color follow the inverse decay length $1/l$ (see legend). Configurations where folds at a vertex become collinear lie on $\gamma = \beta$, and the green points along that line were constructed in experiment (along this line, (γ, β) and $(-\gamma, -\beta)$ are related by a rotation in 3D).

pair of dihedral angles is coupled by the kinematics of the intervening vertex. As each vertex contributes a DOF and a constraint, this origami structure has marginal rigidity.

We analyze the mechanical response of the origami strip by determining its configurations analytically as functions of the fold pattern angles $\beta_1, \beta_2, \gamma_1$ and γ_2 (defined in Fig. 1(a)). We define a generalized displacement $u(j) = \cos f_2(j) + 1$. The function $u(j)$ encodes the dihedral angle f_2 of the right-most fold of unit cell j , and satisfies

$$u(j+1) = \kappa(\alpha, \beta_1, \beta_2, \gamma_1, \gamma_2)u(j), \quad (1)$$

where

$$\kappa = \left[\frac{\sin(\alpha - \beta_1) \sin(\alpha - \gamma_1)}{\sin(\alpha + \beta_1) \sin(\alpha + \gamma_1)} \right] \left[\frac{\sin(\alpha - \beta_2) \sin(\alpha - \gamma_2)}{\sin(\alpha + \beta_2) \sin(\alpha + \gamma_2)} \right]. \quad (2)$$

The derivation is an application of the spherical law of cosines and is given in the SI. The fact that $u(j)$ de-

termines $u(j+1)$ implies that the strip has one degree of freedom, globally. Eq. (1) is solved by an exponential $u(j) = u(0) \exp[j \ln(\kappa)]$ with deformation localized to one side or the other, following the sign of the inverse decay length $l^{-1} = \ln \kappa$.

The mechanical “phase diagram” in Fig. 1(c) shows the values of l^{-1} for patterns with $\gamma_1 = \gamma_2 \equiv \gamma, \beta_1 = \beta_2 \equiv \beta$. There are two “phases” distinguished by the sign of $\ln \kappa$, which is determined here by the sign of $\gamma + \beta$, a quantity not obviously related to any symmetry-breaking. When $\gamma + \beta > (<)0, \kappa < (>)1$, and by Eq. (1), the mechanical response is localized to the left (right) of the origami strip. A special role is played by fold patterns with $\kappa = 1$, where the decay length diverges and $u(j)$ neither grows nor shrinks (denoted by the dashed line). This is precisely the condition for which a global kinematic mechanism exists and the fold pattern is *deployable* [32]. As an example, when $\gamma = \beta = 0$, the strip realizes a row of the Miura ori fold pattern, which has a single collapse motion. More generically, however, as long as $\ln \kappa$ never changes sign, the deformation in a strip, $u(j)$, is localized even if the values of $\alpha, \beta_j, \gamma_j$ vary due to disorder or imperfections, i.e. as long as the material remains within the same phase. The existence of phases of robust, boundary-localized zero-energy deformations separated by critical configurations with bulk zero modes suggests that the origami strip has *topologically protected properties*.

To make the topology explicit, we calculate a topological invariant of the above phases. Unlike in periodic spring networks with marginal rigidity [17, 33, 34], a linear analysis is inadequate to capture the topology of the origami strip. Coplanar hinges in the flat state are redundant constraints, and this results in extra zero modes at linear order which do not extend to higher order. In the SI, we derive a rigidity matrix capturing the *second-order* deformations of this structure and show that it has the same pattern of entries as the Hamiltonian of the Su-Schrieffer-Heeger chain of Refs. 17, 30. Therefore, phases of the origami strip are characterized by their topological polarization \bar{P}_T [17, 18], defined as a winding number of the determinant of the rigidity matrix [38]. Indeed, the sign of $\ln \kappa$ is precisely correlated with the topological polarization, and thus the fact that different edges are soft or stiff in different phases is a manifestation of the bulk-boundary correspondence [19] in this system. While topological modes in 1D linkages have been found to lead to propagating domain walls [20, 35], this is not possible for our 1D strip. In Eq. (2), κ depends only on the fold pattern angles $\alpha, \beta_j, \gamma_j$, not the dihedral angles f_j – this means that the topological polarization of the unit cell cannot change via the zero-energy deformations, which would be necessary for propagation.

To test the consequences of Eq. (1) away from the ideal limit, in a structure where faces can bend and hinges can twist, a mylar sheet (200 μm thick) is perforated by a laser cutter into the desired crease pattern, rendering it foldable along lines of perforations. We strengthen the facets by sandwiching the mylar sheet between pairs of

1 mm thick, plastic plates made of polylactic acid (PLA) on a 3D printer. To mount the plastic plates onto the mylar sheet, we use a pushed-in clip design: one facet has clips and the corresponding facet has holes. Equivalent holes are cut on the mylar sheet so that the clips can be pushed through to meet the holes on the plate on the other side of the mylar. An example of the assembled origami structure is shown in Fig. 2(a). Here, we fixed the angle $\alpha = \pi/3$ and varied $\gamma \equiv \beta_1 = \gamma_1 = \beta_2 = \gamma_2$ to explore the localization of the deformation within one phase (with $\kappa < 1$) [39]. A video camera captured the deformation of the strip from above as it was symmetrically compressed. The position of each vertex was obtained via image analysis, and fit with a 3D model to reconstruct the complete morphology of the origami strip, as shown in Fig. 2(b). Finally, the folding angles along the interior creases were extracted from the 3D shape and were used to compute the generalized strain u . Fig. 2(c) shows the strain as a function of distance along the strip for samples with different values of the pattern parameter γ . Observe that there is a “soft” edge (cell index 0), where the deformation is high, and on the other end a “stiff” edge, with low deformation.

As shown by a semi-log fit (dashed lines in Fig. 2(c)), the strains decay exponentially at small distances from the soft edge. For small γ , the folding angles level off to a roughly constant value at larger distances, which violates Eq. (1). The constant folding angle background corresponds to the activation of a mode with uniform deformation. This mode is easy to excite as it is the zero energy mode at $\gamma = 0$ and thus remains very low energy for small γ . A deviation from the ideal geometrical limit is possible due to the finite flexibility of the facets and the finite crease thicknesses. Despite the non-ideality of the experimental origami strip, the decay lengths extracted from the fit are in good agreement with $1/l = \ln \kappa$ (Fig. 2(d)), confirming the robustness of our topological design principle.

Two-dimensional origami.— Having established that marginally rigid 1D periodic origami can exhibit topological phases, we now ask whether marginality also leads to similar phases in 2D origami. We first characterize the class of *marginally rigid* 2D periodic origami and show that they must have a triangulated crease pattern. To avoid trigonometric complexity inherent to a folding angle representation, we model the kinematics of triangulated origami as a central-force spring network with vertices as joints and hinges as springs. Triangles in such a network automatically enforce the no-bending constraint on the facets. Arbitrary origami can be modeled with spring networks, but nontriangular faces require additional internal springs to remain rigid.

In this framework, each joint has 3 degrees of freedom and each spring adds one constraint, so marginal structures satisfy $E = 3V$ where E is the number of bonds and V is the number of joints. In a triangulated surface without a boundary, each of the F faces is a triangle, so $3F = 2E$. The Euler characteristic χ is defined as

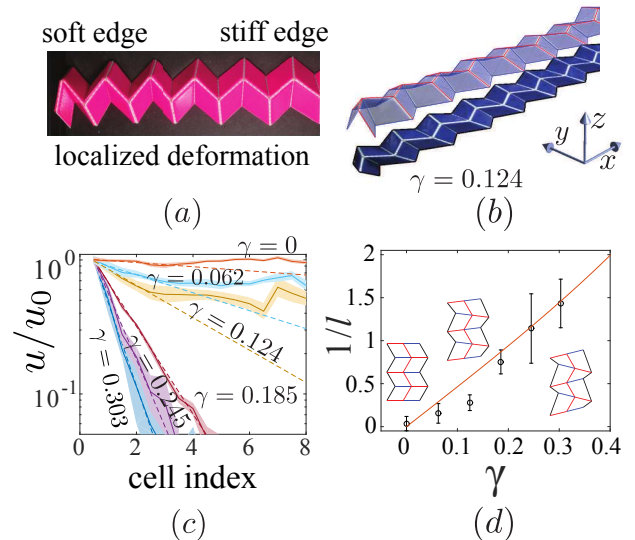

FIG. 2: (a) Localized deformations in an experimental realization of the origami strip ($\alpha = \pi/3, \gamma_1 = \gamma_2 = \beta_1 = \beta_2 = 0.062$). (b) 3D reconstruction of the configuration of the strip from a flat image ($\gamma = 0.124$). (c) Normalized generalized strain u/u_0 as a function of distance from the deformable boundary (measured in number of unit cells) from experiments (shaded curves) with fits to an exponential decay (dashed lines). Each curve shows the average of data from 6 – 30 experimental images and has a width equal to the standard error. Folding angles $f_2(1)$ (related to u_0 via $u_0 = 1 + \cos f_2(1)$) at cell 1 varied from 1.06 to 1.45. (d) Inverse decay lengths ($1/l$) versus γ , where data points are averages over the fitting coefficients of all images for each γ and error bars show 95% confidence bounds. The analytical result for $l^{-1} = \ln \kappa$ (Eq. 2) is plotted as a solid red line. The deviations for small γ arise from a “uniform bending mode” (see text).

$\chi = V - E + F$; thus we obtain $E = 3(V - \chi)$.

Periodic origami structures in 2D have the topology of the torus and thus $\chi = 0$, which shows that *triangulations are marginally rigid*. While achieving marginality in granular packings and glassy networks requires some fine-tuning in pressure or coordination, the analogous origami triangulations arise naturally. Any non-triangular plate in an origami pattern can be triangulated by adding diagonals, and the bending of non-triangular plates in real origami can be modeled as the addition of new creases [4, 6].

One might now expect a variety of topological phases upon changing the angles and lengths of a triangulated crease pattern, by analogy with the 1D strip. Surprisingly, our calculations indicate otherwise. As discussed above, an analysis of the rigidity of *flat* origami must go beyond linear order. To bypass this complication, we consider periodic triangulated origami where we break the flat-state degeneracy by introducing small vertical displacements to the vertices. The linear rigidity and

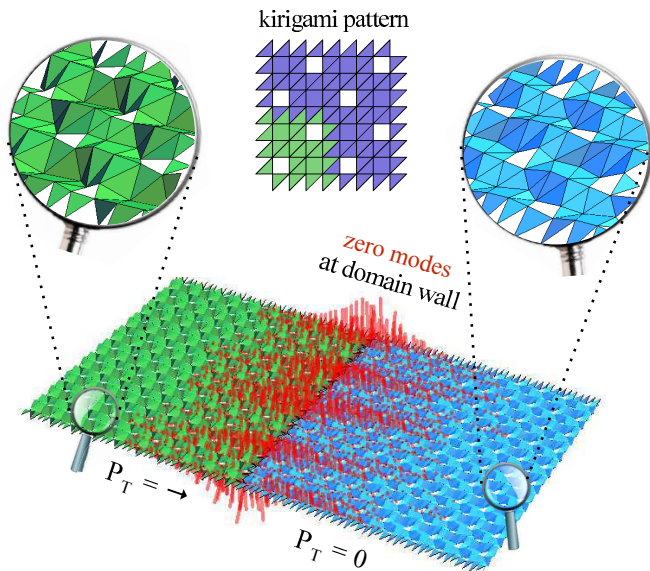

FIG. 3: Topologically protected zero mode (red) in a kirigami heterostructure (left green with topological polarization $\vec{P}_T = (1, 0)$ / right blue with $\vec{P}_T = (0, 0)$). Numerically the mode depicted has energy nearly indistinguishable from the translation modes. This is a close-up of a larger periodic 50×5 system, divided into two 25×5 domains (two copies in the shorter direction are shown). The magnifying glass insets show the fine structure of four unit cells of each type, and between them is a schematic showing how the quadrilateral plates, strips of triangles, and quadrilateral holes are joined by hinges. The schematic shows four unit cells, with the lower left cell highlighted in green.

topological properties of such a structure can then be expressed in terms of the (Fourier-transformed) rigidity matrix \mathbf{R} for its associated spring network [17, 18]. However, for all triangulated periodic fold patterns we have considered, the function $\det \mathbf{R}(\mathbf{q})$, *a priori* a complex-valued function, is in fact real-valued for all \mathbf{q} in the Brillouin zone [40]! Though a proof of this statement for all triangulated origami eludes us, extensive numerical tests on a large number of distinct fold patterns bear out this conjecture. We give details and partial results in the SI.

A consequence of the “reality” property is that the winding numbers of $\text{Arg } \det \mathbf{R}(\mathbf{q})$ along any closed curves in the Brillouin zone must be zero (when defined), and hence the topological polarization \vec{P}_T must vanish. Localized boundary modes for such origami still exist, but must be isotropically distributed. Even if the hinges in a unit cell break left-right symmetry, the number of boundary modes per unit cell on each edge of a finite patch is left-right and up-down symmetric. If in fact all triangulated periodic origami structures have this property, the only way to get an imbalance in the number of zero modes at the boundary of origami is by locally adding or removing constraints. This behavior contrasts

with that of the 1D strip of origami studied above as well as 3D periodic networks and marginal spring networks confined to 2D.

Topological kirigami.— Thus the question remains: do there even exist 2D periodic hinged structures with a nonzero topological polarization? The answer is yes, but we must go beyond origami to *kirigami*, folded structures with holes. There is a simple way to generate marginal kirigami from triangulated origami. Cutting out an adjacent pair of triangles removes one bond from the associated spring network, eliminating a constraint. Likewise, merging two triangles into a rigid quadrilateral plate adds a constraint. We therefore modify a triangular lattice by cutting and merging twice, resulting in a structure with two quadrilateral plates and two quadrilateral holes per unit cell (top center of Fig. 3). Now $\det \mathbf{R}(\mathbf{q})$ is complex-valued, and by randomly perturbing a flat realization, we find the “green” (left) and “blue” (right) structures depicted in Fig. 3, which have $\vec{P}_T = (1, 0)$ and $(0, 0)$, respectively (see SI for more details). With free boundary conditions, the boundary soft modes in the green kirigami are polarized to the $+x$ edge (analogous to the 1D strip and in contrast to the blue kirigami and all triangulated origami structures we tested).

Finding the green kirigami answers the question above positively, and we leave a determination of the possible phases that can occur in the modified triangular lattice to future work. A full characterization will likely be difficult due to the high dimensionality of the realization space (c.f. Ref. 36 which shows the complexity of the phase diagram in a simpler mechanical system). We thus switch gears and present an example of localized modes designed into a kirigami “heterostructure” to illustrate the power of our techniques. In Fig. 3, we show a kirigami structure that exhibits zero modes localized at a domain wall (one per unit cell) between the two kirigami structures described above. The zero modes render the heterostructure flexible in the vicinity of the domain wall (the mode depicted leads to out-of-plane wrinkling), while keeping it rigid further away. By contrast, a domain wall between distinct patterns with equal polarization has no such localized modes (see SI). In general, domain walls between structures with different polarizations create either “soft” lines along which the system easily deforms, or “stressed” lines which first bear the loads under applied strains [21]. Similar effects may arise at point defects in otherwise uniform polarized structures [37].

Outlook.— We have demonstrated that origami and kirigami structures are characterized by a topological polarization that classifies the ways that a marginally rigid fold pattern can be floppy close to its boundaries. Our results give strong constraints on the types of boundary modes that can be created in origami and will guide the design of fold patterns that achieve a targeted mechanical response. In the design space of geometric realizations, two structures with different polarizations must be separated by globally flexible, i.e. deployable, realizations. Thus not only can structures with distinct phases

be combined in real space to form domain walls with useful functionality, but also they can be used to find deployable patterns in design space. These realization spaces are high dimensional in general, so the problem of determining simple rules to create a given polarization remains open.

- [38] For structures with $\kappa = 1$, that lie on the transition between the two distinct topological phases, the winding number and hence polarization is not defined.
- [39] Note that by rotating the structure by 180° one ends up with a “new” unit cell with $\gamma \rightarrow -\gamma$ and $\beta \rightarrow -\beta$, which is in the opposite topological phase.
- [40] More precisely, since the function $\det \mathbf{R}(\mathbf{q})$ is gauge dependent, the claim is that this is true in the gauge arising from a “balanced” unit cell as defined in Ref. [17, 18].

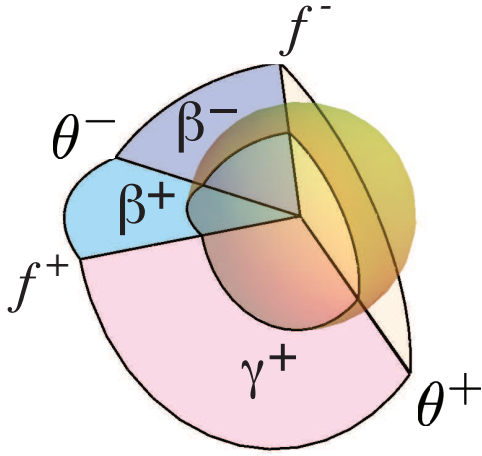

FIG. SI-1: Spherical polygons for a four-fold vertex. Angle variables are different from those used in the main text.

Supplementary Information

Appendix A: Vertex kinematics and spherical polygons

The intersection between an origami vertex and a sphere traces out a spherical polygon on the sphere surface [31] (Fig. SI-1). For a four-fold vertex, this polygon is a quadrilateral whose side lengths are inherited from the angles between adjacent folds in the fold pattern (the unlabeled fourth angle in Fig. SI-1 is $\gamma^- = 2\pi - \beta^+ - \beta^- - \gamma^+$). The relationship between dihedral angles f^\pm is

$$\begin{aligned} \cos \beta^+ \cos \gamma^+ + \sin \beta^+ \sin \gamma^+ \cos f^+ &= \\ \cos \beta^- \cos \gamma^- + \sin \beta^- \sin \gamma^- \cos f^- & \end{aligned} \quad (\text{S1})$$

Since $\beta^+ + \gamma^+ = 2\pi - \beta^- - \gamma^-$, Eq. (S1) becomes

$$\sin \beta^+ \sin \gamma^+ (\cos f^+ + 1) = \sin \beta^- \sin \gamma^- (\cos f^- + 1) \quad (\text{S2})$$

A similar relationship between θ^+ and θ^- can be derived as

$$\sin \gamma^+ \sin \gamma^- (\cos \theta^+ + 1) = \sin \beta^+ \sin \beta^- (\cos \theta^- + 1) \quad (\text{S3})$$

The relationship between f^+ and θ^+ , however, is more complex (Fig. SI-2). Define ϵ to be the angle between θ^+ and θ^- given by

$$\cos \epsilon = \cos \beta^+ \cos \theta^+ + \sin \beta^+ \sin \theta^+ \cos f^+. \quad (\text{S4})$$

and such that $\epsilon = \beta^+ + \gamma^+$ when the vertex is flat. Then

$$\begin{aligned} \theta^+ &= \cos^{-1} \left(\frac{\cos \beta^+ - \cos \epsilon \cos \gamma^+}{\sin \epsilon \sin \gamma^+} \right) \\ &\pm \cos^{-1} \left(\frac{\cos \beta^- - \cos \epsilon \cos \gamma^-}{\sin \epsilon \sin \gamma^-} \right). \end{aligned} \quad (\text{S5})$$

FIG. SI-2: The angle θ^+ versus f^+ for two cases: (solid) $\beta^+ = \beta^- = \pi/3$, $\gamma^+ = \gamma^- = 2\pi/3$ and (dashed) $\beta^+ = \pi/3 - \pi/10$, $\beta^- = \pi/3 + \pi/10$, $\gamma^+ = \gamma^- = 2\pi/3$. In each case, there are two distinct branches joined only at the flat state. Note that one of the branches for the solid curves lies along $f^+ = 0$.

Either sign in Eq. (S5) satisfies the geometric constraint equations; this ambiguity arises from the different branches of \cos^{-1} . Yet, the branches are physical, and correspond to different ways of choosing which folds are “mountain” and which folds are “valley” folds. In particular, there is a branch in which f^+ and f^- are both either mountain or valley folds and one in which they have the opposite sense [8]. In either case, however, $\cos f^\pm$ remains the same and the exponential solution for $u = 1 + \cos f$ in Eqs. 1 and 2 of the main text is valid.

One special case bears additional analysis. When the vertex has $\gamma^\pm + \beta^\pm = \pi$, the folds θ^+ and θ^- are collinear. In that case, one branch of the vertex has both f^+ and f^- as mountain (valley) folds. For the other branch, however, $f^+ = f^- = \pi$ is strictly satisfied and $\theta^+ = \theta^-$. That is simply the case that a vertex is folded along the line shared by θ^+ and θ^- , and this prevents the two adjacent folds f^\pm from folding at all. This motivates the choice of variables discussed in the main text, for which $\beta^\pm = \alpha \mp \beta$ and $\gamma^\pm = 2\pi - \alpha \mp \gamma$. Then $\beta = \gamma$ precisely when θ^\pm are collinear.

Appendix B: Second-order rigidity matrix for 1D strip

We label each unit cell with an index j and the two vertices within a unit cell with $n = 1, 2$. For convenience, we also express the dihedral angles in terms of their difference from π , $\delta f_n^\pm(j) = f_n^\pm(j) - \pi$ for the folds f^\pm of vertex n within unit cell j . Each vertex has one DOF, which we will parameterize with $\delta\theta_n^+(j)$. Since there is a two vertex unit cell, we combine these parameters into

two vectors,

$$\mathbf{f}(j) = \begin{pmatrix} f_1^-(j) \\ f_1^+(j) \\ f_2^-(j) \\ f_2^+(j) \end{pmatrix}, \quad (\text{S6})$$

and

$$\mathbf{s}(j) = \begin{pmatrix} \theta_1^+(j) \\ \theta_2^+(j) \end{pmatrix}. \quad (\text{S7})$$

Using spherical trigonometry, we compute $\mathbf{f}(j) = \mathbf{J}\mathbf{s}(j)$, where

$$\mathbf{J} = \begin{pmatrix} A_1^- + \sigma_1 B_1^- & 0 \\ A_1^+ + \sigma_1 B_1^+ & 0 \\ 0 & A_2^- + \sigma_2 B_2^- \\ 0 & A_2^+ + \sigma_2 B_2^+ \end{pmatrix}, \quad (\text{S8})$$

$\sigma_n = \pm 1$ is an arbitrary choice of branch in configuration space the vertex should be folded,

$$A_n^\pm = \frac{\sin(\alpha \mp \gamma_n)}{\sin(2\alpha)}, \quad (\text{S9})$$

and

$$B_n^\pm = \frac{1}{\sin(2\alpha)} \sqrt{\frac{\sin(\alpha - \gamma_n) \sin(\alpha + \gamma_n) \sin(\alpha \mp \beta_n)}{\sin(\alpha \pm \beta_n)}}. \quad (\text{S10})$$

For this paper, we have always assumed that $\sigma_n = 1$.

To complete our description, we must enforce the linear constraints $\delta f_1^-(j+1) - \delta f_2^+(j) = 0$ and $\delta f_2^-(j) - \delta f_1^+(j) = 0$. In Fourier space, these constraints lead to an equation of the form

$$\mathbf{R}(q)\mathbf{s}(q) = \mathbf{0}. \quad (\text{S11})$$

for the infinitesimal deformations of the origami strip, where

$$\mathbf{R}(q) = \begin{pmatrix} (A_1^- + B_1^-)e^{iq} & -(A_2^+ + B_2^+) \\ A_2^- + B_2^- & (A_1^+ + B_1^+) \end{pmatrix}. \quad (\text{S12})$$

Appendix C: Real-valuedness of the determinant: a hidden symmetry

We will restate the observed ‘‘reality’’ property here more formally. For all periodic triangulations we have checked, there exists a choice of unit cell so that the determinant of the rigidity matrix $\det \mathbf{R}(\vec{q})$ is real valued for all \vec{q} in the Brillouin zone. The consequence of this is that with such a choice of unit cell, the phase of $\det \mathbf{R}(\vec{q})$ cannot wind and so the topological polarization must vanish. There are also obvious consequences for the set of bulk zero modes which we will not discuss here. In Fig. SI-3 we display a sample calculation and visualization of this property for a small periodic triangulated origami, represented by a spring network.

This real-valuedness can be expressed in the following equivalent way. First, define $z_1 = e^{iq_1 a_1}$ and $z_2 = e^{iq_2 a_2}$,

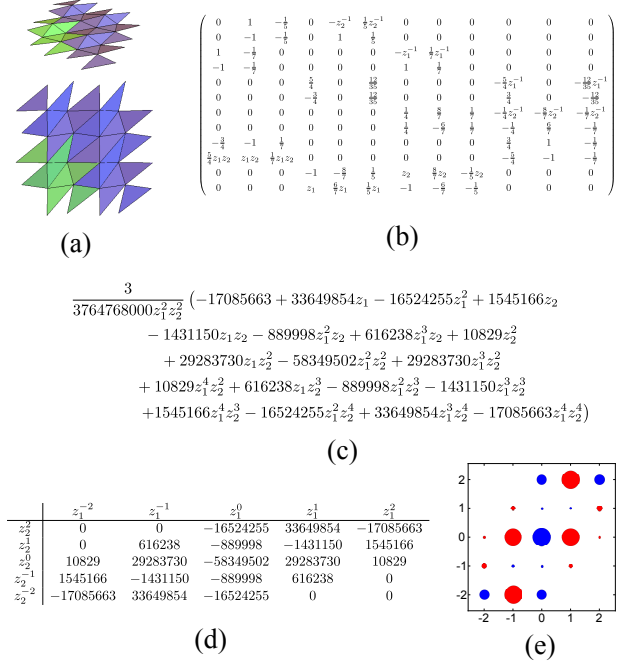

FIG. SI-3: Illustration of the reality property for triangulated origami. (a) A periodic triangulation based on the triangular lattice with four vertices, 12 edges and 8 triangles. The vertex coordinates are $(0, 0, 0)$, $(0, 1, 1/5)$, $(1, 1/7, 0)$, $(3/4, 1, -1/7)$ and the lattice primitive vectors are $(2, 0, 0)$ and $(0, 2, 0)$. Above is a side view and below is a top view. Four unit cells are shown, with one highlighted in green. (b) The Fourier transformed rigidity matrix $\mathbf{R}(z_1, z_2)$, where $z_1 = e^{iq_1 a_1}$ and $z_2 = e^{iq_2 a_2}$. Every row corresponds to an edge in the triangulation. (c) The Laurent polynomial $\det \mathbf{R}(z_1, z_2)$. (d) The table of coefficients of $\det \mathbf{R}(z_1, z_2)$, organized by powers of z_1 and z_2 . The number $3/3764768000$ has been factored out of all entries. (e) A graphical representation of the coefficients of $\det \mathbf{R}(z_1, z_2)$. Red dots are positive coefficients, blue dots are negative, and the area of the disks is proportional to the absolute value of the coefficients (with a minimum disk size imposed for visibility).

and observe that $\det \mathbf{R}(z_1, z_2)$ is a Laurent polynomial in those variables. Next, note that $\det \mathbf{R}(\vec{q})$ is real if and only if:

$$\begin{aligned} \det \mathbf{R}(\vec{q}) &= \overline{\det \mathbf{R}(\vec{q})} \\ \det \mathbf{R}(z_1, z_2) &= \overline{\det \mathbf{R}(z_1, z_2)} \\ &= \det \mathbf{R}(\bar{z}_1, \bar{z}_2) \\ &= \det \mathbf{R}(z_1^{-1}, \bar{z}_2^{-1}). \end{aligned}$$

In the third line, we use the fact that the coefficients of this polynomial are real, and in the final line, we use the fact that all \vec{q} in the Brillouin zone, z_1 and z_2 lie on the unit circle and so $\bar{z}_i = z_i^{-1}$. This shows that for all p, q , the coefficients of the $z_1^p z_2^q$ and $z_1^{-p} z_2^{-q}$ terms must be equal in order for this polynomial to be real-valued on the unit circle.

A change of unit cell merely changes $\det \mathbf{R}$ by a factor $z_1^m z_2^n$ where m and n are integers related to the change in the number of bonds crossing unit cell boundaries [17]. If one imagines the coefficients of $\det \mathbf{R}$ as a table (Fig. SI-3(d)), then such a factor does not change the values in the table, but merely shifts the positions of the entries in the table by a vector (m, n) . Therefore, the “reality property” is equivalent to the polynomial $\det \mathbf{R}(z_1, z_2)$ being “2D palindromic”, i.e.

$$\det \mathbf{R}(z_1^{-1}, z_2^{-1}) = z_1^k z_2^l \det \mathbf{R}(z_1^{-1}, z_2^{-1}), \quad (\text{S13})$$

for some integers k, l . Equivalently, the table of coefficients of $\det \mathbf{R}(z_1, z_2)$ is symmetric under inversion through some point $(k/2, l/2)$.

Examples and tests performed: We generated small triangulations of a torus via flipping edges from the triangular lattice and in all cases checked found that the the polynomial $\det \mathbf{R}(z_1, z_2)$ was a palindrome. To ensure that loss of precision from floating-point operations were not an issue, we did these computations in rational arithmetic in the Mathematica computer algebra system.

Specifically, we began with periodic triangulation “seeds” displayed in Fig. SI-4 and performed random edge flips (transforming two adjacent triangles into two different triangles on the same four vertices) repeatedly onto randomly chosen edges. This procedure is illustrated in Fig. SI-4(a).

For every such crease pattern generated, we used vertex coordinates made by randomly perturbing a flat embedding of the seed triangulation. These were rounded to the nearest rational number with denominator lower than 10. The Laurent polynomial $\det \mathbf{R}(z_1, z_2)$ was then calculated exactly and the coefficients of different terms were compared to check whether the polynomial was indeed palindromic as in Eq. (S13). In some cases, a flip would cause this polynomial to vanish (due e.g. to a degenerate edge connecting a vertex to itself). Afterwards, it is quite likely that further flips would produce triangulations with zero determinant. While the zero polynomial is of course real-valued, if this occurred, in order to get more interesting tests, we rejected this triangulation and flipped another edge instead. Regardless, for all triangulated origami checked we found that Eq. (S13) was always satisfied. In Table I we show a summary of the tests performed.

Partial result: We can show that subdividing a triangle in triangulated origami preserves the property that $\det \mathbf{R}(\vec{q})$ remains real. To see this, note that such a subdivision creates one new vertex and three edges. With an appropriate choice of unit cell we can ensure that this vertex is not on the boundary and thus does not pick up factors of $e^{iq_1 a_1}$ or $e^{iq_2 a_2}$.

The new vertex introduces three columns into $\mathbf{R}(\vec{q})$ whose only nonzero entries can be in the rows corresponding to the three new edges. By reordering the vertices and columns, one finds that the determinant takes a block upper-triangular form with a 3×3 block on the diagonal from the new additions (which we call $\mathbf{R}_n(\vec{q})$)

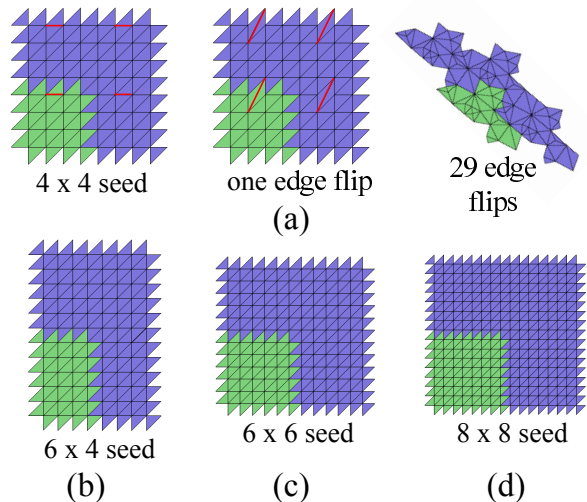

FIG. SI-4: Seed triangulations and edge flips. In each image, four unit cells are shown, with one highlighted in green. The triangulations are only shown with planar embeddings for clarity, the actual tested triangulations were deformed into 3D with random perturbations. (a) left: The 4 by 4 seed triangulation with one highlighted edge, center: the triangulation resulting from the edge flip of the red edge, right: a triangulation resulting from 29 random edge flips on the seed. (b) The 6 by 4 seed triangulation. (c) The 6 by 6 seed triangulation. (d) The 8 by 8 seed triangulation.

seed	$ V $	$ E $	$ T $	(runs, flips)
4 by 4	16	48	32	(100, 1000)
6 by 4	24	72	48	(50, 500)
6 by 6	36	108	72	(20, 200)
8 by 8	64	192	128	(10, 100)

TABLE I: Summary of tests performed of the “reality” property on different families of periodic triangulated origami. Each line of the table corresponds to a different seed (depicted in Fig. SI-4), and displays the number of vertices $|V|$, edges $|E|$ and triangles $|T|$ in the seed and shows the number of runs started as well as the number of random flip operations performed. Note that a flip preserves $|V|$, $|E|$ and $|T|$, and that the computations require computing determinants of symbolic $|E| \times 3|V|$ matrices. In all runs, every single triangulation generated had the reality property, as described in the text.

as well as $\mathbf{R}_0(\vec{q})$ as another block on the diagonal. By a well-known property of the determinant, this implies that $\det \mathbf{R}(\vec{q}) = \det \mathbf{R}_n(\vec{q}) \det \mathbf{R}_0(\vec{q})$.

If we were able to prove an analogous result for edge flips, then we would have shown that the palindromic property holds for all triangulations.

Appendix D: On the design of topological kirigami

We found topologically polarized kirigami via the following steps. We first constructed the pattern of plates and hinges as follows. As in Appendix C, we began with

FIG. SI-5: Schematics of some structures created while designing the kirigami. In each image, four unit cells are shown, with one highlighted in green. These images only show the pattern of hinges and plates, and do not represent 3D embeddings. (a) A triangulated origami based on the triangular lattice. Two families of creases are highlighted in red and blue which are moved to create the next structure. (b) The checkerboard lattice of tetrahedra. This structure consists of tetrahedra joined by universal joints at their vertices. (c) The final kirigami structure. Created by placing rows and columns of additional triangles between tetrahedra, and then replacing the tetrahedra with flat quadrilateral plates.

a periodic spring network with the combinatorics of the standard triangular lattice (drawn in Fig. SI-5(a) as a square lattice with all NE diagonals added). This pattern models a triangulated origami structure, which seems to have a real determinant. To try to break this symmetry we attempted to add holes in the unit cell.

To add holes without changing the marginal rigidity property, we removed one NE diagonal bond from a square A and placed it in an adjacent (already occupied) square B as a NW diagonal bond. This yields a hole in A and a new tetrahedron in B . If one does this for all squares in a checkerboard pattern, one ends up with the so-called checkerboard lattice of tetrahedra (Fig. SI-5(b)). This is the simplest 2D periodic structure in 3D which admits geometric realizations with distinct topological polarizations. However, the tetrahedra are joined at vertices, not along hinges, so it is neither origami nor kirigami.

To remedy this, we may add rows and columns of triangulated strips between the holes and the tetrahedra. Now we do have a structure made of solid bodies joined along

FIG. SI-6: Three kirigami unit cells with different topological polarizations. A top view and side view of the 3D unit cells are shown above exploded versions that have been cut into strips and then flattened into the plane. The dashed lines indicate how the strips are to be joined to create the 3D structure shown above and the faces labeled by letters indicate the periodicity of the structure.

hinges, but the bodies are tetrahedra and not yet flat plates. Flat plates can be modeled by a spring network with pyramids. By adding an additional vertex above the plate and attaching it to the four vertices of the we create a minimally rigid body which is attached to the structure by four coplanar hinges. The final pattern of hinges and plates is shown in Fig. SI-5(c) (pyramids not shown for clarity).

Given this design, we still have to find a suitable realization of this structure as a 3D object. We did this by beginning with a flat embedding of a unit cell and perturbing the vertices randomly, subject to the condition that the quadrilateral plates remain planar. These randomly generated unit cells were then checked to determine if they had a topological polarization. Fig. SI-6 shows the unit cells of three kirigami structures with this crease pattern but with differing topological polarizations: kirigami I has polarization $(1,0)$, and kirigami II and III have polarization $(0,0)$. Their 3D structures are also displayed in an “exploded” view, where they have been cut apart into flattened strips which must be bent in space and then glued together to form the kirigami structures. Unit cells I and II were used to construct the domain wall in Fig. 3 in the main text.

In Fig. SI-7 we show kirigami structures consisting of pairs of unit cells from Fig. SI-6. The domain walls do

not contain any extra or missing bonds, so there are no differences in the local counting of degrees of freedom. These kirigami structures are rectangular sheets with periodic boundary conditions in both directions, so one might expect the lowest energy vibrational modes to be bulk bending modes. This is indeed the case when the two unit cells used have the same polarization vector (Fig. SI-7(a)). However, when a structure is made

of unit cells with two distinct polarizations, one of the domain walls carries localized very low-energy modes (Fig. SI-7(b) and Fig. 3 in the main text). The eigenvalue corresponding to the energy of the topological mode is $\omega^2 = 1.42 \times 10^{-16}$ (comparable to the eigenvalues corresponding to the translational zero modes), whereas the eigenvalue corresponding to the bending mode is much larger, $\omega^2 = 1.82 \times 10^{-9}$.

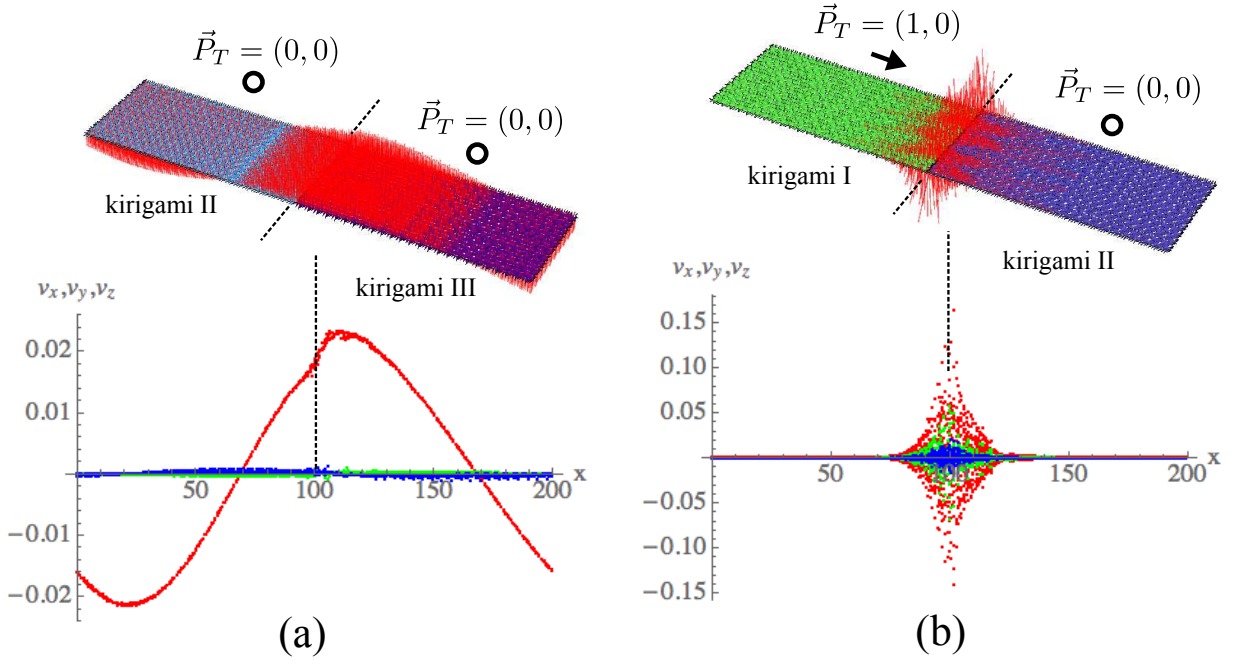

FIG. SI-7: Composite kirigami systems constructed from unit cells I, II and III from Fig. SI-6 and their lowest energy eigenmodes. Both structures depicted consist of 50 unit cells (along the x -direction) by 5 unit cells (along the y -direction), which are divided into two domains each of size 25 by 5. Two copies in the shorter direction are shown in the upper figures, and the displacements in the mode are overlaid as red lines. The structures are periodic in both directions, so there are domain walls at $x = 0 = 200$ and $x = 100$. The domain wall at $x = 100$ is marked with dashed lines. The lower plots show the x -, y - and z -components (in blue, green, and red, respectively) of the displacement vectors of all vertices as a function of the x -positions. (a) Composite structure of kirigami II and III, both of which have polarization $(0,0)$. The lowest eigenmode has eigenvalue $\omega^2 = 1.82 \times 10^{-9}$ and resembles a bulk bending mode. (b) Composite structure of kirigami I (polarization $(1,0)$) and II (polarization $(0,0)$). The lowest eigenmode has eigenvalue $\omega^2 = 1.42 \times 10^{-16}$ and is highly localized near the domain wall at $x = 100$.
