# The Divergence Index: A Decomposable Measure of Segregation and Inequality

Elizabeth Roberto<sup>\*†</sup>

February 20, 2024

#### Abstract

Decomposition analysis is a critical tool for understanding the social and spatial dimensions of segregation and diversity. In this paper, I highlight the conceptual, mathematical, and empirical distinctions between segregation and diversity and introduce the Divergence Index as a decomposable measure of segregation. Scholars have turned to the Information Theory Index as the best alternative to the Dissimilarity Index in decomposition studies, however it measures diversity rather than segregation. I demonstrate the importance of preserving this conceptual distinction with a decomposition analysis of segregation and diversity in U.S. metropolitan areas from 1990 to 2010, which shows that the Information Theory Index has tended to decrease, particularly within cities, while the Divergence Index has tended to increase, particularly within suburbs. Rather than being a substitute for measures of diversity, the Divergence Index complements existing measures by enabling the analysis and decomposition of segregation alongside diversity.

#### Introduction

Decomposable measures of segregation and diversity are essential tools for understanding the multi-level dynamics of social and spatial phenomena. For example, recent studies have shown that the U.S. population is becoming more racially and ethnically diverse as a whole, but also that the speed and extent of this change varies greatly across different geographic scales (Frey 2015; Hall, Tach, and Lee 2016; Lichter, Parisi, and Taquino 2015), as rising residential segregation among municipalities offsets increasing opportunities for inter-racial and -ethnic contact at the neighborhood level (Lichter et al. 2015). These dynamics have important implications not only for the social integration of everyday life but also for the spatial construction of social divisions that continue to segregate housing and job opportunities, school districts, gerrymandered voting jurisdictions, and other socially consequential spaces.

Because of the importance and multiscalar complexity of these spatial dynamics, it is important to develop and utilize new decomposable measures that extend beyond more conventional measures to allow decomposition both within and between different groups and categorical (often spatial) units. In the present study, I introduce and demonstrate such a measure, which I call the Divergence Index.

The Dissimilarity Index (Duncan and Duncan 1955; Jahn, Schmid, and Schrag 1947; Taeuber and Taeuber 1965) is the most widely used measure of residential segregation, but it is not additively decomposable into the segregation occurring within and between groups or places (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004; Theil 1972). Due to this limitation, scholars have turned to the Information Theory Index (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004; Theil and Finizza 1971; White 1986) to conduct decomposition analyses of segregation (Bischoff 2008; Farrell 2008; Fiel 2013; Fischer, Stockmaver, Stiles, and Hout 2004; Fischer 2008; Fowler, Lee, and Matthews 2016; Lichter et al. 2015; Owens 2019; Owens and Rich 2023; Parisi, Lichter, and Taquino 2011). However, the indexes represent different concepts: the Information Theory Index compares the diversity of local areas to the overall diversity of a region (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004; White 1986), and the Dissimilarity Index measures the difference between the local and overall proportions of each group. Although studies have acknowledged this difference, they commonly interpret values of the Information Theory Index as carrying the same meaning as the Dissimilarity Index. Given its characteristics, the Information Theory Index should be interpreted as a measure of diversity and it should be used alongside measures of segregation rather than as a substitute.

The Divergence Index is a decomposable measure of segregation and inequality. As an index of racial residential segregation, it measures how surprising the racial composition of local areas is given the overall racial composition of the region. In this way, it is similar to more conventional indexes, like the Dissimilarity Index, that measure the "evenness" dimension of segregation (Massey and Denton 1988). However, the Divergence Index also differs from and thus complements such indexes by being additively decomposable. This property is useful because it allows us to compare the segregation occurring within and between groups or spatial units, such as nested levels of geography. Additionally, the Divergence Index can be calculated for both discrete and continuous distributions as well as for joint distributions, such as income by race.

Below I introduce the Divergence Index in more detail. I begin by comparing the concepts of segregation, inequality, and diversity, and noting the key distinctions between them. I then illustrate what can be learned through decomposition analyses of segregation with an empirical example. Next, I provide a brief review of entropy measures of diversity. I then introduce the Divergence Index and

describe its unique features. In the next section, I compare the mechanics of the Divergence Index and Information Theory Index using stylized and empirical examples.

Finally, I demonstrate the importance of the preserving the conceptual distinction between segregation and diversity with a decomposition analysis of the 100 largest metropolitan areas in the United States from 1990 to 2010. The analysis shows that the Information Theory Index has tended to decrease overtime, particularly within cities, while the Divergence Index has tended to increase, particularly within suburbs. I explain how these differences can arise due to the the mechanics of the indexes as well as different underlying population processes. The Information Theory Index reveals the tendency for blocks to increase in diversity at roughly the same pace as the region, but the Divergence Index reveals the tendency for diversity promoting moves to reproduce or intensify segregation. Despite a general tendency for segregation and diversity to have a positive association — the direction and strength of the relationship varies across metros. In some metros increases in diversity may reflect the transience of racial turnover that eventually reproduces segregation, while in others it may be associated with the gradual formation of stably integrated communities.

Analyzing segregation alongside diversity can enable richer, deeper understandings of the rapidly but unevenly changing demographics of societies such as the United States. The Divergence Index complements existing measures by providing a distinct lens for understanding the dimensions and dynamics of segregation.

#### Inequality, Segregation, and Diversity

Social inequality and segregation are tightly coupled concepts. Inequality refers to the uneven distribution of resources, opportunities, or outcomes across a population (e.g., among individuals or groups). Segregation refers to the uneven distribution of the population across separate or distinct places, occupations, or institutions. Hence inequality and segregation both involve the uneven distribution of some quantity across units.

All measures of inequality and segregation have an implied or explicit comparative reference that defines equality or evenness (Coulter 1989), such as the uniform distribution of income across individuals or the random distribution of individuals across neighborhoods. Measures evaluate the degree of inequality or segregation for a given distribution by measuring it against the comparative reference. For example, when a small portion of the population holds a large share of income, the income distribution is unequal. When the racial composition of neighborhoods differs widely across a city, racial segregation is high. Segregation and inequality are relative and relational concepts linked to social processes and mechanisms that scholars often seek to understand.

The concept of diversity is another way to describe the composition of a population, but it is not a relational concept. Diversity describes the variety of "types" or groups in the population (Blau 1977; Page 2007, 2011). Diversity indexes measure the number of groups and in what proportion they are represented. Like segregation and inequality, diversity represents the outcome of social processes. Diversity has important relevance for sociological theories, such as Blau's (1977) theory of the structure of social association, but it is less relevant than segregation and inequality to examinations of hierarchical relations.

Unlike the relational concepts of segregation and inequality, diversity is its indifferent to the specific groups that are over- or under-represented in a population. For example, a neighborhood that is 75 percent White and 25 percent Black has the same amount diversity as a neighborhood that is 25 percent White and 75 percent Black. Diversity measures are only concerned with the variety or relative quantity of groups, whereas inequality and segregation measures are concerned

with which groups (or which parts of a distribution) are over- and under-represented. The two neighborhoods could have different segregation values, and the level of segregation for each would depend upon the city's composition.

Hierarchical relations are embedded within the concepts of segregation and inequality. Groups may differ in their relative symbolic, economic, or political advantage and measures of segregation and inequality can preserve the distinction between groups. For example, measures of segregation can distinguish between a neighborhood that is 75 percent White and one that is 75 percent Black in a city that is 75 percent White and 25 percent Black, and their group compositions imply different levels of segregation within the city context.

In contrast, diversity indexes "flatten fundamentally hierarchical relations between groups. ... As an analytic concept, 'diversity' (i.e. 'heterogeneity') not only sidesteps issues of material and symbolic inequalities, it masks the distinction between in-group and out-group contact" (Abascal and Baldassarri 2015: p. 755). This becomes problematic when a diversity index is interpreted as a measure of segregation. Despite having the same amount of diversity, there may be different social processes unfolding in neighborhoods with different racial compositions and different levels of segregation. Segregation and diversity are distinct concepts that allow us to answer different questions about social processes and their outcomes (see also Abascal, Xu, and Baldassarri 2021).

#### **Decomposition Analysis of Segregation**

Scholars who use diversity as a measure of segregation are drawn to it, I posit, in part because it permits decomposition analysis. In this section, I provide an example of what can be learned through a decomposition analysis that more traditional analyses do not provide, and why decomposition is important for understanding segregation patterns and processes. Decomposition, I seek to illustrate, is an essential tool for understanding the multi-level dynamics of social and spatial phenomena.

From 2000 to 2006, Westchester County received \$50 million in federal housing funds, which required that the county affirmatively further fair housing (Anti-Discrimination Center 2023). In 2009, a federal judge ruled that the county "had misrepresented its efforts to desegregate overwhelmingly white communities when it applied for the federal housing funds" (Santos 2009). Almost two-thirds of the county's Black and Latinx residents lived in the county's four cities. Among the county's 39 villages and towns, only 8 had substantial Black or Hispanic populations, while the other 31 remained White and segregated.

Westchester County settled the case and entered into a consent decree (i.e. a binding federal court order), which prohibited it from "ignoring either the residential racial segregation that continues to plague it, or the municipal resistance to affordable housing development that stymies the possibility of changing those patterns" (Anti-Discrimination Center 2023). The federal monitor who later evaluated the county's compliance with the consent decree pointed to low segregation within the 31 villages and towns as evidence of compliance. However, the levels of segregation within these municipalities obscures the county-wide context – it ignores the segregation between municipalities and in the county at large. A decomposition analysis of segregation, measured with the Divergence Index, allows us to examine the segregation occurring both within and between municipalities and how each contributes to the county's overall segregation.

The additive decomposability property of the Divergence Index means that the sum of segregation within areas and between areas is equal to the overall segregation of the region. This allows us to answer questions about the spatial organization of segregation by comparing the levels of segregation within and between the areas. A drawback of using an index that is not additively decomposable, such as the Dissimilarity Index, for such a comparison is that it is possible to observe changes within or between areas that leave the overall index unchanged.

Using the Divergence Index, the total segregation among the census blocks<sup>1</sup> in Westchester County is equal to the sum of two quantities: the segregation between areas in the county and the average within-area segregation. Between-area segregation represents how surprising the racial composition of each area is given the county's overall racial composition, and the within-area segregation represents how surprising the racial composition of blocks within each area is given the area's overall racial composition. I analyze segregation for municipalities categorized into three groups (i.e., "areas") defined by the consent decree: the 4 cities, the 8 municipalities excluded from the consent decree (i.e., "excluded areas"), and the 31 municipalities included in the decree (i.e., "included areas") (Beveridge 2016).

The decomposition results indicate that about a third of the segregation in the county occurs between the cities, the excluded areas, and included areas. The remaining two-thirds of the county's segregation occurs among the blocks within each area, primarily within the cities and excluded areas. This indicates that the blocks within the cities and excluded areas are not very representative of each area's overall racial composition. In contrast, as the monitor's report indicated, the included areas have relatively low levels of within-area segregation — the meager Black and Latinx populations are distributed more evenly across blocks. However, the included areas are responsible for most of the segregation occurring between the areas in the county — they have a much higher proportion of White residents, compared to the other areas or the county overall.

The segregation in Westchester County is occurring at two different levels of spatial organization: among the areas within the county (primarily in the included area), and among the blocks within each area (primarily in the cities and excluded areas). Decisions about the placement of affordable housing have important implications for reducing segregation within the county, especially since Black and Latinx residents occupy the majority of the county's subsidized and public housing units (Santos 2009). Increasing the number of affordable housing units in the cities and excluded areas could *increase* between-area segregation by further concentrating Black and Latinx residents in these areas. Placing affordable housing in the included municipalities could *decrease* between-area segregation by creating affordable housing options across the county and affirmatively furthering fair housing.

In the next section of the paper, I describe how entropy has been used to measure diversity. I then introduce the Divergence Index as a decomposable measure of segregation. Although the Divergence Index is also an entropy-based measure, its formulation makes it well-suited to measuring segregation and allows us to answer different types of questions than a traditional entropy index or the Information Theory Index.

#### Entropy and the Measurement of Diversity

#### Entropy

Entropy is a commonly used measure in physics and information theory to represent the randomness of a system or the information content of a message (Coulter 1989; Cover and Thomas 2006; Shannon 1948; Theil 1967). Theil and Finizza (1971) introduced the concept of entropy to the social sciences as a measure of population diversity (see also Reardon and Firebaugh 2002; White 1986). Entropy-based measures are decomposable and have long been a staple of decomposition studies.

Entropy is the amount of information needed to describe a probability distribution. If two

outcomes are equally likely (e.g., a coin toss), there is high uncertainly about what the outcome will be and high entropy. If one outcome has a higher probability, there is less uncertainty about what the outcome will be and lower entropy.<sup>2</sup> Entropy measures the probability of an outcome (m) occurring, weighted by its probability of occurrence  $(\pi_m)$ . The entropy of each outcome (m) is  $E_m = \log \frac{1}{\pi_m}$ . Weighting each outcome by the probability of its occurrence, the overall entropy is:

$$E = \sum_{m=1}^{M} \pi_m \log \frac{1}{\pi_m}.$$

The entropy equations can be defined using logarithms to any base. The base of the logarithm defines the units of the index (Shannon 1948; Theil 1972). Log base 2 (log<sub>2</sub>) is typically used in information theory, which gives results in units of binary bits of information. It is common for inequality measures to use the natural logarithm (ln), which has the mathematical constant (e) as its base. Following standard usage, we can define  $0 \log 0 = 0$ , because  $\lim_{x\to 0} (x \log x) = 0$ .

Interpreted as a measure of diversity, m indexes the groups (e.g., race or income group) in a population and the "probability of an outcome" is the proportion of each group. If all individuals in a population are associated with the same group, there is no diversity in the population. There is no uncertainty about a randomly selected individual's group membership, and entropy is equal to 0. On the other hand, if individuals are evenly distributed among two or more mutually exclusive groups, there is maximum diversity in the population, and entropy is equal to 1.

The properties of entropy have been well documented (e.g., Cover and Thomas 2006; Shannon 1948; Theil 1967), and are summarized in Table B5. It can be calculated for any number of groups, and it has known upper and lower bounds with substantive interpretations. Importantly, entropy and entropy-based measures are additively decomposable (see Appendix C for equations). The additivity of entropy comes from one of the properties of logarithms:  $log(\pi_1 \cdot \pi_2) = log(\pi_1) + log(\pi_2)$ .

#### The Information Theory Index

The Information Theory Index is an entropy-based measure developed by Theil and Finizza (1971) to study racial segregation in Chicago public schools. The index has also been proposed as a measure of residential segregation (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004; White 1986). For a single area (i), the Information Theory Index measures the extent to which the area's entropy  $(E_i)$  is reduced below the region's entropy (E), standardized by dividing by the region's entropy (Theil and Finizza 1971):

$$H_i = \frac{E - E_i}{E}.$$

Or, equivalently, it is one minus the ratio of local diversity to overall diversity (Reardon and Firebaugh 2002):

$$H_i = 1 - \frac{E_i}{E}$$

The region's index value is the weighted average of  $H_i$  across all local areas:

$$H = 1 - \sum_{i=1}^{N} \frac{\tau_i E_i}{TE} = 1 - \frac{\bar{E}_i}{E}$$
 or  $H = \sum_{i=1}^{N} \frac{\tau_i}{T} H_i$ ,

where T is the overall population count, and  $\tau_i$  is the population count for area *i*. H represents the relative reduction in the average entropy of components  $(\bar{E}_i)$  below the maximum attainable entropy (E) (Theil and Finizza 1971). Or, equivalently, it is one minus the ratio of average local diversity to overall diversity (Reardon and Firebaugh 2002).

The Information Theory Index is additively decomposable, meaning that we can aggregate residential locations into districts and calculate the index values within and between the districts in a region (Reardon and Firebaugh 2002). The sum of the within-district  $(H_j)$  and between-district  $(H_0)$  components is equal to overall index for the region:

$$H = H_0 + \sum_{j=1}^{J} \frac{T_j E_j}{TE} H_j$$
 (1)

where T is the overall population count and  $T_j$  is the population count for district j. The sum of the within-district values is weighted by the relative population of the district  $\left(\frac{T_j}{T}\right)$  and the relative diversity of the district  $\left(\frac{E_j}{E}\right)$ . Districts that are more populous and more diverse contribute more to the overall index than less populous and less diverse districts.

The Information Theory Index typically ranges between 0 and 1. A value of 1 indicates that there is no diversity in local areas. A value of 0 indicates that all local areas are as diverse as the region. The minimum value can be less than 0, and Reardon and O'Sullivan (2004) interpret negative values of the index as indicating "hyper-integration," which occurs when localities are more diverse, on average, than the region as a whole. In other words, groups are more equally represented in local areas than in the overall population. Additional properties of the Information Theory Index are summarized in Table B5.

In recent years, scholars have turned to the Information Theory Index as the best alternative to the Dissimilarity Index in decomposition analyses of segregation (Bischoff 2008; Farrell 2008; Fiel 2013; Fischer et al. 2004; Fischer 2008; Fowler et al. 2016; Lichter et al. 2015; Owens 2019; Owens and Rich 2023; Parisi et al. 2011). However, the indexes represent different concepts: the Information Theory Index compares the diversity of local areas to the overall diversity of a region (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004; White 1986), whereas the Dissimilarity Index measures the difference between the local and overall proportions of each group. Although studies have acknowledged this difference, they commonly interpret the Information Theory Index as carrying the same meaning as the Dissimilarity Index. Given its characteristics, the Information Theory Index should be interpreted as a measure of diversity and it should be used alongside measures of segregation rather than as a substitute.

#### The Divergence Index

The Divergence Index addresses the need for a decomposable measure of segregation. Decomposition is useful because it allows us to compare the segregation occurring within and between groups or spatial units, such as nested levels of geography. The additive decomposability property of the index means that the sum of segregation within and between areas is equal to the overall segregation of the region. This allows us to answer questions about the spatial organization of segregation by comparing the within and between components of the decomposition. In contrast, when using indexes that are not additively decomposable, such as the Dissimilarity Index, it is possible to observe changes within or between areas while the overall index is unchanged. Decomposition is an essential tool for understanding the multi-level dynamics of segregation, as illustrated earlier in the case of Westchester County.

The Divergence Index is based on relative entropy, an information theoretic measure of the difference between two probability distributions (Cover and Thomas 2006), also known as Kullback–Leibler (KL) divergence (Kullback 1987). Relative entropy, shares many properties with entropy, including being decomposable, but instead of characterizing a single distribution, it compares one distribution to another. The index can be used to measure inequality as well as segregation.

The Divergence Index measures the difference between a distribution, P, and another empirical, theoretical, or normative distribution, Q.<sup>3</sup> The index represents the divergence of a model (Q) from reality (P). It can be interpreted as a measure of surprise: How surprising are the observations (P), given the expected value (Q)? Or, how surprising is an empirical distribution (P), given a theoretical distribution (Q)?

For discrete probability distributions P and Q, the divergence of Q from P is defined as:

$$D\left(P \parallel Q\right) = \sum_{m=1}^{M} P_m \log \frac{P_m}{Q_m},$$

where *m* represents groups or categories.<sup>4</sup> (Following standard usage, we can define  $0 \log 0 = 0$ , because  $\lim_{x\to 0} (x \log x) = 0$ .) The *Q* distribution defines the standard against which segregation or inequality is measured. It should represent the expected state of equality or evenness in the *P* distribution. *Q* can be theoretically determined or empirically derived. For example, it can be a standard probability distribution (e.g., a normal or uniform distribution), a prior state of the *P* distribution, or the mean of the observed data (*P*).

The Divergence Index has known upper and lower bounds with substantive interpretations. The minimum value is 0, indicating no difference between P and Q. The maximum value can be less than or greater than 1. The index can be standardized to have a range of 0 to 1 by dividing by its maximum value for a given population. However, standardizing the index transforms it from an absolute to a relative measure of inequality and segregation, and negates several of its desirable properties, including aggregation equivalence and independence. (See B5.)

The Divergence Index is a non-symmetric measure of the difference between two distributions (Bavaud 2009).<sup>5</sup> The divergence of Q from P does not necessarily equal the divergence of P from Q. The asymmetry is an intentional feature of the measure. As Bavaud (2009) states, "the asymmetry of the relative entropy does not constitute a defect, but perfectly matches the asymmetry between data and models" (p. 57).

In the context of segregation measurement, this property means that the divergence of each local area's composition from a region's composition — the divergence P from Q — is not necessarily the equal to the divergence of the region's composition from the composition of local areas — the divergence of Q from P. In the first case, the region's composition is the reference distribution that the local compositions are compared to in evaluating segregation. The region's composition represents the expected state of the local compositions if there is no segregation in the region. In the second case, each local area's composition is a reference distribution that the region's composition is inconsistent with practice of measuring segregation by evaluating how an aggregate population is distributed across units. It is possible to calculate a symmetric version of the index as the sum of  $D(P \parallel Q)$  and  $D(Q \parallel P)$ , but such an index would likewise not represent the common conceptualization of segregation as the uneven distribution of the population across separate or distinct places, occupations, or institutions — the concept of

segregation that motivates this paper.

One of the unique features of the Divergence Index is that it can be calculated for either discrete distributions (relative entropy) or continuous distributions (differential relative entropy) (Cover and Thomas 2006).

For continuous probability distributions P and Q, the divergence of Q from P is defined as:

$$D(P \parallel Q) = \int p(x) \log \frac{p(x)}{q(x)} dx,$$

where p and q represent the probability densities of P and Q. The desirable properties of both relative entropy and differential relative entropy have been well documented (e.g., Bavaud 2009; Cover and Thomas 2006). (Table B5 summarizes the properties of the Divergence Index.)

#### Measuring Residential Segregation with the Divergence Index

As a measure of residential segregation, the Divergence Index can be calculated for discrete distributions, such as the proportion of each race group, or continuous distributions, such as the distribution of income. In this section, I focus on using the Divergence Index to measure residential segregation for discrete groups.

To study residential segregation, the Divergence Index measures the difference between the overall proportion of each group in the region (e.g., a city or metropolitan area) and the proportion of each group in local areas within the region (e.g., census tracts). The overall proportion of each group in the region is the reference distribution (Q), which represents the expected local proportion of each group if there is no segregation. The index asks: how surprising is the composition of local areas given the overall population of the region? If there is no segregation in the region. More divergence between the overall and local proportions indicates more segregation.

Like the Dissimilarity Index, the Divergence Index measures how evenly the population of each group is distributed across locations in the region. However, the Dissimilarity Index uses a linear function to evaluate segregation and the Divergence Index uses a logarithmic function. This means that, with the Dissimilarity Index, any departure from evenness is treated equally, whereas the Divergence Index evaluates small departures from evenness as contributing proportionally less to segregation than larger departures from evenness.<sup>6</sup> For example, in a city with two equally sized groups, the local Divergence Index values for neighborhoods with a 5 percent difference in their group compositions will be more similar if their compositions are closer to the city's 50-50 composition (e.g., 45-55 and 40-60) than if their compositions are very different from the city's composition (e.g., 5-95 and 0-100). In other words, the further from evenness the local composition is, the more surprising each unit of departure becomes. With the Dissimilarity Index, however, any departure from evenness contributes equally to the segregation value.<sup>7</sup>

The Divergence Index for location i is:

$$D_i = \sum_{m=1}^M \pi_{im} \log \frac{\pi_{im}}{\pi_m},$$

J

where  $\pi_{im}$  is group *m*'s proportion of the population in location *i*, and  $\pi_m$  is group *m*'s proportion of the overall population. If a location has the same composition as the overall population, then  $D_i = 0$ , indicating no segregation. To measure segregation spatially, a proximity-weighted contribution from nearby areas is included in each location's population. This creates overlapping local environments or *ego-centric neighborhoods* (Lee, Reardon, Firebaugh, Farrell, Matthews, and O'Sullivan 2008; Reardon, Farrell, Matthews, O'Sullivan, Bischoff, and Firebaugh 2009; Reardon, Matthews, O'Sullivan, Lee, Firebaugh, Farrell, and Bischoff 2008; Roberto 2018). In the equation for the Divergence Index, we would replace  $\pi_{im}$  with  $\tilde{\pi}_{rim}$ , which is group *m*'s proportion of the spatially weighted population within a given distance *r* of location *i* (for examples, see Roberto 2018):

$$\tilde{D}_{ri} = \sum_{m=1}^{M} \tilde{\pi}_{rim} \log \frac{\tilde{\pi}_{rim}}{\pi_m}.$$
(2)

A proximity function, such as a uniform or distance-decay function, weights the relative contribution of distant vs. nearby locations to the spatially weighted population of each location. The proximity weighted population composition for location *i* is calculated by dividing the proximity weighted population count of each group in *i*'s local environment,  $\tilde{\tau}_{rim}$ , by the total proximity weighted population count in the local environment,  $\tilde{\tau}_{ri}$ :

$$\tilde{\pi}_{rim} = \frac{\tilde{\tau}_{rim}}{\tilde{\tau}_{ri}}.$$
(3)

The value of  $\tilde{\pi}_{rim}$  represents the population composition experienced by the residents of location *i* in their local environment with a reach of *r*, where the populations of other locations are weighted according to the proximity function (Roberto 2018).

Overall segregation in the region is the population-weighted average of the divergence for all locations:

$$D = \sum_{i=1}^{N} \frac{\tau_i}{T} D_i,$$

where T is the overall population count, and  $\tau_i$  is the population count for location *i*. If all locations have the same composition as the overall population, then D = 0, indicating no segregation in the region.

The Divergence Index is additively decomposable, meaning that we can aggregate residential locations into districts and calculate the segregation occurring within and between the districts in a region. The sum of the within and between components of segregation is equal to overall segregation for the region. For example, to measure residential segregation for districts within a city, we rewrite the Divergence Index as the sum of between-district segregation and the average within-district segregation. The average within-district segregation for district j is:

$$D_j = \sum_{i \in S_j} \frac{\tau_i}{T_j} \sum_{m=1}^M \pi_{im} \log \frac{\pi_{im}}{\pi_{jm}},$$

where  $S_j$  is the set of locations in district j. The reference distribution,  $\pi_{jm}$ , is the population composition of district j, which is calculated as the population-weighted average of the group proportions for all localities (*i*) within the district:  $\pi_{jm} = \sum_{i \in S_j} \frac{\tau_i}{T_j} \pi_{im}$ , where  $T_j$  is the population count for district j. The between-district segregation is:

$$D_{0} = \sum_{j=1}^{J} \frac{T_{j}}{T} \sum_{m=1}^{M} \pi_{jm} \log \frac{\pi_{jm}}{\pi_{m}}$$

Total segregation is the sum of the between-district segregation  $(D_0)$  and the average within-district segregation  $(D_j)$ :

$$D = D_0 + \sum_{j=1}^{J} \frac{T_j}{T} D_j.$$
 (4)

The within component of segregation is a population-weighted sum of the within-district segregation for all districts. In contrast, the decomposition of the Information Theory Index, H, applies two weights in calculating the within component: it is a population *and* relative diversity weighted sum of the within-district index values for all districts (see Equation 1).

#### Related Indexes

Several other measures of inequality and segregation have been derived from relative entropy. Theil's index of income inequality is a special case of relative entropy, which measures the difference between the observed distribution of income and the mean (Theil 1967). The theoretical state of equality is one in which everyone's income is equal to the mean. Theil's index belongs to the generalized entropy class of measures, which also includes mean log deviation, half the coefficient of variation, and the Atkinson Index (Breen and Salazar 2011; Cowell 1980a,b; Cowell and Kuga 1981; Shorrocks 1980, 1984).<sup>8</sup> The Divergence Index can likewise be used to compare a distribution to a single value (see Appendix D), but also provides the flexibility to holistically compare two distributions.

The use of relative entropy was incorporated into the "relative distribution" method for measuring inequality (Handcock and Morris 1999). The relative distribution method compares distributions rather than summarizing their individual shapes, as with the Theil Index. The method also includes the median relative polarization index, which summarizes changes in the relative distribution. Relative distribution measures are used to analyze specific distributional shifts in income and have been reviewed in detail elsewhere (Handcock and Morris 1998, 1999; Hao and Naiman 2010; Liao 2002).

Additional applications of relative entropy in sociology have included a summary measure of racial disparity that compares the distribution of income for White and Black households (Bloome 2014) and a measure of educational disparities in adult mortality (Sasson 2016). In economics, divergence is used to study industrial localization and agglomeration (e.g., Mori, Nishikimi, and Smith 2005). More generally, divergence underlies popular statistical methods of model selection, including the Akaike Information Criterion (AIC) (Akaike 1974).

A related information theoretic measure called mutual information is a special case of relative entropy (Cover and Thomas 2006). Whereas relative entropy measures the difference between two probability distributions, mutual information measures the amount of information shared between two random variables. It quantifies the reduction in uncertainty about one random variable, given knowledge about another random variable.

In the social sciences, a mutual information index has been proposed as a measure of school segregation (Frankel and Volij 2011; Mora and Ruiz-Castillo 2009, 2011), residential segregation (Elbers 2023; Kramer and Kramer 2018), and occupational segregation (Alonso-Villar and del Río

2010). In these cases, the random variables represent groups (e.g., racial or income groups) and locations (e.g., schools or census tracts). For example, the index can measure how much we know about a person's race by knowing where they go to school. Because it is a symmetric measure, it also tells us how much we know about where a person goes to school by knowing their race.

Differences between the Divergence Index and Mutual Information. Mutual information can be written as the relative entropy between a joint distribution and the product of its marginal distributions, and in many cases it can produce the same segregation value as the Divergence Index. However, the indexes differ in important ways, including how they are formulated and their potential use cases.

Mutual information is calculated using a joint probability distribution and its marginal distributions, each of which sum to 1. Because of this, the comparative reference of segregation cannot be independently specified. In contrast, the Divergence Index measures the difference between two probability distributions, and the distribution that represents the comparative reference can be a marginal distribution or another theoretically relevant distribution.

Segregation indexes typically use conditional probabilities to measure segregation rather than joint probabilities (see Grannis 2002). For example, datasets used for measuring residential segregation are structured so that each row represents a neighborhood and the proportion of each group in a neighborhood's population are included in the columns. Each row of the dataset — each neighborhood — sums to 1. A joint probability distribution used for the mutual information index would have the same basic structure, with neighborhoods in rows and groups in columns, but proportions for the entire dataset would sum to 1, so that each cell represents the proportion of the region's population in a given neighborhood and group.

This distinction matters in cases when the relevant comparative reference for segregation the Q distribution — is a counterfactual or theoretical distribution, or any time the aggregate proportions used as the comparative reference are not equal to the product of the marginals of a joint distribution. This can occur when using non-exclusive subunits, such as studying overlapping relationships in personal and business networks (e.g., Smith and Papachristos 2016), or when measuring spatial segregation or local segregation for a subset of locations. In such cases, we may wish to use the composition of the network or region as the Q distribution rather than the product of the marginals of a joint distribution.

For example, when measuring spatial segregation with overlapping local environments around each location in a city (e.g., Roberto 2018), the populations of the local environments are not mutually exclusive — they include the residents of the location itself, as well as the populations of other nearby locations within a particular distance. Such an approach allows us to compare the level of segregation for differently sized local environments and examine the geographic scale of segregation patterns. We would use the region's composition as the Q distribution in order to evaluate the difference between the local and regional proportions as the size of local environments changes. As the local environments increase in size and include more and more of the region's population, they would eventually begin to converge on the regional proportions.

The overlapping nature of the local environments means that if we used the product of the marginals of the joint distribution as the Q distribution, a single location's population could be counted multiple times. Thus the aggregate population of all local environments may not be equal to the region's population composition, and the population of more central locations may be counted more heavily than outlying locations in the aggregate population if they fall within more locations' local environments. In such cases, it is preferable to use the Divergence Index and specify the probability distributions being compared, rather than using mutual information, which necessitates

using a joint probability distribution and its marginal distributions.

#### Comparing the Divergence Index and Information Theory Index

In this section, I compare the mechanics of the Divergence Index and Information Theory Index using stylized and empirical examples. The Divergence Index and Information Theory Index share many desirable properties, particularly their decomposability. A key difference between them is the concepts they measure. The Divergence Index measures segregation and inequality, and the Information Theory Index measures diversity. The concept of diversity concerns the variety or relative quantity of groups in a population, whereas segregation concerns the degree to which specific groups are over- or under-represented in the local areas compared to the region's composition.<sup>9</sup> I provide this comparison between the indexes because the Information Theory Index has been widely used in decomposition studies of segregation.

#### Equivalence between the Overall Indexes

The Information Theory Index, H, measures the ratio of local diversity to overall diversity. Whereas the Divergence Index, D, measures the difference between the local and overall group proportions. It is possible to derive an equivalence between H and D at the aggregate level of a city or region, but only if overall entropy (E) is nonnegative and greater than or equal to the average local entropy  $(\bar{E}_i): 0 \leq E \geq \bar{E}_i$ . However, no such equivalence exists at the local-level for locations or districts within a city or region.

If both conditions hold then, we can derive the equivalence between H and D by first rewriting the equation for D as:  $D = E - \bar{E}_i$  (see Appendix A). Recall that we can write the equation for Has:  $H = \frac{E - \bar{E}_i}{E}$ . From this, we can derive the equivalence as:

$$H = \frac{D}{E}$$
 and  $D = HE$ .

H is equivalent to D standardized by E, or the ratio of D to E. Next, I describe the conditions that lead E to be negative or less than the average local entropy — if either occurs, then the equivalence does not apply.

Overall Entropy is Negative. The entropy of a discrete distribution is always nonnegative, however Cover and Thomas (2006:244) show that the entropy of a continuous distribution (called "differential entropy") can be negative. For example, the differential entropy of a uniform distribution U(0, a) is

negative for 0 < a < 1. This occurs because the density of the distribution is  $\frac{1}{a}$  from 0 to a, and

$$E = -\int_0^a \frac{1}{a} \log \frac{1}{a} \, dx = \log a.$$

Because a < 1, therefore  $\log a < 0$ . In contrast, both relative entropy and differential relative entropy (the discrete and continuous versions of the Divergence Index) are always nonnegative (Cover and Thomas 2006).

Average Local Entropy is Greater than Overall Entropy. Average local entropy  $(\bar{E}_i)$  can be greater than overall entropy (E) if three conditions hold: if the overall population is not maximally diverse (i.e. the groups have different population sizes), if any subunits have more diversity than the overall population (e.g., if there are local areas where groups are more similar in size than in the overall population), and if the subunits are not mutually exclusive.

The first two conditions are quite common when measuring segregation. The third condition — non-exclusive subunits — arises when measuring segregation spatially. Spatial segregation measures, including the spatial version of the Divergence Index in equation 2 (Roberto 2018), include a proximity-weighted contribution from nearby areas in each location's population. This creates overlapping local environments or *ego-centric neighborhoods* (Lee et al. 2008; Reardon et al. 2009, 2008), which are not mutually exclusive: they include the residents of the location itself, as well as the populations of other nearby locations within a particular distance. Non-exclusive subunits are also common in social network analysis, such as studying overlapping relationships in personal and business networks (e.g., Smith and Papachristos 2016).

When the three conditions listed above occur, then average local entropy  $(E_i)$  can be greater than overall entropy (E), and E can not be used to derive the equivalence between the Information Theory Index and the Divergence Index. Moreover, when  $\overline{E}_i$  is greater than E, then the Information Theory Index will be negative.<sup>10</sup>

#### Comparing the Local Indexes

To illustrate the similarities and differences between the Divergence Index and Information Theory Index, Figure 1 compares the functional form of the local indexes for three hypothetical cities. For the sake of the illustration, the two conditions listed above are both satisfied — overall entropy in the cities is positive, and average local entropy is not greater than overall entropy — and an equivalence exists between the city-level indexes, though not the local indexes. For reference, Figure 1 also includes the functional form of local values for the Dissimilarity Index.

Each city is divided into mutually exclusive local areas, and there are two groups in the cities' populations. The proportion of each group varies across cities: 50-50 in city A, 75-25 in city B, and 90-10 in city C. The horizontal axes in Figure 1 show the proportion of group 1 in the local areas within each city. The vertical axes show the index values for local areas within the city across the full range of possible values for the local proportions of group 1. The dark solid lines plot the local index values for  $D_i$ , the dashed lines plot the local index values for  $H_i$ , and for reference, the light solid lines plot the local index values for the local index values for  $D_i$ .

#### [Figure 1 about here.]

The minimum and maximum values of  $D_i$  and  $H_i$  vary across the three hypothetical cities in Figure 1. Local values of the Divergence Index,  $D_i$ , take their minimum value, which is always 0, when the local population composition is the same as the overall composition of the city.  $D_i$  reaches its maximum value when a city's minority group is 100 percent of the local population. In a city where two groups are equally represented, like city A, it is just as surprising to observe a location where 100 percent of the residents are in group 1 as a location where 100 percent of the residents are in group 2. However, when there is a large majority group, as in cities B and C, it is more surprising to observe a location where all residents are in the minority group than a location where all residents are in the majority group. Further, it is more surprising to observe a location where all residents are in the minority group in a city C with a 10 percent minority population than in a city B with a 25 percent minority population. This is demonstrated in Figure 1 by comparing the local value of the Divergence Index in cities A, B, and C when the local proportion of the majority group (group 1) is 0.

By contrast, local values of the Information Theory Index,  $H_i$ , reach their maximum value when any group is 100 percent of the local population, regardless of the city's population composition.  $H_i$ equals 0 when local diversity is the same as the city's diversity, regardless of whether any group is over- or under-represented in the local population. For example, Figure 1b shows that  $H_i = 0$  when the proportion of group 1 in the local population is either 0.25 or 0.75, even though the proportion of group 1 in the city is 0.75. The functional form of  $H_i$  for a two-group index is always symmetric around 0.5 — even proportions of each group — regardless of the overall population composition. In contrast, the Divergence Index and Dissimilarity Index are symmetric only if there are even proportions of each group in the overall population, otherwise local values of both indexes are zero only if the local proportion of each group is the same as the overall population.

 $H_i$  takes its minimum value, which is typically less than zero, when a local area has an even mix of groups, regardless of the city's diversity. The minimum value of  $H_i$  is a decreasing function of the city's overall diversity. (Recall that  $H_i$  is 1 minus the ratio of local diversity to overall diversity.) Given the same level of local diversity, the value of  $H_i$  will be lower in a city with a less overall diversity than in a city with more overall diversity. This is demonstrated in Figure 1 by comparing across cities. The inflection point, or minimum value, of the function for  $H_i$  is 0 in city A where there is an even mix of groups, slightly negative in city B, and even more negative in city C, which is the least diverse city with a 90-10 mix of groups.

If local areas are marginally more diverse, on average, than the overall population, then H will be negative.<sup>11</sup> Reardon and O'Sullivan (2004) interpret negative values of H as indicating "hyper-integration" — each group is more equally represented in local areas, on average, than in the overall population. In contrast, D and  $D_i$  are never negative (Cover and Thomas 2006).

The values of the indexes are the *same* when there is an even mix of groups in the city population, as in city A (Figure 1a). If the proportion of each group in local areas is the same as the city proportions, then both indexes equal zero. If all local areas are monoracial, such that each group is either 100 percent or 0 percent of the local population, then both city-level indexes reach their maximum value. If the proportion of each group varies across local areas, then the measures would each find some degree of segregation or relative homogeneity. Moreover, the values of both indexes will be the same in the rare case that the overall population is maximally diverse.

The difference between the indexes is greatest when there is a small minority group in the population. At the extreme, if there is only one group present in the city and all local areas are monoracial, D and H give opposite results. H would show that the city is maximally homogenous (all  $H_i = 1$  and H = 1) because there is no diversity in either the local areas or the city.<sup>12</sup> In contrast, D would find that the city is not at all segregated (all  $D_i = 0$  and D = 0), because there is no difference between the composition of local areas and the city as a whole — each local area is a microcosm of the city. Although there does not seem to be a reason to compute the indexes when there is only one group in a city, this situation can arise when, for example, computing the indexes for multiple cities where a particular ethnoracial group may be present in some cities but not others. The typical approach with H (or the Dissimilarity Index) is to restrict the sample of cities to those with a population of at least 1,000 for all groups. This selection criteria is not necessary when using D — the groups can be of any size or absent in some contexts but not others.

Table 1 lists local index values for hypothetical neighborhoods in city B that each have the same population count but different group proportions. The table shows the correspondence between local and overall values of the indexes, and illustrates the conditions when they indexes give disparate results.

The value of  $H_i$  is 0 in the neighborhood with 75-25 group proportions, the same as city B, and 1 in the neighborhood with 100-0 group proportions. In contrast, the values of  $D_i$  are 0 and .415 in these two neighborhoods. The difference between these neighborhoods is greater for  $H_i$  than  $D_i$ . As noted earlier, the value of  $H_i$  is always 1 in neighborhoods with only majority group residents, regardless of the region's group proportions. (See Figure 1.) In contrast, the value of  $D_i$  adapts to represent the degree of difference between the local and overall group proportions.

An implication of this is that the overall value of H is always greater than D — when measured for two groups — and the difference is greater in regions where 1) the overall group proportions are more unequal, and 2) the local group proportions tend to be more extreme (i.e., all one group or the other).

#### [Table 1 about here.]

The most notable difference between the Dissimilarity Index  $(DI_i)$  and both  $D_i$  and  $H_i$  is that local values of  $DI_i$  follow a linear function, whereas both  $D_i$  and  $H_i$  are logarithmic functions of the local proportions. Local values of the Dissimilarity Index  $(DI_i)$  are always greater than or equal to  $D_i$ . Local values of the  $DI_i$  are greater than or equal to  $H_i$ , except in locations where the majority group approaches 100 percent of the local population.

In the previous section, I explained the conditions under which E can be used to derive an equivalence between D and H and noted that no such equivalence exists for the local values of the indexes. If the local values of the Divergence Index,  $D_i$ , are divided by overall entropy, E, the resulting values have a functional form that is similar to  $D_i$  but with the same population-weighted mean as  $H_i$ . Figure 2 uses the population and index values of city C to illustrate this point. The values for  $D_i$  and  $H_i$  are unchanged from Figure 1c, and the dotted line represents the values of  $D_i/E$ .

#### [Figure 2 about here.]

Despite having the same population-weighted mean as  $H_i$ ,  $D_i/E$  does not share the unique symmetry property of  $H_i$ , where regardless of the city's composition,  $H_i$  always takes its minimum value when there is an even mix of groups in the local population (e.g., 50-50 for a two-group index) and always takes its maximum value when any group is 100 percent of the local population. As with  $D_i$ ,  $D_i/E$  takes its minimum value when local areas have the same composition as the city and reaches its maximum value when the city's minority group is 100 percent of the local population. As illustrated in Figure 2, the values of  $D_i/E$  are always greater than  $D_i$  when E < 1, such as with a two-group index when there are uneven group proportions. This is also true for the overall values of H - H > D when E < 1 — but not for the local values.

 $D_i/E$  may be a better alternative to  $H_i$  for local values. However, using D/E does not resolve an additional issue with the decomposition of H, where the within components for each subarea are not equal to the population-weighted index values for each subarea alone. D/E, like H, has an additional diversity weight that must be applied. As a result, subareas that are more populous and more diverse contribute more to the overall index than less populous and less diverse districts. I will illustrate this point in greater detail in the following section.

#### Decomposing the Divergence Index and Information Theory Index

In this section, I decompose racial residential segregation and relative homogeneity in the Detroit, MI, metropolitan area using the Divergence Index and Information Theory Index. I provide this comparison because previous studies have used the Information Theory Index as the best alternative to the Dissimilarity Index for decomposing segregation within and between communities, municipalities, or school districts (Bischoff 2008; Farrell 2008; Fiel 2013; Fischer et al. 2004; Fischer 2008; Fowler et al. 2016; Lichter et al. 2015; Owens 2019; Owens and Rich 2023; Parisi et al. 2011) and commonly interpret the Information Theory Index as a measure of segregation. The analysis demonstrates key differences in the calculation and interpretation of decomposition results for the Divergence Index and Information Theory Index, including the weighting of the within-subarea values and the calculation of local values in the between-subareas component. This section focuses on the mechanics of the indexes, using Detroit as an example, whereas the following section has an empirical focus — describing changes over time in segregation and diversity in the 100 largest U.S. metros.<sup>13</sup>

The Detroit metropolitan area is commonly cited as one of the most racially segregated places in the U.S. A large majority of the city's residents are Black, while the surrounding area's population is predominantly White.<sup>14</sup> To better understand the regional dynamics of segregation, I measure Black-White segregation in the Detroit metro area with the Divergence Index using population data from the 2010 decennial census aggregated at the level of census tracts<sup>15</sup> (U.S. Census Bureau 2011). I then decompose overall segregation in the Detroit metro area into the segregation occurring between the city of Detroit and the remainder of the metro area (the "suburbs"), and the segregation occurring among the tracts within each these subareas. The between-subarea component of segregation measures how surprising the racial composition of each subarea is given the metro area's overall racial composition. The within-subarea component of segregation measures how surprising the racial composition of tracts within each subarea is given each subarea's overall racial composition. Total segregation for the metro area is the sum of the between-subarea segregation and the average within-subarea segregation. The total is equal to measuring the segregation of all tracts in the metro area.<sup>16</sup> In the same fashion, I decompose relative homogeneity into between- and within-subarea components with the Information Theory Index.

The first key difference between the decompositions of the Divergence Index and Information Theory Index is in the weighting of the within-subarea values. Table 2 demonstrates how the decomposition formulas are applied in the Detroit metro area decomposition. It reports the index values for each subarea, the weights applied to each, and the additive value in the decomposition. The index values for the individual subareas are weighted to obtain the additive value, which is the subarea's contribution to the overall index. I also present the percentage contribution of each component to the overall index in Table 3. I present both Tables 2 and 3 to provide greater transparency in how the decomposition formulas are applied to the empirical data and how the values for the percentage contributions are obtained. I will start by describing the within-subarea component of the decomposition, followed by the between-subarea component.

The additive value of the within-subarea component of the Divergence Index is a populationweighted sum of the within-subarea index values for all subareas (see Equation 4). By applying population weights, the index is able to represent the average segregation experienced by individuals. The additive value of the within-subarea components of H and D/E are population and relative diversity weighted sums of the within-subarea index values for all subareas (see Equation 1). Due to the additional relative diversity weight, subareas that are more diverse contribute more to the overall index than less diverse subareas.

An implication of this is that the way each subarea's index value contributes to the within-subarea component and the overall metro index differs for D and for H and D/E. For D, the within-city weight is 0.17, and the within-suburbs weight is 0.83, which represents their relative shares of the

metro population. For H and D/E, the total weight is 0.09 for the within-city component and 0.54 for the within-suburb component, which places more relative weight on the within-suburb component than the within-city component, compared to D.

#### [Table 2 about here.]

The second difference in the decomposition of the indexes concerns the calculation of local values, as seen in the between-subareas component. Table 3 reports the percentage contribution of each decomposition component to the overall indexes. The percentages are calculated using the the additive values – the component values after the relevant weights have been applied. The indexes show the same overall pattern, with the between-subareas component accounting for about two-thirds of the metro's overall index value. The decomposition reveals that the largest differences in both population composition and diversity occur at the regional level — between Detroit and the suburbs. There are comparatively less differences among the tracts within each subarea. However, if we take a closer look at the local values of the between-subarea component in Table 3, there is a stark difference between the indexes. Results for D and D/E show that Detroit contributes more to the between-subarea value than the suburbs, while results for H show the opposite pattern.

Figure 3 shows the functional form of the indexes for the Detroit metro area population and indicates the local values of the city and suburb components of the between-subarea index. The figure shows the unweighted between-subarea index values — the same values found in the "betweensubareas" rows and "index value" columns of Table 2. The horizontal axis shows the proportion White, and the vertical axis shows the index values. The solid line shows the functional form of segregation measured with  $D_{0j}$ , and the dashed line shows relative homogeneity measured with  $H_{0j}$ , and the dotted line shows the value of  $D_{0j}/E$ . The points in each figure indicate the unweighted index value for each subarea — the city of Detroit and the suburbs. The figure shows the pronounced difference between the between-subarea index values for the city and suburbs measured with D and D/E, but not with H, which is similar for both the city and suburbs.

The between-subarea Divergence Index measures the difference between each subarea's composition and overall metro area composition. The proportion White is 0.75 in the metro area, compared to 0.09 in Detroit and 0.88 in the suburbs. From the perspective of the Divergence Index, 0.09 is a very surprising local proportion, more so than 0.88, given that the overall proportion White is 0.75. Therefore, there is greater divergence between the population compositions of Detroit and the metro area than between the suburbs and the metro area, and greater divergence indicates higher segregation. Detroit's between-subarea segregation is sufficiently higher than the suburbs that even after weighting each subarea's value by its share of the metro population (0.17 for Detroit and 0.83 for the suburbs) Detroit's contribution to between-subarea segregation is still larger than the suburbs's contribution. The pattern is similar for the D/E measure.

Results for the Information Theory Index show an opposite trend: Detroit contributes less to overall segregation than the suburbs. White residents are over-represented in the suburbs and Black residents are over-represented in Detroit, relative their metro proportions. But the city and suburban populations both have about the same level of diversity, and each has less diversity than the overall metro population. The Information Theory Index is concerned only with the mix of groups in each subarea relative to the metro, not the specific group proportions. The difference in the percentage contributions of the city and suburbs is mainly due to their share of the metro population, which is much smaller for the city than the suburbs.

This analysis demonstrates key differences in the calculation and interpretation of decomposition results for the Divergence Index and Information Theory Index. First, the within-subarea components of each index differ in the weights that are applied to each subarea. Both indexes apply population weights, but H (and D/E) applies an additional relative diversity weight, which means that more diverse subareas contribute more to the within component and overall index than less diverse subareas. Second, the between-subareas component calls our attention to differences in the calculation of local values and what each index is measuring. H measures the level of diversity in the city and suburban populations relative to the overall diversity of the metro area's population, and D measures the over/under representation of groups in the city and suburban populations relative to the metro area's populations relative to the metro

> [Table 3 about here.] [Figure 3 about here.]

#### Analyzing Changes in the 100 Largest Metros from 1990 to 2010

In this section, I analyze and compare the Divergence Index and Information Theory Index for Asian, Black, Latinx, and White ethnoracial groups from 1990 to 2010 in the 100 most populous U.S. metropolitan area divisions as of 2010.<sup>17</sup> The indexes reveal different trends: the Information Theory Index has tended to decrease overtime, particularly within cities, while the Divergence Index has tended to increase, particularly within suburbs. The different properties of the indexes and how they respond to changes in local and overall population composition offer insight into why we observe empirical differences between the indexes.

I use U.S. Census data at the block level for each decade (Manson, Schroeder, Van Riper, Kugler, and Ruggles 2021; U.S. Census Bureau 2011). I apply the 2010 boundaries for blocks, central cities, and metropolitan areas to data from 1990 and 2000 to create constant area boundaries across time (Manson et al. 2021). Using stable areal units means that the changes that we observe in the index values are net of the effect of any boundary changes that may have occurred.

I decompose the overall indexes into within and between components, using the primary central city, suburbs (census defined places), and fringe (nonplace areas) of each metro as the subareas (see: Lichter et al. 2015; Owens 2019; Parisi et al. 2011). Figure 4 illustrates the relationship between the components of the decomposition, with the between component on the left and the within component and its three subcomponents on the right.

#### [Figure 4 about here.]

The decomposed index values and change over time are presented in Table 4. For comparability, I have included the unweighted index values for the within central city, within suburbs, and within fringe areas subcomponents, rather than the weighted additive values, because D and H apply different weights to each subcomponent: D applies population weights and H applies population and relative diversity weights when aggregating each subarea's value into the within component and overall index. (The weights are provided in Equations 1 and 4, and the discussion of Table 2 explains the implications of the different weighting.)

## [Table 4 about here.]

Overall, the within component of the decomposition accounts for the majority of the overall segregation and relative homogeneity in the metro areas across all time periods. On average, the differences in population composition and diversity between the central city, suburbs, and fringe area of each metro is relatively small compared to the differences among the blocks within each subarea. This is consistent with the findings of previous decomposition studies using the Information Theory Index (Farrell 2014; Lichter et al. 2015; Owens 2019).

#### Change Overtime

The H index reveals a dominant trend of declines in overall metro H from 1990 to 2010 in 93 of the 100 metros, which is consistent with the findings of Lichter, Parisi, and Taquino (2015) and other studies (e.g., Elbers 2021; Kye and Halpern-Manners 2023; Parisi, Lichter, and Taquino 2015).<sup>18</sup> The average change across metros is a decrease of 0.081. (See Table 4.) Also consistent with previous studies, the decreases were more pronounced for the within component of H, compared to the between component.

Changes in overall metro D over this period show a different trend, with decreases in only 27 of the metros. The average change across the 100 metros is an increase of 0.036. The largest increases were in the within suburb and within fringe area segregation (0.056 each). In contrast, the segregation within central cities decreased on average, though to a lesser degree than the decreases in H.

Comparing patterns of change for individual metros in the overall metro indexes and the within components of the indexes reveals opposite trends in two-thirds of the metros: H decreases and D increases from 1990 to 2010. (See Table 5.) The contrast between the indexes is less pronounced for the between component: only one-quarter of the metros show opposite trends for H and D.

To summarize, the overall and within component of the H index *decrease* in all but a few metros, and the between component of the index decreases in about two-thirds of the metros. The overall and within component of the D index *increase* in three-quarters of the metros, and the between component of segregation increases in about two-thirds of the metros.

[Table 5 about here.]

#### Within-City and Within-Suburbs Changes Overtime

Analyzing the within-city and within-suburbs subcomponents of the indexes for each metro area provides a further comparison of changes from 1990 to 2010. Figure 5 shows the relationship between the within-city and within-suburb changes over this time period for the Divergence Index (Figure 5a) and Information Theory Index (Figure 5b). The four quadrants of each panel indicate metros where there were increases in both the within-city and within-suburb measures (upper right), increases in within-city and decreases in within-suburb measures (lower right), decreases in both within-city and within-suburb measures (lower left), decreases in within-city and increases in within-suburb measures (upper left). The color and shape of the points indicates the trend of the overall metro measures — the blue down-pointing triangle indicates decreases in the metro index and the red up-pointing triangle indicates increases in the metro index from 1990 to 2010 — and illustrate the finding of decreasing metro H and increasing metro D in most metro areas over this period.

#### [Figure 5 about here.]

There are two key takeaways from Figure 5. First, consistent with the overall metro D trend, most of the metros (84 of 100) show increases in within-suburb D, as indicated by the majority of the points falling in the top two quadrants of Figure 5a. In the suburbs of these metro areas, the ethnoracial composition of blocks has become increasingly different from the overall suburban population composition over time. These trends are found amid overall increases in diversity (measured with the Entropy Index) at each level of aggregation: the metros, cities, suburbs, and fringe areas. (See Table E1 in Appendix E.) In fact, the biggest increases in diversity occurred within suburbs.

However, many of these same metros (46) show accompanying decreases in within-city D, as

indicated by the large number of points falling in the top left quadrant of Figure 5a. These results are consistent with the literature that finds declines in neighborhood-level segregation within cities alongside the increasing prevalence of "ethnoburbs" (Li 1998) in suburban places (Lee, Iceland, and Farrell 2014; Lichter 2013; Logan and Zhang 2010).

Second, nearly all metros (94 of 100) show decreases in within-city H, as indicated by the majority of the points falling in the left two quadrants of Figure 5b. In these metro areas, the racial diversity of city blocks has come to more closely resemble the overall diversity of the city population. In most of these metros (78), within-suburb H has also decreased, as indicated by the large number of points falling in the bottom left quadrant of Figure 5b. There were relatively small increases in within-suburb H in 19 of the metros, shown in the upper left quadrant of Figure 5b, suggesting that the diversity of blocks within these suburban communities did not quite keep pace with the rising racial diversity of the suburbs as a whole during this time period.

#### Differences between the Indexes

The different properties of D and H and how they respond to changes in local and overall population composition offer insight into why we observe empirical differences between the indexes.

When there are equal proportions of each group, the H and D indexes are the same. The difference between the two measures increases as the overall group proportions become more unequal. Practically what this means is that D adjusts the expected local proportions of an even distribution as the overall population composition changes. Whereas H adjusts the expected local mix of groups as the overall diversity changes.

For example, in a metro area with one very large group and one small group, like city C in Figure 1c, there is less potential for high levels of D than in a second metro area where the groups are about equal in size, like city A in Figure 1a. If group members do not co-reside in any local areas, each of the metros would be maximally segregated.

In the first metro, local areas composed entirely of the group that is a small proportion of the metro population would be the most surprising — their composition is very different than the expected local proportion of each group if there is no segregation. These areas would have the highest local segregation values, but the number of such areas would be limited given the overall population composition. Local areas composed entirely of the group that is a very large proportion of the metro population would not be too different from the expected proportions — the metro's population composition — and would contribute little to overall segregation.

In the second metro area, with groups that are about equal in size, D expects groups to be equally represented in local areas if there is no segregation in the metro. It would be very surprising to observe local areas composed entirely of one group — more surprising than a local area in the first metro composed entirely of the very large group — and this could occur in every local area of the metro, generating very high levels of segregation.

In contrast with H any local area in the first metro with the same relative group proportions — regardless of which group is large and which is small — would have a zero index value. Local areas with more equal group sizes than the metro would have a negative index value. Any local area composed entirely of one group would have a positive index value of 1, regardless of whether that group is large or small in the overall metro population. In the second metro, results would be similar for H and D, since the indexes would return the same value when there are equally sized groups. A Note about Composition Invariance. It may seem counter-intuitive that there could be lower segregation in the first metro area than the second: with one very large group in the first metro, there are likely to be local areas composed of that group alone, which would seem to indicate very high segregation. However, measures of over/under representation necessarily adjust for the expectation of an even or random local distribution of the group populations using the overall proportion of each group in the region as the baseline for comparison.

There has been a long debate over whether segregation indexes should be compositionally invariant, or free from margin dependence. In recent years, methods have been developed to isolate differences in segregation that are due to differences in the distribution of the population across areal units and groups (also called unit and group marginals), and "structural change" (also called "pure segregation") (e.g., Elbers 2023; Mora and Ruiz-Castillo 2009, 2011). However, a key limitation of compositionally invariant indexes or focusing only on "structural change" is the assumption that differences in the marginal distributions and differences in the "structural" component are independent of one another. There is a wealth of segregation literature that suggests that changes in the marginals, especially group proportions, may activate mechanisms associated with segregation, such as, racially restrictive covenants (e.g., Rothstein 2017), exclusionary zoning (e.g., Rothwell and Massey 2009), White flight (e.g., Lichter et al. 2015), and racial steering by real estate agents (e.g., Besbris and Faber 2017). A poignant example is the Great Migration, in which millions of Black people moved from the South to Northern, Midwestern, and Western states between the 1910s and 1970s. Racist policies and practices in response to these demographic changes fueled housing discrimination against Black southerners and created segregated neighborhoods.

The Divergence Index is not compositionally invariant by design. The index uses the overall population composition as the comparative reference for segregation, which captures our expectation about what the local compositions would be if there is no segregation. If there is an influx of a population group to a city from one time period to the next, the comparative reference adapts to represent our updated expectation about the local compositions: the compositional changes from demographic processes, including migration in and out of the region and residential resorting within the region, are relevant for understanding segregation patterns and change. Making the index invariant to differences in population composition, would create a substantively different index that no longer carries the same meaning or interpretation. (For a longer discussion of the topic of compositional invariance, see Appendix B.)

How the Indexes Respond to Changes in Diversity. As metro areas became more diverse from 1990 to 2010, the D index adjusts the expected local proportions of an even distribution accordingly. Drawing on the previous example, if the group proportions of a metro changed from resembling the first metro area — with one very large group and one small group — in 1990 to looking more like the second metro area — with similarly sized groups — by 2010, then blocks composed entirely of one ethnoracial group would be more segregated in 2010 than they were in 1990, and segregation in the metro area and subareas would likely increase. In order for metro segregation to remain the same or decrease over time, current residents would need to relocate from blocks where their ethnoracial group is overrepresented to blocks where their ethnoracial group is underrepresented, newcomers to the metro area would need to move to blocks where their ethnoracial group is underrepresented, or current residents of blocks where their ethnoracial group is overrepresented to move out of the metro area. The observed increases in the D index for metros from 1990 to 2010 suggest that population redistribution has not occurred in this way or has not kept pace with changes to the overall metro composition.

By comparison, H compares local diversity in each block to overall diversity in the metro. H adjusts the relative mix of groups expected in each block as the overall metro diversity changes. If the group proportions of a metro changed from resembling the first metro area in 1990 to looking more like the second, more diverse metro area by 2010, the index value for a block composed entirely of one ethnoracial group would not increase, as it does with D. Instead, it would have the same index value in 2010 as it did in 1990, a value of 1.

In order for the H index to remain the same or decrease over time, current residents would need to relocate from blocks where the ethnoracial group proportions are unequal and their group is the largest to another block with unequal proportions and their group is the smallest, newcomers to the metro area would need to move to blocks with unequal proportions and their group is the smallest, or current residents of blocks with unequal proportions and their group is the largest would need to move out of the metro area.

Some of the moves that would lead to decreases in H would be associated with increases in D. For example, in the first metro area with one large group and one small group, if members of the largest group move from blocks where the group proportions match the metro composition to blocks where the group proportions are inverted, so that the largest group in the metro is the smallest group in the block and the smallest group in the metro is the largest in the block, the H index would decrease and the D index would increase in those blocks.

The empirical results suggests that H is capturing the tendency for blocks to increase in diversity at roughly the same pace as the region, but D is capturing the tendency for diversity promoting moves to reproduce or intensify segregation.

#### Changes in Segregation and Diversity within Suburbs

An informative approach for understanding the dimensions and dynamics of residential differentiation is to analyze segregation alongside diversity using the Divergence and Entropy Indexes. As an illustration, Figure 6 shows the relationship between changes in within-suburb diversity and segregation from 1990 to 2010. The four quadrants of the figure indicate the suburbs of metros where there were increases in both the segregation and diversity (upper right, red), increases in diversity and decreases in segregation (lower right, green), decreases in both segregation and diversity (lower left, blue), decreases in diversity and increases in segregation (upper left, purple).

As noted earlier, both segregation and diversity within suburbs tended to increase over this period, as demonstrated by the heavy concentration in the upper right quadrant of Figure 6. Although there is a tendency for segregation and diversity to increase together, the relationship is not deterministic. Fifteen of the metros whose suburbs increased in diversity experienced decreases in segregation.

#### [Figure 6 about here.]

As an example, the suburbs of the Jackson, MS, and Columbia, SC metros had similar increases in diversity and levels of diversity in 1990 and 2010 (see Table 6). The suburbs of both metros also had similar population sizes and racial demographics in each time period. In 1990, the Jackson suburbs had considerably more segregation than the Columbia suburbs (0.60 and 0.46). But by 2010, their levels of segregation were nearly the same (0.53 and 0.54). This change represents a decrease in segregation in the Jackson suburbs and an increase in segregation in the Columbia suburbs, despite both experiencing similar increases in diversity.

As this example illustrates, the average trends in segregation and diversity do not imply a

deterministic relationship. The variation in the direction and strength of the relationship between segregation and diversity suggest different underlying population processes across metro areas. For example, in some places increases in diversity may be associated with stable residential integration, while in others the increases may be driven by processes of White flight and racial turnover: White residents may leave predominantly White, segregated neighborhoods as new non-White residents enter the neighborhood, generating fleeting increases in diversity as the process unfolds and reproducing segregation in the long run (Farrell and Lee 2011; Krysan and Crowder 2017; Kye and Halpern-Manners 2023; Rastogi and Curtis 2020).

[Table 6 about here.]

#### Conclusion

In this paper, I have highlighted the conceptual, mathematical, and empirical distinctions between segregation and diversity and introduced the Divergence Index as a decomposable measure of segregation. Decomposition analysis is a critical tool for examining the social and spatial dimensions of diversity, segregation, and inequality. Previous scholarship has used the Information Theory Index as the best alternative to the Dissimilarity Index to decompose segregation within and between communities, municipalities, or school districts (e.g., Bischoff 2008; Farrell 2008; Fiel 2013; Fischer et al. 2004; Fischer 2008; Fowler et al. 2016; Lichter et al. 2015; Owens 2019; Owens and Rich 2023; Parisi et al. 2011), however the indexes represent different concepts. Although studies have acknowledged this difference, they commonly interpret the Information Theory Index as carrying the same meaning as the Dissimilarity Index. This blurs the conceptual distinction between segregation and diversity, as well as having empirical implications for our understandings of segregation, diversity, and their relationship.

I illustrated what can be learned through decomposition analyses with the case of Westchester County, which highlights the implications of decisions about the placement of affordable housing on reducing (or increasing) segregation in the county. Next, I provided a brief review of entropy-based measures of diversity before introducing the Divergence Index, and I compared the mechanics of the Divergence Index and Information Theory Index using stylized and empirical examples.

I illustrated the importance of preserving the conceptual distinction between segregation and diversity with an empirical analysis. I decomposed and compared the Divergence Index and Information Theory Index for Asian, Black, Latinx, and White ethnoracial groups from 1990 to 2010 in the 100 most populous U.S. metropolitan areas. The indexes reveal different trends: the Information Theory Index has tended to decrease overtime, particularly within cities, while the Divergence Index has tended to increase, particularly within suburbs.

I offered insight into why we observe empirical differences between the indexes by explaining the different properties of indexes and how they respond to changes in local and overall population composition. I also highlighted that despite the general trend of increases in segregation alongside increases in diversity, the relationship is not deterministic. Differences across metros in the direction and strength of the relationship suggests the possibility of different underlying mechanisms, where in some metros increases in diversity may reflect the transience of racial turnover that eventually reproduces segregation, while in others it may be associated with the gradual formation of stably integrated communities.

There is no one perfect measure. In this paper, I have highlighted the distinctions between multiple indexes to promote a greater understanding of what each index is measuring and their potential use cases, and to help scholars make informed choices about which index(es) are most appropriate for a given analysis.

Segregation and diversity are important aspects of residential differentiation. Rather than being a substitute for measures of diversity, the Divergence Index is an additional tool for measuring and decomposing segregation. It complements existing measures by enabling the analysis and decomposition of segregation alongside diversity. The Divergence Index offers a distinct lens, which enables richer, deeper understandings of the dimensions and dynamics of segregation.

#### Endnotes

<sup>1</sup>I use publicly available population data for census blocks — the smallest unit of census geography — from the 2010 decennial census (U.S. Census Bureau 2011).

<sup>2</sup>Entropy can be thought of as the uncertainty associated with the value of a random draw from a probability distribution. If an outcome has a probability of 100 percent, the entropy of the distribution is 0 — there is no uncertainty. If there are two equally likely outcomes, such as with a fair coin toss, the entropy of each outcome  $(E_m)$  is 1 and the average uncertainty (E) is 1, its maximum value. In other words, when two outcomes are equally likely, we have maximum uncertainty about what the outcome will be.

<sup>3</sup>The index measures the entropy of P relative to Q, or the relative entropy of P with respect to Q.

<sup>4</sup>Using the properties of logarithms, the Divergence Index can also be written as  $D(P \parallel Q) = \sum_{m=1}^{M} P_m (\log P_m - \log Q_m).$ 

<sup>5</sup>In contrast, entropy (E) is symmetric in P(x) and 1 - P(x).

<sup>6</sup>The greater the divergence of Q from P, the lower the probability of observing the local proportions (P) if there is no segregation in the region (Q).

<sup>7</sup>The Dissimilarity Index measures the deviation of each location's population composition from the overall population composition. Or, equivalently, it measures how evenly the population of each group is distributed across a region. It is calculated as the absolute difference between the proportion of groups A and B in the  $i^{\text{th}}$  location, summed over all locations and divided by 2:

$$DI = \frac{1}{2} \sum_{i=1}^{N} \left| \frac{\tau_{iA}}{T_A} - \frac{\tau_{iB}}{T_B} \right|,$$

where  $\tau_{iA}$  is group A's population count in location *i* and  $T_A$  is the total population of group A, and likewise for group B. If group A and B are distributed across locations in the same proportions, then there is no segregation. Segregation is measured as the extent to which the spatial distribution of group B deviates from that of group A. Although the index is typically used to measure segregation for two mutually exclusive groups, it can be rewritten to measure the segregation of multiple groups (Morgan 1975; Reardon and Firebaugh 2002; Sakoda 1981). It is also used to measure inequality, known as mean relative deviation (Reardon and Firebaugh 2002). The Dissimilarity Index has a number of notable limitations, which have been well documented and are summarized in Table B5.

- <sup>8</sup>The Theil Index is approximately equivalent to Atkinson's inequality index with weights that are close to 0 in its social welfare function (Schwartz and Winship 1980).
- <sup>9</sup>Measures of diversity can not distinguish between a setting in which the proportion of a minority group and a majority group match their proportions in the overall population, and one in which the proportions of the minority and majority groups are swapped.
- <sup>10</sup>It is possible to observe nonnegative values of H when E is negative, but only if  $\bar{E}_i$  is also negative.
- <sup>11</sup>Negative values of H occur when  $\overline{E}_i$  is greater than E. (Recall that  $H = 1 \frac{E_i}{E}$ .) In a previous section, I explained the conditions under which this occurs.

- <sup>12</sup>Technically, H is undefined if there is only one group in the population, because  $H = 1 \frac{0}{0}$ . If there are two groups in the population, the limit of H as the minority group's population count approaches 0 (and E and  $\bar{E}_i$  approach 0) is 1.
- <sup>13</sup>All analysis were conducted using R software (?).
- <sup>14</sup>Using the U.S. Census Bureau's categories of race and ethnicity, I define two mutually exclusive ethnoracial groups for this analysis: non-Hispanic Black ("Black") and non-Hispanic White ("White").
- <sup>15</sup>Census tracts are geographic units defined by the Census Bureau. They have an average population of 4,000 individuals and are intended to approximate neighborhoods. Most studies of residential segregation use census tract data. In cases where a tract is bisected by the city boundary, I create separate population counts for the city and suburban portions of the tract by aggregating census block-level data.
- <sup>16</sup>Note that it is not possible to use the Dissimilarity Index for this decomposition because it is not additively decomposable.
- <sup>17</sup>Using the U.S. Census Bureau's categories of race and ethnicity, I define four mutually exclusive ethnoracial groups: Hispanic or Latino of any race ("Latinx"), non-Hispanic Asian and Pacific Islander ("Asian"), non-Hispanic Black ("Black"), and non-Hispanic White ("White"). For continuity across census years, the "Asian" ethnoracial group includes those who identified as Pacific Islanders. I use the metropolitan statistical area definitions that were updated by the Office of Management and Budget in 2013 (U.S. Census Bureau 2013).
- <sup>18</sup>Note that Lichter et al. (2015) use different race group combinations, include 222 metropolitan areas, and further decompose the within-suburbs component in their decomposition. Nonetheless, their results and those shown here have notable similarities.

## Alternative Equation for the Overall Divergence Index

At the aggregate level of a city or region, we can rewrite the equation for the Divergence Index as:  $D = E - \overline{E}_i$ . No such reformulation exists at the local-level for locations or districts within a city or region.

We use the following quantities in the equations below:  $\tau_i$  is the population count for location *i*, *T* is the overall population count,  $\pi_{im}$  is group *m*'s proportion of the population in location *i*, and  $\pi_m$  is group *m*'s proportion of the overall population.

The entropy for location i is:

$$E_i = \sum_{m=1}^M \pi_{im} \log \frac{1}{\pi_{im}}$$

The average local entropy is the population-weighted mean of the local entropies:

$$\bar{E}_i = \sum_{i=1}^N \frac{\tau_i}{T} E_i$$
$$= \sum_{i=1}^N \frac{\tau_i}{T} \sum_{m=1}^M \pi_{im} \log \frac{1}{\pi_{im}}$$

The region's entropy is:

$$E = \sum_{m=1}^{M} \pi_m \log \frac{1}{\pi_m}$$

The Divergence Index for location i is:

$$D_i = \sum_{m=1}^M \pi_{im} \log \frac{\pi_{im}}{\pi_m}$$

The overall Divergence Index for the region is the population-weighted mean of the local divergences:

$$D = \bar{D}_i = \sum_{i=1}^N \frac{\tau_i}{T} D_i$$

Using these equations, we can rewrite the equation for D as:

$$D = \sum_{i=1}^{N} \frac{\tau_i}{T} \sum_{m=1}^{M} \pi_{im} \log \frac{\pi_{im}}{\pi_m}$$
$$= \sum_{i=1}^{N} \frac{\tau_i}{T} \sum_{m=1}^{M} \pi_{im} \log \frac{1}{\pi_m} + \sum_{i=1}^{N} \frac{\tau_i}{T} \sum_{m=1}^{M} \pi_{im} \log \pi_{im}$$
$$= \sum_{m=1}^{M} \pi_m \log \frac{1}{\pi_m} - \sum_{i=1}^{N} \frac{\tau_i}{T} \sum_{m=1}^{M} \pi_{im} \log \frac{1}{\pi_{im}}$$
$$= E - \bar{E}_i$$

## Appendix B

#### Desirable Properties of Measures

Previous research has identified a set of desirable properties for inequality and segregation measures (Allison 1978; Bourguignon 1979; Coleman, Hoffer, and Kilgore 1982; Jahn et al. 1947; James and Taeuber 1985; Morgan and Norbury 1981; Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004; Schwartz and Winship 1980; Taeuber and Taeuber 1965; White 1986). Measures are commonly evaluated with respect to how well they meet these criteria.

First, I review the criteria concerning the conceptual and methodological qualities of measures. They address how measures should respond to distributional changes (e.g., changes to the distribution of individual incomes or the population count of each group). I organize these criteria into three categories: features of the distribution, changes to the whole distribution, and changes within the distribution. Next, I review the desirable technical qualities and quantities of measures. This second set of criteria address how a measure should be calculated and interpreted.

*Conceptual and Methodological Qualities of Measures.* Measures should be invariant to the following features of a distribution (Table B1):

Criteria	Description	Citations
Individual Cases	All cases should be treated the same.	Symmetry requirement (Bourguignon 1979)
Population Size	Proportionate increases or decreases in the size of the population have no effect on inequality.	Symmetry axiom for population (Bourguignon 1979; Sen 1973) Size invariance (James and Taeuber 1985; Reardon and Firebaugh 2002) Population density invariance (Reardon and O'Sullivan 2004)
Aggregations of Cases	Inequality should be invariant to the aggregation of components with identical compositions into a single unit, or dividing a single unit into components with the same composition.	Organizational equivalence (James and Taeuber 1985; Reardon and Firebaugh 2002) Location equivalence (Reardon and O'Sullivan 2004) Arbitrary boundary independence (Reardon and O'Sullivan 2004)

Table B1: Criteria Concerning Features of the Distribution

Measures should satisfy the following criteria about changes to the whole distribution of cases (Table B2):

Criteria	Description	Citations
Additive Increases	Additive increases to the whole distribution should reduce inequality, because it reduces the relative difference between cases.	Scale invariance (Allison 1978)
Proportionate Increases	Multiplying the whole distribution by a constant should have no effect on inequality, because it has no effect on the relative difference between cases.	Scale invariance (Allison 1978) Income-zero-homogeneity property (Bourguignon 1979) Composition invariance (Jahn et al. 1947; James and Taeuber 1985; Morgan and Norbury 1981; Taeuber and Taeuber 1965)

Table B2: Criteria Concerning Changes to the Whole Distribution

The proportionate increases criterion is also known as composition invariance in the segregation literature. Recent scholarship (e.g., Elbers 2023; Mora and Ruiz-Castillo 2009, 2011) has renewed interest in a long debate over whether segregation indexes should be compositionally invariant, or free from margin dependence. James and Taeuber (1985) explain the principle of composition invariance with reference to racial segregation in schools: "proportional changes in the numbers of students of a specific race enrolled in each school do not affect the measured level of segregation" (p. 16). By their definition, a segregation index is not compositionally invariant if its value is a function of the overall population composition, which is also called margin dependence.

Coleman et al. (1982) argue that under certain definitions of segregation it is substantively appropriate for an index to be sensitive to the overall population composition. One such example is defining a segregation index in terms of the extent of inter-group contact — no inter-group contact indicates maximum segregation, and contact proportional to the overall group proportions indicates zero segregation. In a population with a small minority group, we could expect less inter-group contact than in a population with equally represented groups, and the index adjusts to these expectations. Making such an index invariant to the population composition would distort its substantive meaning.

Others take a moderate stance (Fossett 2017; Reardon and O'Sullivan 2004), for example noting that "the traditional composition invariance criterion espoused by James and Taeuber (1985) is less important than is ensuring that a measure of segregation has a sound conceptual basis. If a segregation index measures exactly that quantity that we believe defines spatial segregation, then the index will be composition invariant by definition" (Reardon and O'Sullivan 2004:134).

In recent years, methods have been developed to isolate differences in segregation that are due to differences in the distribution of the population across units (e.g., census tract population counts), the distribution of the population across groups (e.g., racial composition of a city), and "structural change" (e.g., Elbers 2023; Mora and Ruiz-Castillo 2009, 2011). These three components are also referred to as unit marginals, group marginals, and "pure segregation." Decomposition analyses can be used to compare how much each component contributes to overall segregation, and compositionally invariant versions of indexes have been proposed that remove the influence of the

unit and group marginals.

A key limitation of compositionally invariant indexes is the assumption that differences in the marginal distributions and differences in the "structural" component are independent of one another. There is a wealth of segregation literature that suggests that changes in unit marginals and especially group marginals may activate mechanisms associated with segregation, such as, racially restrictive covenants (e.g., Rothstein 2017), exclusionary zoning (e.g., Rothwell and Massey 2009), White flight (e.g., Lichter et al. 2015), and racial steering by real estate agents (e.g., Besbris and Faber 2017). A poignant example is the Great Migration, in which millions of Black people moved from the South to Northern, Midwestern, and Western states between the 1910s and 1970s. Racist policies and practices in response to these demographic changes fueled housing discrimination against Black southerners and created segregated neighborhoods.

Elbers (2023) argues that segregation indexes should be purged of the influence of marginal differences and only represent the third component – "structural" ("pure") segregation. Mora and Ruiz-Castillo (2009) argue that it is reasonable to work with segregation indexes that include all three components, and in stylized examples they show that compositionally invariant indexes can mask important changes in segregation.

The Divergence Index is not compositionally invariant by design. The index uses the overall population composition as the comparative reference for segregation, which captures our expectation about what the local compositions would be if there is no segregation. Compositional changes from demographic processes, including migration in and out of the region and residential resorting within the region, occur and are relevant for understanding segregation. If there is an influx of a population group to a city from one time period to the next, the comparative reference adapts to represent our updated expectation about the local compositions: the compositions of all local areas should reflect this influx if there is no segregation in the city.

Measures should satisfy the following criteria about changes within the distribution (Table B3):

Criteria	Description	Citations
Transfers and Exchanges	<ol> <li>Any transfer from a unit (e.g., individual, group, or location) with more of the relevant quantity (e.g., income) to another with less should decrease inequality, provided that the rank order remains the same.</li> <li>Likewise, any transfer to a unit with more of the relevant quantity should increase inequality.<sup>a</sup></li> </ol> <sup>a</sup> For example, from Allison (1978): "measures of inequality ought to increase whenever income is transferred from a poorer person to a richer person, regardless of how poor or rich or the amount of income transferred" (p. 868).	Pigou-Dalton principle (Dalton 1920; Pigou 1912) Inter-group transfers (James and Taeuber 1985; Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004) Inter-group exchanges (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004)

*Technical Qualities and Quantities of Measures.* In addition to desirable conceptual and methodological qualities of measures, a second set of criteria concern the technical qualities and quantities of inequality measures. The criteria — additive decomposability, and upper and lower bounds are summarized in Table B4.

Additive decomposability is a desirable property because it allows for a deeper analysis of the sources of inequality. The relative contribution of each component or group to overall inequality can be identified, and the inequality occurring within- and between-subpopulations can be analyzed (Bourguignon 1979).

Many measures are bounded between 0 and 1, with 1 indicating maximum inequality. If a measure has known upper and lower bounds, it can be rescaled to conform to a 0 to 1 range. However, rescaling the measure may shift the definition of inequality from absolute to relative. It is most important for the bounds of the index be known and interpretable.

Criteria	Description	Citations
Additive Decomposability	Measures should be decomposable into the sum of inequality within and between sub-populations	Aggregativity and additivity (Bourguignon 1979) Decomposition (Allison 1978) Additive decomposability <sup><i>a</i></sup> (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004) <sup><i>a</i></sup> For segregation measures, this includes additive organizational decomposability (Reardon and Firebaugh 2002), additive grouping decomposability (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004) and additive spatial decomposability (Reardon and O'Sullivan 2004).
Upper and Lower Bounds	A measure should have known upper and lower bounds and each should have a substantive interpretation.	Scale interpretability (Reardon and O'Sullivan 2004) Upper and lower bounds (Allison 1978) Principle of Directionality (Fossett and South 1983)
Relative or Absolute Inequality	Relative and absolute measures are differentiated based on whether inequality is independent of, or a function of, the number of categories (respectively).	Sensitivity to the number of components (Waldman 1977)

 Table B4: Technical Qualities and Quantities of Measures

## Summary of the Desirable Properties of Measures

Table B5 summarizes the desirable properties of the Dissimilarity Index, Theil's Inequality Index, the Information Theory Index, and the Divergence Index. The rows of the table correspond to the properties detailed in the previous section, as well as the comparative standard used by the measure and which types of distributions it can be used with.

Criteria	Dissimilarity Index	Theil Index	Information Theory Index	Divergence Index
Individual Cases	$\checkmark$	$\checkmark$	$\checkmark$	$\checkmark$
Population Size	$\checkmark$	$\checkmark$	$\checkmark$	$\checkmark$
Aggregations of Cases	$\checkmark$	$\checkmark$	$\checkmark$	$\checkmark$
Proportionate Increases	X <sup>i</sup>	$\checkmark$	Х	$\checkmark$
Additive Increases	$\checkmark$	$\checkmark$	$\checkmark$	$\checkmark$
Transfers and Exchanges	X <sup>ii</sup>	$\checkmark$	$(\checkmark)$ iii	$(\checkmark)$ <sup>iii</sup>
Additive Decomposability	X	$\checkmark$	$\checkmark$	$\checkmark$
Upper and Lower Bounds	$(\checkmark)^{\text{iv}}$	$\checkmark$	$\checkmark$	$\checkmark$
Relative or Absolute Inequality	Relative	Either	Absolute	Either

Table B5:	Properties	of the	Measures
-----------	------------	--------	----------

<sup>&</sup>lt;sup>i</sup>It is debatable whether or not the Dissimilarity Index satisfies the proportionate increases criterion. Cortese, Falk, and Cohen (1976) found that it is sensitive to the minority group proportion, while others found no such association (James and Taeuber 1985; Lieberson and Carter 1982; Taeuber and Taeuber 1965). Reardon and colleagues (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004) find that it is only composition invariant when calculated for two groups.

<sup>&</sup>lt;sup>ii</sup>The Dissimilarity Index satisfies a weak form of the transfers and exchanges criteria (Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004).

<sup>&</sup>lt;sup>iii</sup>The transfers and exchanges criterion generally only applies when components are mutually exclusive, as described in the text.

<sup>&</sup>lt;sup>iv</sup>The the Dissimilarity Index is bounded between 0 and 1, but the expected value of the index is greater than 0 (Cortese et al. 1976; Mazza and Punzo 2015).

Criteria	Dissimilarity Index	Theil Index	Information Theory Index	Divergence Index
Comparative Standard	Evenness (mean of the distribution)	Evenness (mean of the distribution)	Randomness	Any
Distribution Types	Discrete with nominal categories	Continuous	Discrete	Discrete or continuous
Citations	(Bourguignon 1979; Cortese et al. 1976; Coulter 1989; Duncan and Duncan 1955; Falk, Cortese, and Cohen 1978; Fossett and South 1983; Jahn et al. 1947; James and Taeuber 1985; Lieberson and Carter 1982; Massey and Denton 1988; Morgan 1975; Reardon and Firebaugh 2002; Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004; Sakoda 1981; Taeuber and Taeuber 1965; Theil 1972; Winship 1978: Mazza and Punzo (2015))	(Allison 1978; Bourguignon 1979; Cowell 1980b; Cowell, Flachaire, and Bandyopadhyay 2013; Shorrocks 1980, 1984, 2012; Theil 1967, 1972)	(Reardon and Firebaugh 2002; Reardon and O'Sullivan 2004; Theil 1967, 1972; White 1986)	(Bavaud 2009; Cover and Thomas 2006; Cowell 1980b; Cowell et al. 2013; Magdalou and Nock 2011; Mori et al. 2005; Shorrocks 1980, 1984, 2012; Theil 1967; Walsh and O'Kelly 1979)

The Information Theory Index does not satisfy the proportionate increases criterion according to the definition of composition invariance described by James and Taeuber (1985) — the value of the index should not be a function of the overall population composition. However, Reardon and O'Sullivan (2004) show that the index does conform to other definitions of composition invariance. For instance, it is invariant to compositional changes as long as the relationship between local population diversity and overall population diversity remains constant.

Reardon and O'Sullivan (2004) show that the Information Theory Index satisfies the transfers and exchanges criteria when used to measure aspatial segregation. None of the indexes they evaluated satisfy the transfers criterion when used to measure spatial segregation. Spatial approaches often include a proximity weighted contribution from neighboring areas in each location's population. This makes it difficult for any index to satisfy the transfers and exchanges criteria because the local populations are not mutually exclusive. They show that the Information Theory Index satisfies the exchanges criterion under certain general conditions (see Reardon and O'Sullivan 2004).

The entropy-based measures (Theil Index, Information Theory Index, and Divergence Index) can be defined using logarithms to any base. The selected base defines the units of the index (Shannon 1948; Theil 1972). Log base 2 ( $\log_2$ ) is typically used in information theory, which gives results in units of binary bits of information. It is common for inequality measures to use the natural logarithm (ln), which has the mathematical constant (e) as its base.

Using a fixed log base, such as base 2 ( $\log_2$ ) or e (ln), entropy is an absolute measure. Results are a function of the number of groups in the population (Waldman 1977). Given a uniform distribution of groups (indicating maximum diversity), entropy is an increasing function of the number of groups. At first blush, this may seem undesirable, but it has the benefit of maintaining entropy's aggregation equivalence and independence. This means that inequality calculated for a population of two groups is the same as if there were three groups in same population, but no individuals associated with the third type.

For discrete distributions, it may be preferable to use the number of groups as the base. The result is equivalent to dividing by the maximum entropy  $(\log M)$ , given by the number of groups (M). With the number of groups as the log base  $(\log_M)$ , values are scaled to have the same maximum entropy no matter how many groups are in the population. This transforms entropy from an absolute to a relative measure of inequality. It allows for easier comparison across indexes with different numbers of groups, but comes at the cost of one of the desirable properties of entropy — aggregation equivalence and independence.

For example, using  $\log_2$  to measure Black-Latinx-White residential segregation in a city with no Latinx residents gives the same values whether all three races are included in the measure or only the two with population. This is not the case using  $\log_M$ , because the values are scaled according to the number of groups included in the index. Which of these options is preferable depends on the analytic aim of the research, but it is important to be aware of this trade-off.<sup>v</sup>

<sup>&</sup>lt;sup>v</sup>This choice does not affect the values of the information theory index, because the log appears both in the numerator and denominator of the equation.

## Appendix C

#### Entropy Decomposition

Entropy-based measures are additively decomposable, which is a particularly desirable property (Theil 1972).<sup>vi</sup> It is simple to aggregate (and disaggregate) the entropy for multiple groups and to decompose total entropy into the entropy occurring within- and between-groups. The entropy for each component (i) is the sum of the entropy across groups within that component (m):

$$E_i = \sum_{m=1}^M \pi_{im} \log \frac{1}{\pi_{im}}$$

The entropy for all components is the mean of the individual entropies, weighted by the relative size of each component:

$$\bar{E}_i = \sum_{i=1}^N \frac{\tau_i}{T} E_i$$

Theil (1972) showed that total entropy can be calculated for any subdivision of the population and written as the sum of a between-subdivision entropy and the average within-subdivision entropies. For example, if the groups are aggregated into supergroups  $(S_g)$ , where  $\prod_{ig} = \sum_{m \in S_g} \pi_{im}$  is the proportion in each supergroup (g) within component (i). The entropy within supergroup g for component i is:

$$E_{ig} = \sum_{m \in S_g} \frac{\pi_{im}}{\Pi_{ig}} \log \frac{\Pi_{ig}}{\pi_{im}}$$

And the between-supergroup entropy is:

$$E_{i0} = \sum_{g=1}^{G} \frac{\Pi_{ig}}{\pi_{i.}} \log \frac{\pi_{i.}}{\Pi_{ig}}$$

The total entropy for component *i* can then be written as the between-supergroup entropy  $(E_{i0})$  plus the average within-supergroup entropy  $(E_{ig})$ :

$$E_i = E_{i0} + \sum_{g=1}^G \frac{\Pi_{ig}}{\pi_{i.}} E_{ig}$$

<sup>&</sup>lt;sup>vi</sup>The additivity of entropy comes from one of the properties of logarithms:  $log(\pi_1 \cdot \pi_2) = log(\pi_1) + log(\pi_2)$ 

## Appendix D

#### Comparing the Theil Index and Divergence Index

Theil's inequality index (I) and the Divergence Index (D) both measure inequality relative to a defined standard. The Theil Index measures the difference between the observed shares of income across individuals or groups and a theoretical uniform distribution — one in which everyone's income is equal to the mean.

There is a straightforward equivalency between I and D for continuous distributions, such as income.<sup>vii</sup> Theil's index can be written like the Divergence Index, where  $P_i$  is *i*'s share of total aggregate income,  $\frac{\tau_i x_i}{T\bar{x}}$ , and  $Q_i$  is the theoretical uniform share  $\frac{\tau_i}{T}$ :

$$D(P \parallel Q) = \sum_{m=1}^{M} P_m \log \frac{P_m}{Q_m}$$
$$I = \sum_{i=1}^{N} P_i \log \frac{P_i}{Q_i}$$
$$= \sum_{i=1}^{N} \frac{\tau_i x_i}{T\bar{x}} \log \frac{\frac{\tau_i x_i}{T\bar{x}}}{\frac{\tau_i}{T}}$$
$$= \frac{1}{T} \sum_{i=1}^{N} \frac{\tau_i x_i}{\bar{x}} \log \frac{x_i}{\bar{x}}$$

If  $\tau_i = 1$  and T = N, then we get:

$$I = \frac{1}{N} \sum_{i=1}^{N} \frac{x_i}{\bar{x}} \log \frac{x_i}{\bar{x}}$$

We can see that I is a specific case of D applied to measuring income inequality, using uniform shares of income as the comparative standard.

<sup>&</sup>lt;sup>vii</sup>Moreover, the equivalency applies to any distribution for which a mean can be calculated, such as a discrete simplification of a continuous distribution.

## Appendix E

	Entropy Index			
	1990	2000	2010	Change 1990- 2010
Metro Area	.905	1.047	1.193	.289
Within Central Cities	1.154	1.297	1.408	.255
Within Suburbs	.759	.914	1.096	.338
Within Fringe Areas	.573	.677	.827	.254

Table E1: Asian-Black-Latinx-White Entropy Index from 1990 to 2010, Mean for the 100 Largest Metropolitan Areas

Data Source: Author's calculations of block-level population data from the decennial census using 2010 boundaries (Manson et al. 2021; U.S. Census Bureau 2011)

Table E2: Number of Metros with Changes in Within-City and
Within-Suburb Index Values for the Divergence Index in the 100 Largest
Metropolitan Areas, $1990$ to $2010$

	Within-Suburbs Decrease	Within-Suburbs Increase	Total
Within-City Decrease	12	46	58
Within-City Increase	4	38	42
Total	16	84	100
