The importance of integrated quantum photonics in the telecom band resides on the possibility of interfacing with the optical network infrastructure developed for classical communications. In this framework, femtosecond laser written integrated photonic circuits, already assessed for quantum information experiments in the 800 nm wavelength range, have great potentials. In fact these circuits, written in glass, can be perfectly mode-matched at telecom wavelength to the in/out coupling fibers, which is a key requirement for a low-loss processing node in future quantum optical networks. In addition, for several applications quantum photonic devices will also need to be dynamically reconfigurable. Here we experimentally demonstrate the high performance of femtosecond laser written photonic circuits for quantum experiments in the telecom band and we show the use of thermal shifters, also fabricated by the same femtosecond laser, to accurately tune them. State-of-the-art manipulation of single and two-photon states is demonstrated, with fringe visibilities greater than 95%. This opens the way to the realization of reconfigurable quantum photonic circuits on this technological platform.

Keywords: Femtosecond laser micromachining; Integrated quantum photonics; Thermal shifters; Tunable optical circuits

I. INTRODUCTION

The inherent advantages of using photons to encode information in computing applications¹⁻⁴ and to implement future quantum networks^{5,6} have drawn in the last years increasing attention to the field of quantum optics. In particular, a significant boost has been recently provided by the use of integrated photonic circuits as a stable and compact platform for producing quantum optical devices⁷⁻¹¹. Among the different fabrication technologies employed to produce integrated optical circuits, femtosecond laser writing is rapidly gaining a relevant role thanks to its several advantages^{8,12,13}. In fact this technique, being maskless, allows one to rapidly prototype high-quality photonic circuits in glass with a very fast optimization loop and cost-effective process. In addition, it produces low birefringence waveguides, which are required for polarization encoding of single photons 14-16 and has unique three-dimensional capabilities, enabling unprecedented device layouts^{17–19}. Employing this technology for devices working in the telecom band can add further advantages since the insertion losses of these devices in an optical fiber network are very low, thanks to the almost perfect mode matching and to the reduced propagation losses^{20,21}. The quality of photonic circuits written by femtosecond lasers has been proven by the demonstration of several classical devices in glass as waveguide amplifiers, lasers, broadband couplers and demultiplexers $^{22-25}$, as well as electro-optic modulators in crystals.^{26,27} Although the use of this fabrication technology has been widely employed in the production of quantum devices in the 800 nm wavelength range, no investigation on the performances of these devices at telecom wavelength in the quantum regime has been performed yet.

For future application of integrated photonic devices to quantum information, a very important feature is their reconfigurability^{9,11,28–33}. This capability could bring a two-fold advantage: on the one hand it would prove very useful to compensate for errors due to fabrication tolerances; on the other hand, it would allow one to implement several quantum protocols that require changing the functionality of the circuit dynamically. In the first case, a static compensation is necessary; in the second case, the needed device reconfiguration rate is rather low due to the currently limited brightness of multiphoton sources that require long measurement times. For this reason, thermal tuning is considered a convenient choice due to its simple implementation and its stability. In fact thermal shifters are widely employed in several integrated photonic platforms, from silicon photonics to silica-on-silicon^{9,11,28–30}; however, they have never been employed in femtosecond laser written circuits.

In this work we report on the fabrication, characterization and application of a reconfigurable integrated photonic circuit for quantum information at telecom wavelengths. Femtosecond laser micromachining is employed to inscribe waveguide Mach-Zehnder interferometers in a glass chip and to pattern gold resistive heaters on the chip surface. A reliable modeling of the thermal tuning is

reported, and a full experimental characterization of the response of the interferometers is performed by injecting coherent light. Moreover, tunable Hong-Ou-Mandel interference and super-resolved fringes based on N00N states are successfully demonstrated with two-photon input states.

II. MATERIALS AND METHODS

A. Fabrication of the integrated device

The fabrication process of the reconfigurable devices consists in three steps: fabrication of the threedimensional waveguide circuits by femtosecond laser writing, deposition of a gold layer on the surface of the sample, patterning of the surface metallic layer (again realized with femtosecond laser pulses) to define the resistor shape (see Fig. 1). Waveguides are fabricated in Corning EAGLE2000 alumino-borosilicate glass substrate using a Yb:KYW cavity-dumped mode-locked laser oscillator, that produces pulses with 1030 nm wavelength, 300 fs duration and 1 MHz repetition rate. To inscribe the waveguides, pulses with 330 nJ energy were used, focused by a $50 \times$ objective (NA = 0.6), with a translation speed of 20 mm s⁻¹ (three-axes translation stage, Aerotech ANT). The fabricated waveguides yield single mode operation at 1550 nm, with mode diameter $(1/e^2)$ of about 13.5 μ m and propagation losses of about 0.6 dB cm⁻¹. Such mode size enables coupling losses to standard single-mode telecom fibres of 0.2 dB per facet (retrieved from the overlap integral of the measured mode-intensity profiles for waveguides and fibres 34).

The interferometers are composed of two cascaded directional couplers, inscribed at 70 μ m depth below the substrate surface, in which the two waveguides are brought as close as 14 μm for a length of 200 μm to achieve a balanced splitting ratio. In between the two couplers, the waveguides are straight and separated by 1.02 mm for a 12-mm long segment. Such straight segments have different depth in the two arms: one is brought up to 25 μm depth, to be closer to the surface where resistors are placed, while the other is brought down to 115 μ m depth. Curved waveguide segments consist in sinusoidal bends, with a minimum curvature radius of 60 mm. The overall length of the chip is 45 mm; thickness is 1 mm. This geometry for the interferometers, which presents two quite long and well separated straight segments in the central part, was chosen to facilitate the characterization of thermal diffusion effects and model the operation of the thermal shifter, described in Sec. III A. Much more compact devices could be realized by choosing a smaller separation between the waveguides in the central part and by minimizing the length of the straight segments. Ablation lines were also machined on the substrate surface just after the waveguide inscription, to serve as alignment markers for the following processes.

A 50-nm gold layer was deposited on the substrate sur-

Figure 1. Femtosecond laser microfabrication process. (a) Direct writing of Mach-Zehnder interferometers in the bulk of a borosilicate slide. (b) After gold coating of the sample top surface, the resistors are patterned by ablation with the same femtosecond laser. Accurate alignment ($\sim 1~\mu m$) between the resistors and the Mach-Zehnder arms is achieved by reference markers inscribed on the glass surface together with the interferometers.

face using a sputter coater (Cressington 108auto). The resistor pattern was defined by laser ablation, focusing on the sample surface the same femtosecond laser beam used for waveguide inscription. Here 100 nJ pulses were employed, with a translation speed of 1 mm $\rm s^{-1}$. Each laser scan produces a 2.7 μ m wide ablation line in the gold layer, with negligible damage of the glass surface. To safely isolate each resistor from the neighbouring ones, nine successive scans, spaced by 0.5 μ m, were performed. Six rectangular resistors (0.3 mm wide and 20 mm long) were inscribed on the sample surface, terminating with larger areas employed to facilitate the electric connection to external circuits. Each resistor is placed just above one interferometer's arm. Some of the fabricated interferometers have two resistors, placed respectively above each of the two arms; other interferometers have been inscribed at different distances from the resistors, to allow a wider experimental investigation on the influence of the heaters

on interferometers in different geometric conditions.

Resistance of the fabricated heaters was measured, giving an average value of 67 Ω for the resistor and 13 Ω for the plates and connections. The chip was finally mounted on an aluminium base (4.5 cm×6 cm×1 cm) which serves as thermostat, to stabilize the boundary temperature during the device operation.

B. Characterization setup

The fabricated devices were first characterized with classical light input. To this purpose, light from a tunable laser source (Santec MLS-2000), set at 1550 nm wavelength, was injected in the chosen device input by a standard telecom fibre. The output light from the chip was collected by a 0.65 NA objective. For static measurements, both outputs of the interferometer were simultaneously monitored using two photodiode heads of a Coherent LabMaster Ultima power meter, while the driving voltage to the resistors was provided by a TDK-Lambda Zup 6-66 stabilized power supply. Both the optical power meter and the voltage supply were computer controlled and this allowed to completely automatize the voltage scans used to characterize the static thermal response of the interferometers. The same setup was used for the stability measurement. On the contrary, to measure the dynamic step response, the resistor was driven by a function generator (Textronix CFG 280) and an InGaAs photodiode (Thorlabs PDB410C) was used as detector, connected to an oscilloscope (Tektronix DPO 2024B); a single output of the interferometer was monitored for this measurement.

For the characterization with quantum light couples of horizontally-polarized identical photons were generated at 1550 nm wavelength, by spontaneous parametric down-conversion (SPDC), in a Type-I bismuth borate (BiBO) biaxial crystal³¹ (see Fig.2a). The crystal was pumped by 160 fs laser pulses at 76 MHz repetition rate, from a Ti:Sapphire oscillator (775 nm wavelength), with the possibility to switch to CW mode. Typical detected count rates were about 16 kHz for singles and 0.5 kHz for coincidences in pulsed regime with an incident power of 600 mW, and about 17 kHz for singles and 2 kHz for coincidences in CW mode with an incident power of 900 mW. A longpass (LPF) and a bandpass (BPF, 8.8 nm bandwidth centred at 1550 nm) interference filters were used in each of the two SPDC modes, to perform a narrow wavelength selection prior to injection into single mode-fibres for spatial selection. A pair of delay lines (see Fig. 2), equipped with a set of waveplates, was used for path synchronization and polarization compensation

Input and output coupling to the chip was carried out by a pair of fibre arrays, each mounted on a micrometric roto-translational stage.

Detection was performed by a pair of InGaAs/InP single-photon avalanche detectors (ID210 by ID Quantique). Coincidences were counted by an external elec-

tronic board, connected to a computer for data analysis. Details of the detectors operation are reported in Supplementary Note 1.

Indistinguishability of the downconverted photons was tested by performing Hong-Ou-Mandel (HOM) interference measurements in a symmetric 50/50 single-mode fibre beam-splitter, both in the pulsed and CW regimes. Raw visibility values were $\mathcal{V}_{\text{HOM}}^{(1,1)} = 0.967 \pm 0.002$ in the CW at 800 mW incident power and $\mathcal{V}_{\text{HOM}}^{(1,1)} = 0.923 \pm 0.004$ in the pulsed regime at 200 mW incident power ($V_{\text{HOM}}^{(1,1)} = 0.986 \pm 0.002$ and $\mathcal{V}_{\text{HOM}}^{(1,1)} = 0.994 \pm 0.006$ by correcting for the accidental coincidences, in CW and pulsed mode respectively), comparable to what has been observed in the literature 31,36. The visibility $\mathcal{V}_{\text{HOM}}^{(i,j)}$ is defined as $\mathcal{V}_{\text{HOM}}^{(i,j)} = (N_{\text{clas}}^{(i,j)} - N_{\text{quan}}^{(i,j)})/N_{\text{clas}}^{(i,j)}$, where $N_{\text{clas}}^{(i,j)}$ is the number of detected coincidences for distinguishable photons and $N_{\text{quan}}^{(i,j)}$ for indistinguishable photons. The superscript (i,j) stands for the number of photons i and j measured on the two output modes of the device.

III. RESULTS AND DISCUSSION

A. Device operation

A relative phase delay is induced between the two arms of the interferometer by the temperature increase caused by the resistive heater. Given the linearity of heat equation, which governs the heat diffusion from the resistor in the glass, the temperature variation in a certain point of the glass is proportional to the dissipated power \mathcal{P} (see Supplementary Note 2). The temperature-induced refractive index variation in the glass is also linear, at least in the limited temperature operation range that here is considered. Thus, the induced phase difference between the arms $\phi = \varphi_1 - \varphi_2$ is linear with \mathcal{P} .

Considering a single resistor acting on a single interferometer, for coherent light injected in one input, interference fringes will be observed monitoring the intensity of either one of the two outputs, following:

$$I_{\text{out}} = \frac{I_{\text{tot}}}{2} \left[1 + \mathcal{V} \cos \phi \right] = \frac{I_{\text{tot}}}{2} \left[1 + \mathcal{V} \cos \left(\Phi_0 + \alpha \mathcal{P} \right) \right]$$
(1)

where $I_{\rm tot}$ is the sum of the intensities on the two outputs, \mathcal{V} is the fringe visibility, Φ_0 is a phase term present in the interferometer when no power is applied to the heater and α is a constant which depends on all the geometric, thermal and optical properties of the interferometers. The fringe visibility is influenced by several factors, such as degree of coherence of the input light, splitting ratio of the directional couplers composing the interferometers and differential losses in the two arms. In addition, in case of ohmic resistive heaters, as in our case, one can write $\mathcal{P} = \Delta V^2/R$ where ΔV is the imposed voltage on the resistor and R the resistance value. Note that the phase depends on \mathcal{P} , but is independent

Figure 2. Setup for device characterization with quantum light in the telecom band. (a), Schematic of the two-photon source adopted in the experiment: pairs of photons are emitted in two different spatial modes and injected into single-mode fibres. L = Lens (50 cm focal length); P = Pinhole; BiBO = bismuth borate crystal; BPF = Band Pass filter; LPF = Long Pass Filter; PBS = Polarizing Beam Splitter; WPs = Wave Plates for polarization compensation. (b), The generated photons are then injected in spatial delay lines for temporal synchronization, propagating through a set of waveplates for polarization compensation. (c), Single mode fibre arrays (SMFA) are used to inject the photons in both the interferometer's inputs and to collect photons from both output modes. (d), Schematic of the integrated tunable Mach-Zehnder interferometer. The phase ϕ in the interferometer is controlled by tuning the driving voltage on the resistive heating plate, placed on the chip surface.

Figure 3. Experimental characterization of the interferometer operation with classical light at 1550 nm wavelength. The transmission of the interferometer in the cross-arm is plotted as a function of the thermal power dissipated by the resistor. The best fit of the data with the function reported in Eq. (1) is also shown as a solid line.

from the absolute values of the temperatures involved; i.e., thermal drifts of the environment do not affect the interferometer behaviour.

The response of the fabricated interferometers was experimentally characterized as a function of the heat dissipated on different resistors. To this purpose, laser light was fibre-coupled to one input of each interferometer and the optical power from both outputs was measured while varying the voltage across the resistor; this allowed us

to fit for each of them the relevant parameters, α , Φ_0 and \mathcal{V} , in Eq. (1). Figure 3 shows the normalized output intensity, $\overline{I} = I_{\text{out}}/I_{\text{tot}}$, for the interferometer as a function of the power dissipated by a resistor placed directly above its shallower arm. A best-fit of Eq. (1) yields $\alpha = 13.43 \text{ rad W}^{-1}$ and $\Phi_0 = 0.837 \text{ rad}$, while the fringe visibility is $V = 0.964 \pm 0.003$. The good agreement between the fitting curve and the experimental points confirms the linearity of the differential phase ϕ with the dissipated power, as theoretically discussed above. Although the Mach-Zehnder interferometer is nominally balanced, we observed a value $\Phi_0 \neq 0$. This can be explained by the fact that the two arms of the interferometer are written at different depth in the glass substrate. In fact, small variations in the spherical aberrations of the writing beam are responsible for a slightly different refractive index change induced in the two arms, thus introducing the Φ_0 phase bias.

The experimental calibration previously discussed is necessary to retrieve the precise α and Φ_0 values for a given device; however, it may be also desirable to develop simple models to estimate a priori the thermal response of the interferometers, at least for certain standard circuit geometry. In fact, this would greatly facilitate the design of more complex reconfigurable circuits. We will discuss in the following a simple analytical model that applies to our circuit layout.

Assuming a wire-like heater and neglecting power dissipation from the top surface of the glass (air is an insulator) a logarithmic decay law for the temperature, as a function of the distance from the heater, can be easily worked out (see Supplementary Note 2). The latter

approximates well the temperature distribution around the resistor, as confirmed by comparison with a numerical simulation of the heat diffusion (see Supplementary Figure S - 1). Within this simplified model, an analytic expression for α in Eq. (1) can also be derived, given the distances ρ_1 and ρ_2 of the two interferometer's arm from the heater:

$$\alpha = \frac{2n_T}{\lambda} \frac{1}{\kappa} \frac{L_{\text{arm}}}{L_{\text{wire}}} \ln \frac{\rho_1}{\rho_2} \tag{2}$$

where κ is the thermal conductivity of the glass substrate, n_T is its thermo-optic coefficient, λ is the wavelength, $L_{\rm arm}$ is the length of the straight segments in the interferometer's arms and $L_{\rm wire}$ is the length of the wire-like heater. The α coefficients were experimentally characterized for different couples of interferometers and resistors, having different ratios of ρ_1 over ρ_2 . Eq. (2) was found to predict the experimental values with an average accuracy of 10% (see Supplementary Figure S - 2). Thus, this simple model can be used as a robust approximation for designing circuits and estimating the influence of the wire-like resistive heaters on interferometers placed at different distances.

In case of several resistive heaters (and several interferometers) on the same substrate, cross-talks are possible on each interferometer due to the combined effects of the different heaters. However, from the linearity of heat equation, one can easily infer the phase ϕ induced on a single interferometer as:

$$\phi = \varphi_1 - \varphi_2 = \Phi_0 + \sum_i \alpha_i \mathcal{P}_i \tag{3}$$

where \mathcal{P}_i are the dissipated powers from the different resistors. Note that the interferometer is influenced in principle by all the heaters, but with different constants, depending on the geometric configuration. Of course, α_i for distant heaters is expected to be negligible. However, the influence of each heater to each interferometer could be characterized independently (thus characterizing the various α_i) and the combined behaviour could be predicted just by adding the different contributions. This was confirmed experimentally by measuring the output of an interferometer under the action of two heaters, one placed above its shallower arm and one placed above its deeper arm (see Supplementary Figure S - 3), and showing that the response can be accurately predicted even in the case of strong cross-talks of different heaters on the same interferometer.

The operation of multiple heaters on the same chip is not a problem also from the heat sinking point of view; in fact, the power that needs to be dissipated will be rather low, thanks to the fact that a 2π phase shift in a single interferometer is achieved with only 0.5 W (see Fig. 3). In addition, the circuit reconfiguration, even for a repeated number of times, did not affect the alignment between the chip and the input optical fibres. In fact, the induced temperature variations are in the order of ten degrees Celsius and localized around the heater; thus,

they do not induce significant deformation of the whole chip.

In applications such as quantum optics experiments, where measurements may take from several minutes to several hours or days, operation stability for a reconfigurable circuit is crucial. The operation of the interferometer has been monitored for 10 hours under constant voltage driving conditions, imposing a phase of about $\pi/2$ where the sensitivity to variations in voltage is maximum (see Supplementary Figure S - 4): observed phase fluctuations have been smaller than 0.01 rad with no evidence of drifts. Finally, the response of the device to a voltage step has been also characterized (see Supplementary Figure S - 5), showing a rise time of \sim 0.9 s (10% to 90% of the variation). This means that the circuit is completely settled on a new configuration within a few seconds.

B. Two-photon interference

The overall action U^{theo} of an ideal Mach-Zehnder interferometer on the input-output modes $b_i^{\dagger} = \sum_j U_{i,j}^{\mathrm{theo}} a_j^{\dagger}$, being a_i^{\dagger} and b_i^{\dagger} the field operators for the input and output modes respectively, is described by:

$$U^{\text{theo}} = \begin{pmatrix} \sin \phi & \cos \phi \\ \cos \phi & -\sin \phi \end{pmatrix} \tag{4}$$

where a global phase factor $ie^{-i\phi/2}$ has been removed.

We first measured single-photon fringe patterns, by injecting an heralded single photon in input port 1 and by measuring the triggered count rate at output port 2 (see Fig. 4a). The measured raw visibility was $\mathcal{V} =$ 0.930 ± 0.006 ($\mathcal{V} = 0.981 \pm 0.007$ correcting for the accidental coincidences), compatible with the one performed with classical light. We then recorded the interference fringes obtained by injecting two photons into the device in a $|1,1\rangle$ state, where $|i,j\rangle$ stands for i(j) photons on input port 1 (2). In this case, after the first beamsplitter the state evolves into a two-photon N00N state, $\propto (|2,0\rangle - |0,2\rangle)$. The action of the phase shift changes the state into $\propto (|2,0\rangle - e^{-i2\phi}|0,2\rangle)$. The fringe pattern recorded in the two-fold coincidences after the recombination in the second beam-splitter, corresponding to the measurement of the (1,1) output state, lead as expected to a halved period with respect to the single-photon case. The experimental fringe pattern is shown in Fig. 4b. We measured an experimental raw visibility $\mathcal{V}_{N00N}^{(1,1)} =$ $0.864 \pm 0.007 \; (\mathcal{V}_{\rm N00N}^{(1,1)} = 0.913 \pm 0.006 \; {\rm by \; subtracting \; the}$ accidental coincidences), showing the correct operation of the integrated interferometer. The visibility $\mathcal{V}_{\text{N00N}}^{(i,j)}$ is defined as $\mathcal{V}_{\text{N00N}}^{(i,j)} = (N_{\text{max}}^{(i,j)} - N_{\text{min}}^{(i,j)})/(N_{\text{max}}^{(i,j)} + N_{\text{min}}^{(i,j)})$, where the subscripts refer to the maximum and the minimum number of coincidences measured scanning the phase ϕ .

We then measured the events in which the two photons emerge from the same output port 2, by connecting it to a symmetric 50/50 fiber beam-splitter and by

Figure 4. (a), Experimental measurement of a single-photon fringe pattern for input mode 1 and output mode 2, as a function of the dissipated power. Points: normalized counts. Solid red curve: best fit of the measured data with a sinusoidal function. Horizontal red line: estimated contribution of accidental coincidences. (b), Experimental fringe pattern for a two-photon input $|1,1\rangle$ as a function of the dissipated power. Blue points: normalized coincidences of the output (1, 1), with one photon for each output port; statistics of the recorded data was ~ 1200 coincidences for the fringe maximum in 120s. Green points: normalized coincidences of the output (0, 2), with two photons on output port 2; statistics of the recorded data was ~ 600 coincidences for the fringe maximum in 180s. Both fringes show twice the periodicity of single-photon ones (dashed red curve). Solid lines: best fit of the measured data with a sinusoidal function. Horizontal blue and green lines: estimated contribution of accidental coincidences. The error bars are given by Poissonian statistics.

collecting two-fold coincidences between the output of the beam-splitter. The results are shown in Fig. 4b: the (0,2) output contribution exhibits the same superresolved two-fold pattern with opposite relative phase with respect to the (1,1) contribution. The measured visibility was $\mathcal{V}_{\text{N00N}}^{(0,2)} = 0.882 \pm 0.008$, which increases up to $\mathcal{V}_{\text{N00N}}^{(0,2)} = 0.949 \pm 0.007$ by subtracting the contribution from accidental coincidences.

To assess the non-classicality of the observed superresolved two-photon interference fringes, we applied a recently proposed criterion³⁷, which compares the visibility of the pattern with what can be achieved with classical

Figure 5. Hong-Ou-Mandel interference experiment for input state $|1,1\rangle$ at $\Delta V \simeq 1.97$ V ($\phi \sim \pi/2$). Blue Points: coincidences for output (1,1). Green points: coincidences of output (0,2). Solid lines: best fit of the measured data. Horizontal lines: levels for the contribution of accidental coincidences. The error bars are given by Poissonian statistics.

light. While it is possible to obtain fringes oscillating as 2ϕ with perfect visibility $\mathcal{V}^{(1,1)}=1$ with appropriately tailored classical light measuring the (1,1) output contribution, the maximum achievable visibility for the (0,2) output contribution is bounded to $\mathcal{V}_{\rm cl}^{(0,2)}<1/3$. The raw visibility $\mathcal{V}_{\rm N00N}^{(0,2)}$ measured with two-photon input exceeds the classical bound by more than 68 standard deviations (88 for the corrected value $\mathcal{V}_{\rm N00N}^{(0,2)}$), thus showing the quantumness of the observed effect.

We finally performed a Hong-Ou-Mandel interference experiment for a voltage set to $\Delta V \simeq 1.97$ V, corresponding to $\phi \simeq \pi/2$, where the interferometer behaves as a 50/50 beam-splitter. We measured both the (1,1) and (0,2) output contributions as a function of the optical delay between the photons, leading to experimental raw visibilities of $\mathcal{V}_{\rm HOM}^{(1,1)}=0.876\pm0.010$ and $\mathcal{V}_{\rm HOM}^{(0,2)}=-0.925\pm0.039$ respectively ($V_{\rm HOM}^{(1,1)}=0.886\pm0.010$ and $\mathcal{V}_{\rm HOM}^{(0,2)}=-0.976\pm0.041$ by correcting for the accidental coincidences). We attribute the reduced visibility to a voltage set slightly different from the one corresponding to a 50/50 beam splitter.

C. Tomography of the interferometer

To fully characterize the action of the interferometer, we performed the tomography of the corresponding unitary transformation for different values of the phases ϕ . Tomography of linear transformation can be performed by applying a recently proposed method 38,39 based on single-photon probability measurements, or equivalently intensity measurements with classical light, and on two-photon interference Hong-Ou-Mandel experiments. The action of the unitary linear transformations can then be retrieved by applying a suitable analytical 39 , numerical 38 or hybrid 12 algorithm.

In Fig. 6 we report the results of the tomographic char-

Figure 6. Tomography of the interferometer for different values of the phase ϕ . (a), Tomography for $\phi \simeq 2.08$. (b), Tomography for $\phi \sim \pi$, where the interferometer behaves as the identity with an additional (-1) phase factor on mode 2. (c), Tomography for $\phi \sim 3\pi/2$: the interferometer behaves as a symmetric 50/50 beam splitter. (d), Tomography for $\phi \sim 2\pi$: the interferometer behaves as a SWAP gate, exchanging modes 1 and 2. For each panel: red bars correspond to the reconstructed unitary $U^{\rm exp}$ while green bars correspond to the ideal unitary $U^{\rm theo}$. Light red bars correspond to the error in the reconstruction process.

acterization of the device for 4 different relevant values of the phase. We observe a very good agreement between the expected behaviour and the measured one. The average gate fidelity $F=1/2|{\rm Tr}[(\underline{U}^{\rm theo})^{\dagger}U^{\rm exp}]|$, calculated for 12 different values of ϕ , is $\overline{F}=0.998\pm0.001$, thus showing the quality of the fabrication process.

IV. CONCLUSIONS

We have demonstrated the fabrication by femtosecond lasers of an integrated Mach-Zehnder interferometer at an operating wavelength of 1550 nm, which can be dynamically reconfigured by thermal shifters. Measurements with classical light, single-photons and two-photon states confirm the correct functioning of the device, including the observation of quantum interference fringes corresponding to a two-photon N00N state. Full charac-

terization of the thermal response of the interferometric circuit has also been performed, showing good agreement with what expected from fabrication design. This device represents a possible building block of future reconfigurable quantum circuits in the telecom band, paving the way to the use of integrated photonic devices to implement large quantum networks.

While this work was being written, reconfigurable operation of a femtosecond laser written interferometer at 800 nm wavelength was reported⁴⁰.

SUPPLEMENTARY NOTE 1 - DETAILS OF THE SINGLE-PHOTON DETECTORS OPERATING MODE

To achieve best performance, the SPADs (ID210 by ID Quantique) were used in two different operating modes: one was employed in free-running mode, while the other operated in external gating mode, triggered by the output of the first detector, thus significantly reducing the dark count rate (DCR). In free-running mode, the SPADs' efficiency was set to 10% and the best SNR ratio was attained by setting the dead time at 30 μ s giving a 2.5 kHz DCR. The gated detector was set at 100 μ s dead time and 25% efficiency, giving rise to a DCR of less than 2 Hz. In order to compensate the delay of \sim 70 ns induced by the detection and the output pulse emission in the first detector, a 15 m single mode fibre together with a tunable internal gate delay were employed in the gated detector's path.

SUPPLEMENTARY NOTE 2 - MODELLING THE THERMAL DIFFUSION

For a general arbitrary configuration of heat sources and materials, heat diffusion is governed by:

$$q(\vec{r},t) = -\kappa(\vec{r}) \nabla^2 T(\vec{r},t) + c(\vec{r}) \frac{\partial T(\vec{r},t)}{\partial t} \tag{S-1} \label{eq:S-1}$$

where $T(\vec{r},t)$ gives the temperature distribution, $q(\vec{r},t)$ is the thermal power generated per unit volume, $\kappa(\vec{r})$ is the thermal conductivity of the material and $c(\vec{r})$ is the heat capacity per unit volume.

Let us analyse the static case, in which we drop the time dependency in Eq. (S-1). In case of heat generated by a single resistor with a given geometry, dissipating a thermal power \mathcal{P} , linearity of Eq. (S-1) implies a solution of the form:

$$T(\vec{r}) = T_0 + \mathcal{P} g(\vec{r}) \tag{S-2}$$

where T_0 is a base temperature which depends on boundary conditions (it can be assumed as the environment temperature) and $g(\vec{r})$ is a proper spatial function, which depends on the geometry of the resistor. For limited temperature modulations, the dependence of the material refractive index on the temperature can be assumed linear and expressed by means of the thermo-optic coefficient of the material n_T as $n(\vec{r}) = n_0(\vec{r}) + n_T (T(\vec{r}) - T_0)$. It is then easy to show that the phase delay accumulated by light propagating in an arbitrary waveguide segment is a linear function of the dissipated power \mathcal{P} as follows:

$$\varphi(P) = \varphi_0 + \frac{2\pi}{\lambda} \mathcal{P} n_T \int_L g(\vec{r}) dl$$
 (S-3)

with $\varphi_0 = \frac{2\pi}{\lambda} \int_L n_0(\vec{r}) dl$. Therefore, considering a Mach-Zehnder interferometer, the difference between the phase delays φ_1 and φ_2 accumulated in the two arms can be written as:

$$\phi = \varphi_1 - \varphi_2 = \Phi_0 + \alpha \mathcal{P} \tag{S-4}$$

being Φ_0 an offset phase, present in the interferometer when no power is applied to the heater and

$$\alpha = \frac{2\pi}{\lambda} n_T \left(\int_{L_1} g(\vec{r}) dl - \int_{L_2} g(\vec{r}) dl \right)$$
 (S-5)

The integrals $\int_{L_1} g(\vec{r}) dl$ and $\int_{L_2} g(\vec{r}) dl$ are performed respectively along the paths of the first and second arm of the interferometer.

We will now discuss a simple analytical model that allows to estimate approximately the value of α for the device layout adopted in our experiments. We have chosen to use resistive heaters much longer than wide, that are assimilable to wires. In a reference system with polar coordinates ρ, θ centred on one wire, the expression of the heat source is $q = \delta(\rho)$. If such wire is surrounded by a totally isotropic medium, the thermal diffusion follows a cylindrical symmetry and the solution to Eq. (S-1) would be:

$$T = C_1 - C_2 \ln \rho \tag{S-6}$$

with proper integration constants C_1, C_2 dependent on the boundary conditions. In this configuration the heat diffuses radially; if we consider, for instance, a virtual horizontal surface, the temperature gradient is always parallel to it and there is no net heat flux through such surface. Here, the wire-like heater is deposited on a surface which acts as interface between a strong insulator (air, with thermal conductivity $\kappa_{\rm air} \simeq 0.026 \ {\rm Wm^{-1}K^{-1}})$ and a thermal conductor (glass, with thermal conductivity $\kappa_{\rm glass} \simeq 1~{\rm Wm^{-1}K^{-1}} \gg \kappa_{\rm air}$). The heat dissipated in air is negligible with respect to the heat diffused in the glass. Thus, we can approximate the temperature distribution in glass with that calculated in the isotropic case (Eq. (S-6)), but considering all the heat generated by the wire as dissipated on the glass side. In addition, we will consider that the temperature-induced phase change is active only on the straight segments of the interferometer's arms, placed respectively at distance ρ_1 and ρ_2 from the hot wire. Within these approximations, it is easy to derive:

$$\alpha = \frac{2n_T}{\lambda} \frac{1}{\kappa} \frac{L_{\text{arm}}}{L_{\text{wire}}} \ln \frac{\rho_1}{\rho_2}$$
 (S-7)

where $L_{\rm arm}$ is the length of the straight segments in the interferometer's arms and $L_{\rm wire}$ is the length of the wirelike heater.

Supplementary Figure S - 1. (a) Numeric simulation of the temperature distribution inside the glass, considering an infinite-length, 300 μm wide, heater, placed on the top surface. The heater and the base of the glass are assumed at uniform (different) temperatures. (b) Temperature distribution for a wire-like heater, assuming a logarithmic decaying law $(T = C_1 - C_2 \log \rho)$ with the distance from the heater. Constant C_2 is chosen so that the dissipated power through the glass is the same as in the case of the numeric simulation. Constant C_1 is just an additive term which has no influence on the shape of the distribution and is chosen to fit the values of the numeric simulation. Temperature distributions in (a) and (b) are normalized to the same color scale (reported). (c) Absolute values of the relative difference between temperature values in the graphs (a) and (b). White corresponds to null difference, black to difference larger than 10%. The simple logarithmic model appears to predict quite accurately the temperature distribution in a region \sim 1.5 mm wide and \sim 0.5 mm deep around the heater.

Supplementary Figure S - 2. (a) Conceptual picture of the geometry of the fabricated device layout: each interferometer has two arms (waveguides represented as blue circles in the picture), one shallower and one deeper. On the glass surface several heaters are realized (orange rectangles in the picture), placed at different distances ρ_1 and ρ_2 with respect to the two waveguides. (b) Experimental values for the modulus of the α coefficients, measured for interferometers and thermal shifters with different distances between the resistor and the two interferometer arms; the values are plotted as a function of $|\ln \frac{\rho_1}{\rho_2}|$. The expected trend is also reported (solid line), which is obtained by substituting in Eq. (S-7) the values $\lambda=1.55~\mu\text{m},~n_T=1\times10^{-5}~\text{K}^{-1},~L_{\text{arm}}=12~\text{mm},~L_{\text{wire}}=20~\text{mm},~\kappa=0.9~\text{W}~\text{m}^{-1}~\text{K}^{-1}$ found in the literature. Dashed lines delimit a $\pm10\%$ region around the expected trend line; most experimental points fall within this region.

Supplementary Figure S - 3. An interferometer is characterized under the simultaneous action of two different heaters. The graph on the left reports the experimentally retrieved phase $\phi_{\rm exp}$ for 361 different couples of values of dissipated powers on the two heaters. It is noted that the measured values lie on a plane, thus confirming the possibility to express the interferometer's response as a linear superposition of the effects of each resistor. The graph on the right plots, for comparison, the ideal phase $\phi_{\rm th} = \Phi_0 + \alpha_1 \mathcal{P}_1 + \alpha_2 \mathcal{P}_2$ predicted from the values $\alpha_1 = 13.16$ rad W⁻¹, $\alpha_2 = -8.77$ rad W⁻¹ and $\Phi_0 = -0.17$ rad, characterized previously on the same interferometer by acting on one resistor at once. Standard error between the two graphs is 0.11 rad.

Supplementary Figure S - 4. Phase-stability measurement under constant driving voltage of the Mach-Zehnder interferometer.

Supplementary Figure S - 5. Measured time response of the Mach-Zehnder interferometer to an instantaneous voltage step on the heater, from 1.5 V to 2.5 V. Coherent light is coupled to one input and phase ϕ is retrieved by measuring the transmitted light power with a fast photodiode. Rise time (10% to 90%) is \sim 0.9 s.
