Abstract

The problem of practical preparing small impedance particles with a prescribed boundary impedance is formulated and its importance in physics and technology is discussed. It is shown that if this problem is solved then one can easily prepare materials with a desired refraction coefficient and materials with a desired radiation pattern.

1 Introduction

In this section the basic problem of practical preparing (producing, manufacturing) of small impedance particles is discussed. Wave scattering by many small impedance particles is developed in [3], where the basic physical assumption is $a \ll d \ll \lambda$. Here a is the characteristic size of the small particles, d is the minimal distance between neighboring particles, and λ is the wave length in the medium. We refer for this theory to [3]. It is proved there that if one prepares many small particles with prescribed boundary impedance and embed these particles with a specified in [3] density in a given material, then one obtains a material whose refraction coefficient approximates any desired refraction coefficient with an arbitrary small error. In particular, one can create meta-materials. How to embed small particles into a given material physicists know. Therefore the basic practical problem of preparing many small impedance particles with prescribed boundary impedance is of great interest both technologically and physically.

In section 2 the basic definitions are given. It is explained what a small particle is, what an impedance particle is, what a boundary impedance is.

In section 3 a recipe for creating materials with a desired refraction coefficient is formulated. This recipe is taken from [3].

2 Basic definitions

Let $D_1 \subset \mathbb{R}^3$ be a bounded domain with a connected smooth boundary S_1 , $D'_1 := \mathbb{R}^3 \setminus D_1$ be the unbounded exterior domain and S^2 be the unit sphere in \mathbb{R}^3 .

Consider the scattering problem:

$$(\nabla^2 + k^2 n_0^2)u = 0 \quad \text{in } D'_1, \quad u_N = \zeta_1 u \quad \text{on } S_1, \quad u = e^{ik\alpha \cdot x} + v, \quad (1)$$

where $k > 0$ is the wave number, a constant, $\alpha \in S^2$ is a unit vector in the direction of the propagation of the incident plane wave $e^{ik\alpha \cdot x}$, N is the unit normal to S_1 pointing out of D_1 , u_N is the normal derivative of u , ζ_1 is the boundary impedance, $\text{Im}\zeta_1 \leq 0$, $n_0 > 0$ is the refraction coefficient of the small impedance particle D , n_0 is a constant, the scattered field v satisfies the radiation condition

$$v_r - ikv = o\left(\frac{1}{r}\right), \quad r := |x| \rightarrow \infty. \quad (2)$$

The scattering amplitude $A(\beta, \alpha, k)$ is defined by the following formula:

$$v = A(\beta, \alpha, k) \frac{e^{ikr}}{r} + o\left(\frac{1}{r}\right), \quad r := |x| \rightarrow \infty, \quad \frac{x}{r} = \beta, \quad (3)$$

where $\alpha, \beta \in S^2$, β is the direction of the scattered wave, α is the direction of the incident wave. A particle of a characteristic size a is called small if it is much smaller than the wave length, $kn_0 a \ll 1$.

The function $A(\beta, \alpha, k)$ is called the scattering amplitude. It is known (see [1], p.25, or [2]) that the solution to the scattering problem (1)-(3) does exist and is unique.

If there are many small impedance particles D_j , embedded in a bounded domain D filled with material whose refraction coefficient is n_0 , then the wave scattering problem can be formulated as follows:

$$(\nabla^2 + k^2 n_0^2)u = 0 \quad \text{in } D \quad (4)$$

$$u_N = \zeta_m u \quad \text{on } S_m, \quad 1 \leq m \leq M, \quad (5)$$

$$u = u_0(x) + v, \quad (6)$$

where the scattered field v satisfies the radiation condition, $\text{Im}\zeta_m \leq 0$, M is the total number of the embedded particles. The incident field u_0 is assumed known. It satisfies equation (4) in \mathbb{R}^3 , and as was noted earlier, $n_0 = 1$ in D' . For simplicity we assume that all small particles are of the same characteristic size a .

Let G be the Green's function of the scattering problem in the absence of the embedded particles. Outside D the refraction coefficient assume to be equal to 1. Assume that the distribution of small particles is given by the formula

$$\mathcal{N}(\Delta) = \frac{1}{a^{2-\kappa}} \int_{\Delta} N(x) dx [1 + o(1)], \quad a \rightarrow 0, \quad (7)$$

where $\mathcal{N}(\Delta)$ is the number of particles in an arbitrary open subset of D , $N(x) \geq 0$ is a given continuous function, $\kappa \in [0, 1)$ is a number, and the boundary impedance is defined as follows:

$$\zeta_m = \frac{h_m}{a^\kappa}, \quad (8)$$

where $\text{Im}h_m \leq 0$, $h_m := h(x_m)$, $x_m \in D_m$ is an arbitrary point and $h(x)$ is a given continuous function in D . This function, number κ and the function $N(x)$ can be chosen by the experimenter. It is proved in [3]. p. 48, that the field u in D satisfies, as $a \rightarrow 0$, the following integral equation:

$$u(x) = u_0(x) - c_0 \int_D G(x, y) h(y) N(y) dy, \quad c_0 := \mathcal{S}/a^2, \quad (9)$$

where \mathcal{S} is the surface area of a small particle, $h(x)$ and $N(x)$ are defined in (7)-(8). For simplicity we assume here that \mathcal{S} is the same for all small particles. It follows from (9) that the new refraction coefficient in D , which one gets after embedding many small impedance particles, is

$$n(x) = [n_0^2 - c_0 k^{-2} h(x) N(x)]^{1/2}. \quad (10)$$

Since $h(x)$ and $N(x)$ are at our disposal, one can get by formula (10) any desirable refraction coefficient, such that $\text{Im}n^2(x) \geq 0$.

Why the equation (5) should make sense physically regardless of the size of the particle? because a problem whose solution exists and is unique must have sense physically.

Why the small impedance particles with a prescribed boundary impedance should exist?

Because the particles with $\zeta = \infty$, acoustically hard particles, do exist; the particles with $\zeta = 0$, acoustically soft particles, do exist. Small particles with any "intermediate" value of the boundary impedance should also exist. The problem we raise is how to produce practically (fabricate) such particles.

3 Recipe for creating material with a desired refraction coefficient

Let us formulate the result in the following theorem:

Theorem 1. *Given $n_0^2(x)$ and a bounded domain Ω , one can create in Ω a material with a desired refraction coefficient $n(x)$, $\text{Im}n^2(x) \geq 0$, by embedding $M = O(\frac{1}{a^{2-\kappa}})$ small impedance particles according to the distribution law (7). The refraction coefficient $n_a(x)$, corresponding to a finite a , approximates the desired refraction coefficient $n(x)$ in the sense*

$$\lim_{a \rightarrow 0} n_a(x) = n(x). \quad (11)$$

The functions $h(x)$ and $N(x)$ defined in (7)-(8) are found by the Steps 1, 2 of the Recipe formulated below; see als p. 53 in [3].

Finally, let us discuss briefly the possibility to create material with negative refraction coefficient. By formulas (3.1.1) and (3.1.2) in [3] one gets $n(x) < 0$ if the argument of $n_0^2(x) - k^{-2} c_0 N(x) h(x)$ is equal to 2π . Assume that $n_0^2(x) > 0$. We know that $k^{-2} c_0 N(x) \geq 0$. Let us take $h(x) = |h(x)| e^{i\varphi}$, where $\varphi > 0$ is very small, that is, $\text{Im}h(x) \geq 0$ and $\text{Im}h(x)$ is very small. One proves (see also [3], p.52) that equation (9) is uniquely solvable for $\text{Im}h \geq 0$ sufficiently small. For such $h(x)$ one has $\arg(n_0^2(x) - k^{-2} c_0 N(x) h(x))$ is very close to 2π and the square root in (10) is negative, provided that $\text{Re}(n_0^2(x) - k^{-2} c_0 N(x) h(x)) > 0$. This argument shows that it is possible to create materials with negative refraction coefficient

$n(x)$ by embedding in a given material many small particles with properly chosen boundary impedances.

A recipe for creating materials

Problem 1. Given a material with known $n_0(x)$ in a bounded domain D and $n_0(x) = 1$ in D' , one wants to create in D a material with a desired $n(x)$.

Step 1. Given $n_0^2(x)$ and $n^2(x)$, calculate $p(x) := k^2[n_0^2(x) - n^2(x)]$. This is a trivial step.

Step 2. Given $p(x)$ calculate $h(x)$ and $N(x)$ from the equation $p(x) = c_0 h(x) N(x)$. The constant c_0 one can take to be $c = 4\pi$ if the small particles are balls of radius a . This we can assume without loss of generality if we are interested in creating materials with a desired refraction coefficient.

There are infinitely many solutions h and N to the above equation. For example, one can fix arbitrarily $N(x) > 0$ in D , $N(x) = 0$ in D' , and find $h(x) = h_1(x) + ih_2(x)$ by the formulas $h_1(x) = \frac{p_1(x)}{4\pi N(x)}$, $h_2(x) = \frac{p_2(x)}{4\pi N(x)}$. Here $p_1(x) = \text{Rep}(p(x))$, $p_2(x) = \text{Imp}(p(x))$.

Note that $\text{Im}n^2(x) \geq 0$ implies $\text{Im}h(x) \leq 0$, so our assumption $\text{Im}h(x) \leq 0$ is satisfied. For example, one may take $N(x) = \text{const} > 0$.

Step 2 is also trivial.

Step 3. Given $N(x)$ and $h(x) = h_1(x) + ih_2(x)$, distribute $M = O(\frac{1}{a^{2-\kappa}})$ small impedance balls of radius a in the bounded region D according to the distribution law (7), where $\kappa \in [0, 1)$ is the number (parameter) that can be chosen by the experimenter. Note that condition $d \gg a$ is satisfied automatically for the distribution law (7). Indeed, if d is the minimal distance between neighboring particles, then there are at most $\frac{1}{d^3}$ particles in a cube with the unit side, and since D is a bounded domain there are at most $O(\frac{1}{d^3})$ of small particles in D . On the other hand, by the distribution law (7) one has $\mathcal{N}(D) = O(\frac{1}{a^{2-\kappa}})$. Thus $O(\frac{1}{d^3}) = O(\frac{1}{a^{2-\kappa}})$. Therefore $d = O(a^{\frac{2-\kappa}{3}})$. Consequently, condition $a \ll d \ll \lambda$ is satisfied, $\lambda = \frac{2\pi}{kn_0}$. Moreover $\lim_{a \rightarrow 0} \frac{a}{d(a)} = 0$.
