ABSTRACT

We present a detailed spectroscopic study of the optical counterpart of the neutron star X-ray transient Aquila X-1 during its 2011, 2013 and 2016 outbursts. We use 65 intermediate resolution GTC-10.4m spectra with the aim of detecting irradiationinduced Bowen blend emission from the donor star. While Gaussian fitting does not yield conclusive results, our full phase coverage allows us to exploit Doppler mapping techniques to independently constrain the donor star radial velocity. By using the component N III 4640.64/4641.84 Å we measure $K_{\text{em}} = 102 \pm 6$ km s⁻¹. This highly significant detection ($\geq 13\sigma$) is fully compatible with the true companion star radial velocity obtained from near-infrared spectroscopy during quiescence. Combining these two velocities we determine, for the first time, the accretion disc opening angle and its associated error from direct spectroscopic measurements and detailed modelling, obtaining $\alpha = 15.5_{-5}^{+2.5}$ deg. This value is consistent with theoretical work if signifiicant X-ray irradiation is taken into account and is important in the light of recent observations of GX339-4, where discrepant results were obtained between the donor's intrinsic radial velocity and the Bowen-inferred value. We also discuss the limitations of the Bowen technique when complete phase coverage is not available.

Key words: X-rays: binaries – accretion, accretion discs – stars: neutron

INTRODUCTION

Low-mass X-ray binaries (LMXBs) are stellar systems comprising a low-mass star $(\leq 1 \text{ M}_\odot)$ which transfers matter on to a compact object (either a neutron star or a black hole) via an accretion disc. Depending on their long-term behaviour we can distinguish between persistent systems, those constantly accreting material at high rates, and transient systems, which spend the majority of their lives in a dormant, quiescent state. The latter show sporadic outbursts lasting weeks to years, when their X-ray luminosity increases typically to > 10 per cent of the Eddington luminosity, becoming at least as bright as persistent sources (e.g. [van der](#page-6-0)

[Klis](#page-6-0) [2006;](#page-6-0) [Belloni et al.](#page-5-1) [2011;](#page-5-1) Fender & Muñoz-Darias [2016](#page-5-2) for reviews).

Classical dynamical studies of LMXBs rely on the spectroscopic detection of the companion star at optical and/or near-infrared wavelengths (e.g. [Charles & Coe](#page-5-3) [2003;](#page-5-3) [Casares](#page-5-4) [& Jonker](#page-5-4) [2014\)](#page-5-4). However, the optical counterparts of most transient LMXBs are faint in quiescence $(V > 22-23)$ and to obtain phase-resolved spectra during this epoch is not always an easy task. In addition, even if optical spectroscopy is feasible, the companion star features might be veiled by the disc emission (e.g. Mata Sánchez et al. [2015b\)](#page-5-5). The situation is even more complex during outburst, when the radiation coming from the outer accretion disc generally dominates even in the near-infrared (Mata Sánchez et al. [2015a\)](#page-5-6).

The so-called Bowen technique was developed to measure the orbital motion of the donor star using narrow fluo-

[?] [E-mail: felipeji@iac.es](#page-6-0)

rescence lines within the Bowen blend region, a typical spectral feature of LMXBs in outburst. In a few key systems, it has been shown that these narrow components originate as a result of the X-ray reprocessing on the irradiated side of the donor. Thus, a lower limit to the radial velocity of the companion (K_2) can be established by measuring Doppler shifts from these emission components (i.e *K*em, [Steeghs & Casares](#page-6-1) [2002,](#page-6-1) see also Muñoz-Darias et al. [2007](#page-6-2) for Bowen blend time-lags consistent with the donor star). Narrow emission lines in the Bowen region have been observed in a dozen or so objects [\(Cornelisse et al.](#page-5-7) [2008;](#page-5-7) [Mu˜noz-Darias](#page-6-3) [2009\)](#page-6-3), which led to the first estimate of the system parameters in three transient systems in outburst (e.g. [Wang et al.](#page-6-4) [2017\)](#page-6-4) and several persistent sources (e.g. [Casares et al.](#page-5-8) [2006\)](#page-5-8).

Aquila X-1 (Aql X-1) is a neutron star transient LMXB that has shown recurrent outbursts since its discovery by [Friedman et al.](#page-5-9) [\(1967\)](#page-5-9). It has a short outburst recurrence time of ∼ two years, being one of the most prolific and widely studied X-ray transients (e.g. [Miller-Jones et al.](#page-5-10) [2010;](#page-5-10) [Coti](#page-5-11) [Zelati et al.](#page-5-11) [2014;](#page-5-11) Muñoz-Darias et al. [2014\)](#page-6-5). During the 2004 outburst, [Cornelisse et al.](#page-5-12) (2007) constrained K_2 by using the Bowen technique, and obtained $K_{\text{em}} = 247 \pm 8 \text{ km s}^{-1}$. This result is no longer compatible with the dynamical solution derived from near-infrared spectroscopy taken during quiescence Mata Sánchez et al. [\(2017,](#page-5-13) hereafter [MS2017\)](#page-5-13). The discrepancy could result from spurious emission coming from localised regions of the disc that contribute to the Bowen blend [\(Hynes et al.](#page-5-14) [2004\)](#page-5-14). Similarly, a recent spectroscopic study of the black hole transient GX 339-4 [\(Heida](#page-5-15) [et al.](#page-5-15) [2017\)](#page-5-15) during one of its short quiescence epochs ruled out a companion star origin for the *K*em reported by [Hynes](#page-5-16) [et al.](#page-5-16) [\(2003\)](#page-5-16). Both the Aql X-1 and GX 339-4 outburst studies have in common a limited phase coverage.

In this paper we present phase-resolved optical spectroscopy of Aql X-1 taken during the 2011, 2013 and 2016 outbursts. We take advantage of a complete phase coverage to exploit the Doppler mapping technique in order to accurately determine *K*em, deriving a value which is now fully compatible with the near-infrared measurement. Subsequently, we use K_2 from $MS2017$ and the ratio between K_{em} and K_2 (K_c ; as defined in Muñoz-Darias et al. [2005,](#page-6-6) hereafter [MD2005\)](#page-6-6) to determine the opening angle of the accretion disc, therefore constraining its vertical extent during outburst.

2 OBSERVATIONS AND DATA REDUCTION

We obtained phase-resolved spectroscopy of Aql X-1 with the Optical System for Imaging and low-Intermediate Resolution Integrated Spectroscopy (OSIRIS) located in the Nasmyth-B focus of the 10.4m Gran Telescopio Canarias (GTC) at the Observatorio del Roque de los Muchachos (La Palma, Spain). We used the optical grism $R2500V$ (0.8 Å pix⁻¹) centred at 5185 Å with spectral coverage between 4500–6000 Å and two different slit widths $(0.8 \text{ and } 1 \text{ arc}$ sec), which yielded a velocity resolution of 132.3 ± 0.2 and 172.9 ± 0.2 km s⁻¹, respectively [full width at half-maximun $(FWHM)$] at 4624.27 Å.

A total of 65 spectra were acquired during three different outburst episodes, in 2011, 2013 and 2016, as detailed in Table [1.](#page-1-0) Note that in one case we have averaged four spectra

of 300s in two bins (600 s) to increase the signal-to-noise ratio, but the effective integration time is still short compared to the binary orbital period $(<0.02$ in phase). The spectra were taken over 19 different epochs [see Fig. [1](#page-2-1) (bottom)] with seeing in the range 0.75–1.45 arcsec.

The data were de-biased and flat-fielded using $IRAF¹$ $IRAF¹$ $IRAF¹$ standard routines. The pixel-to-wavelength calibration was made using a regular HgAr+Ne+Xe arc lamp exposure taken on each observing block. Before extracting the spectra, cosmic rays were removed from the 2-D spectra using L.A.Cosmic [\(van Dokkum](#page-6-7) [2001\)](#page-6-7). Velocity drifts due to instrumental flexure effects were corrected $(<$ 40 km s⁻¹) using the MOLLY software and the OI 5577.338 Å line from the sky spectra.

3 RESULTS

s

The Bowen blend complex is detected in all 65 GTC spectra. However, its relative strength and shape show strong variability. We can distinguish 3 groups: (i) 38 spectra show narrow lines that we could unambiguously identify as N III 4634.13 and N III 4640.64/4641.84 Å; (ii) 19 spectra show narrow features, but do not enable a clear identification of the N III components, and (iii) 8 spectra do not show narrow components at all (see Fig. [1](#page-2-1) top).

¹ IRAF is distributed by National Optical Astronomy Observatories, operated by the Association of Universities for Research in Astronomy, Inc., under contract with the National Science Foundation.

Figure 1. Top: examples of normalised spectra of Aql X-1 in the Bowen blend region for each of the three groups defined in the text (section [3\)](#page-1-2): spectra with securely identified N III narrow emission lines (red line; positive offset applied), spectra showing unidentified narrow components (green line; positive offset applied) and spectra with no narrow components within the Bowen blend (blue line). Bottom: X-ray light curves of Aql X-1 during the 2011, 2013 and 2016 outbursts obtained with the Monitor of All-sky X-ray Image (MAXI). Arrows indicate the time of our GTC observing blocks using the same colour code as that of the top panel.

3.1 Gaussian fitting

Previous studies of several objects have shown that narrow components within the Bowen blend arise from the irradiated side of the companion star. Thus, $K_{em} < K_2$ can in principle be obtained by directly measuring their radial velocity curve over a full orbital period (e.g. [Steeghs & Casares](#page-6-1) [2002\)](#page-6-1). To this end, we carried out Gaussian fits to the Bowen narrow components on each of the 38 spectra in which we clearly identify N III narrow lines. All the spectra were initially normalised, to then fit the Bowen profile using a 3-Gaussian model. Two narrow components were used to fit the N iii 4634.13 Å and N III $4640.64/4641.84$ Å emission lines. A broad component was added in order to model the underlying broad Bowen blend profile. The position and height of each Gaussian were set as free parameters, but the relative separation between both narrow components was imposed to be constant in order to obtain a single and more stable velocity solution. The FWHM of the Gaussians were fixed to 200 and 1150 km s⁻¹ for the narrow and broad com-

Figure 2. Radial velocity as a function of orbital phase derived from Gaussian fits of the Bowen blend narrow components. The light green area represents the region where the radial velocity is consistent with that arising from the inner side of the companion star. Blue dots indicate velocities compatible (within 3σ) with the expected radial velocity of the donor, while gray triangles correspond to those that are not consistent. Crosses show the phases of those spectra in which N iii lines could not be identified. The velocities obtained from the VLT data [\(Cornelisse et al.](#page-5-12) [2007\)](#page-5-12) are shown as red squares.

ponents, respectively. Thus, 5 parameters were optimized through least-squares fitting, yielding a velocity offset and its associated error for every spectrum. In order to compute the orbital binary phases we used the ephemeris from [MS2017:](#page-5-13) $T_0 = 2455810.387 \pm 0.005$ d and $P_{orb} = 0.7895126$ ± 0.000 0010 d. The velocity offset as a function of the orbital phase is shown in Fig. [2.](#page-2-2) We cannot clearly identify orbital motion of the companion; instead, a more complex distribution is observed (dots and triangles in Fig. [2\)](#page-2-2).

Taken into account the system parameters given in $MS2017$, we used K_c for the case of low orbital inclination to compute limiting cases for the expected *K*em in Aql X-1. Even though a clear radial velocity curve was not observed, 28 points are consistent with the expected radial velocity, i.e. less than 3σ from the region defined by the $K_{\rm em}$ limit cases. The same analysis was applied to the Very Large Telescope (VLT) data presented in [Cornelisse et al.](#page-5-12) [\(2007\)](#page-5-12). The phase-dependent velocity offsets derived from these data are consistent with those originally reported (we consider now the [MS2017](#page-5-13) ephemeris), but are not compatible with those expected for the companion star. Thus, our Gaussian fitting suggests that the Bowen blend is tracing more than one emission region.

3.2 Doppler mapping

Doppler tomography [\(Marsh & Horne](#page-5-17) [1988\)](#page-5-17) inverts phaseresolved data to obtain a brightness distribution in velocity space (i.e. Doppler coordinates). This technique is suitable to search for emission features from the companion star in faint systems or those for which the spectra are contaminated by other components. The Doppler coordinate frame co-rotates with the system, with the origin placed on its centre of mass. The V_x -axis is defined by the line that joins the compact object with the companion star, while the *V*y-axis is

4 F. Jiménez-Ibarra et al.

set in the direction of the velocity of the companion. Thus, when the correct systemic velocity (y) is used as the input to the Doppler code, the centre of mass of the system is placed at the origin on the Doppler map [i.e. $(V_{x}, V_{y}) = (0,0)$]. The emission from the donor should appear as a compact spot along the $V_{\rm v}$ axis and $K_{\rm em}$ can be determined from the position of the centroid of this spot if spectra are folded on the correct ephemeris. Doppler tomography makes use of spectra that ideally sample the orbital period in full. It uses all at once, being able to separate out the different emission sources.

Following [Wang et al.](#page-6-4) [\(2017\)](#page-6-4), we used all our 65 spectra to compute Doppler maps. These were constructed by using the second generation ($PYTHON/C++$ based), maximum entropy Doppler tomography code[2](#page-3-0) developed by T. Marsh. We computed the Doppler tomogram for the strongest Bowen narrow component, N $_{III}$ 4640.64/4641.84 Å using the ephemeris from [MS2017](#page-5-13) and also their systemic velocity ($\gamma = 104 \pm 3 \text{ km s}^{-1}$). We present the resulting Doppler map in Fig. [3,](#page-3-1) where a compact spot along the positive V_y is clearly detected. We computed the position of this spot via 2D-Gaussian fitting and found $V_x \sim -39$ km s⁻¹, $V_y \sim 94$ km s⁻¹. This corresponds to a phase shift of $\Delta\phi \sim -0.06$, which is compatible with the irradiated donor star (see Fig. [3;](#page-3-1) the angular size of the donor is ∼ 0.1 in phase, while the absolute error in the orbital phase is only \sim 0.01). We also detected a bright extended region, which is consistent with the gas-stream trajectory and/or the region where the infalling material impacts the outer edge of the disc (i.e. the hot spot).

In a second step, we used bootstrap techniques to compute confidence intervals for the above results. To this end, we model a data set of 2000 bootstrapped maps from the original data (see [Wang et al.](#page-6-4) [2017\)](#page-6-4). We computed the peak height and *K*em via a 2D Gaussian fit to each bootstraped map. Subsequently, histograms of both parameters were constructed. Since these bootstrap distributions were roughly Gaussian, we estimated the mean and the 1σ error for each parameter via Gaussian fitting (Fig. [4\)](#page-3-2). We found $K_{\text{em}} = 102$ \pm 6 km s⁻¹. Additionally, we estimated the significance of the spot to be $\geq 13\sigma$.

3.3 Opening angle of the accretion disc

The *K*em and *K*² projected radial velocities can be related using K_c (= K_{em}/K_2) from [MD2005.](#page-6-6) This correction mainly depends on the mass ratio (*q*) and the opening angle of the accretion disc (α) , which partially shadows the companion star, preventing the closest regions to the inner Lagrangian point from being irradiated. Given that *K*em, *K*² and *q* are constrained, we carried out a Monte Carlo analysis to determine the range of accretion disc opening angles compatible with the observables. We proceeded as follows:

(i) We sampled *K*em and *K*² by using Gaussian distributions from the values reported in Table [2.](#page-4-0) We created a synthetic distribution of $K_c = K_{\text{em}}/K_2$, that is, we obtained a K_c value for each combination of the two observables.

(ii) We produced synthetic K_c values from [MD2005.](#page-6-6)

Figure 3. The Doppler tomogram of N III $4640.64/4641.84$ Å computed using the updated binary period, ephemeris and $\gamma =$ 104 km s^{-1} from [MS2017.](#page-5-13) The origin (denoted by a black cross) corresponds to the centre of mass of the system. We overplot the gas-stream trajectory and the Roche lobe of the companion assuming $K_2 = 136$ km s⁻¹ and a mass ratio of 0.41. The true orbital velocities of the companion $(0, K_2 = 136 \text{ km s}^{-1})$ and the neutron star $(0, -K_1 = -56 \text{ km s}^{-1})$ are denoted by red crosses.

Figure 4. Distributions of the relative peak height (left) and *K*em (right) determined from 2000 bootstrapped maps iterated to reach the same image entropy $(S = -0.04)$ as that of the original image (Fig. [3\)](#page-3-1). Dashed lines indicate the mean and the $\pm 1\sigma$ confidence intervals. The emission feature is significant at the $\geq 13\sigma$ level, providing a radial velocity semi-amplitude of $K_{\text{em}} = 102 \pm 6$ km s^{-1} .

These can be approximated by fourth-order polynomials on *q* using the form:

$$
K_{\rm c} \simeq N_0 + N_1 q + N_2 q^2 + N_3 q^3 + N_4 q^4 \tag{1}
$$

where $N_0...N_4$ are tabulated as a function of α for high and low inclination systems (90 deg and 40 deg, respectively). Based on [MS2017,](#page-5-13) we considered the low inclination case.

(iii) Using the value reported in Table [2,](#page-4-0) we adopted a Gaussian distribution for *q*. This distribution was sampled

 2 This code is available at https://github.com/trmrsh/trmdoppler, see DOCS/FEATURES.RST for its notable features.

Table 2. Observed values

Figure 5. Probability density functions obtained from the Monte Carlo analysis method with 8×10^7 trials. The red line indicates the position of the 50th percentile. The 90 per cent and 68 per cent confidence regions are shown as dark and light shaded areas respectively.

from 0.05 to 0.85 in steps of 0.01; likewise, α was sampled from 0 to 22 deg in steps of 0.5 deg. For those α values not tabulated in [MD2005,](#page-6-6) we performed a second-order polynomial interpolation using the K_c corresponding to the three nearest tabulated values, keeping the correction accurate to \leq 2 per cent.

(iv) We produced the probability density function of α by comparing each K_c Monte Carlo trial with the synthetic values for a given q and within the α boundaries given by the Paczyński approximation [i.e. $0 < \alpha < \alpha_M$; where $\sin \alpha_M \approx 0.462(q/1+q)^{1/3}$ Paczyński [\(1971\)](#page-6-8)]. The projected 1D probability density function of the disc opening angle was obtained using 8×10^7 Monte Carlo trials and then marginalized over *q* (Fig. [5\)](#page-4-1). Considering 90 per cent confidence levels we obtained $\alpha = 15.5 \frac{+2.5}{-5}$ deg.

4 DISCUSSION

We have presented results from a detailed optical spectroscopic campaign of the neutron star transient Aql X-1 obtained during 3 different outbursts. The analysis is focussed on the Bowen blend spectral region and, in particular, we present a Doppler map of the N III $4640.64/4641.84$ Å emission line, which shows a highly significant spot at the expected Doppler coordinates of the donor star. The *K*em derived from this map is fully compatible with the true K_2 velocity reported in [MS2017.](#page-5-13) The Gaussian-fitting technique, on the other hand, yields very complex results, which are in many cases inconsistent with a companion star origin. We interpret this as being the result of additional components that we are not able to fully resolve and appear blended with the emission arising from the irradiated side of the donor. In addition, the largely differing Bowen blend profiles observed over the observing campaign (Fig. [1](#page-2-1) top) shows that the relative contribution of the different emission regions contributing to the Bowen blend change with time.

The *K*em proposed in [Cornelisse et al.](#page-5-12) [\(2007\)](#page-5-12) using the Bowen technique is ruled out by the K_2 velocity reported in [MS2017.](#page-5-13) The spectral resolution of the former work is ~ 100 km s⁻¹ (i.e. significantly better than $130 - 170$ km s⁻¹ used in the present work), but the data covered only a limited orbital phase range (∼0–0.3) with all the spectra taken over 3 consecutive nights. Indeed, our re-analysis of the VLT data (which includes the new ephemeris; Fig [2\)](#page-2-2) shows that none of the velocity measurement from this dataset were compatible with a donor star origin. Therefore, at least for the particular epoch and orbital phases covered by the VLT 2004 observations, the Bowen blend narrow emission was not dominated by the companion star contribution. These results together with the recently reported study of the black hole transient GX 339-4 [\(Heida et al.](#page-5-15) [2017\)](#page-5-15) demonstrate that complete phase coverage is a mandatory requirement in order to be able to confidently apply the Bowen technique. A complete phase coverage also allows the application of more robust analysis techniques, such as Doppler tomography, which enables us to be able to disentangle the different emission regions and single out the companion star contribution. In this particular case, different emission regions are resolved in velocity space, including a very significant companion star contribution ($\geq 13\sigma$). Misidentification effects were minimized due to the amount and time distribution of the data, as we used 65 spectra taken over 3 different outbursts at different orbital phases. We obtained $K_{\text{em}} = 102 \pm 6 \text{ km s}^{-1}$, which implies $K_c \sim 0.75$. This result is in the expected range, as computed by [MD2005.](#page-6-6) Using the constraints to the orbital inclination and the mass ratio provided in [MS2017,](#page-5-13) we ran Monte Carlo simulations to determine the opening angle of the accretion disc, $\alpha = 15.5 \begin{array}{c} +2.5 \\ -5 \end{array}$ deg, where errors are given at 90 per cent significance level. We note that this value is, in principle, independent of any assumed disc geometry, as it just represents the angle subtended by the largest vertical structure of the accretion disc. It can be easily interpreted as the angle subtended by the outer disc rim but also as that related to a more complex structure (e.g. a inner disk torus, [Corral-Santana et al.](#page-5-18) [2013\)](#page-5-18).

Several works have attempted to constrain the accretion disc opening angle by modelling optical fluxes and light curves (from photometric data). Considering a simple geometric model for X-ray reprocessing on LMXBs and comparing the absolute visual magnitude with the amplitude of the outburst light curve, [de Jong et al.](#page-6-9) [\(1996\)](#page-6-9) proposed an average value of $\alpha \sim 12$ deg. Likewise, [Gerend & Boynton](#page-5-19) [\(1976\)](#page-5-19) obtained $\alpha \sim 10$ deg for Hercules X-1 whilst [Motch et al.](#page-6-10) [\(1987\)](#page-6-10) estimated $\alpha \sim 9$ –13 deg for XB 1254-690. On purely theoretical grounds, [Meyer & Meyer-Hofmeister](#page-5-20) [\(1982\)](#page-5-20) studied the role of X-ray heating on the vertical structure of the accretion disc and showed that X-ray radiation is expected to thicken the accretion disc significantly. They obtained $\alpha \sim 6$ deg using models with no X-ray heating, while a thicker disc with $\alpha \sim 18-22$ deg was determined when X-ray irradiation was taken in account. However, the latter value is probably overestimated as the disc is assumed to absorb every X-ray photon (see also [de Jong et al.](#page-6-9) [1996\)](#page-6-9).

In this paper we have presented the first solid determination of the accretion disc opening angle through a (relatively direct) spectroscopic method. It directly compares day-side and centre of mass velocities to infer the size of the accretion structure that shadows the donor. Even though we have carried out an accurate study (including detailed error analysis), the reader must bear in mind that the value presented here depends on the K-correction modelling (i.e. [MD2005\)](#page-6-6) and therefore is likely subject to systematic effects. Nevertheless, our results are clearly consistent with an irradiation-driven thick accretion disc, providing strong support for the aforementioned theoretical works. Values lower than ∼ 10 deg seem very difficult to reconcile with our results, while the upper limit is roughly consistent with the maximum disc opening angle for the donor to be irradiated at all (whose value depends on *q*); see section [3.3.](#page-3-3) Indeed, opening angles close to this limit might explain the complex and very variable evolution of the Aql X-1 Bowen blend narrow components. On one hand, emission from the donor would be weak in this case and, on the other hand, variable X-ray irradiation could produce small changes in the vertical structure of the disc, which might, in some cases, go beyond the previous limit, preventing the donor from being irradiated. In light of this, we searched for trends relating the strength/presence of narrow emission lines with the Xray flux measured by the MAXI monitor (Fig. [1\)](#page-2-1) and found no conclusive evidence.

Finally, we remark that our results are valid for the outburst state, as thinner accretion discs are expected in quiescence (see above). To test this scenario, we carried out the Monte Carlo analysis presented here using literature data from the neutron star transient Centaurus X-4. We considered K_{em} = 122.8 \pm 11.8 km s⁻¹ (obtained from a Doppler map of the HeI 5876 Å emission line while the source was in quiescence; [D'Avanzo et al.](#page-5-21) [2005\)](#page-5-21), *K*2= 144.6± 0.3 km s^{-1} and $q=0.20 \pm 0.03$ (from [Casares et al.](#page-5-22) [2007\)](#page-5-22). We obtained $\alpha = 12.5$ $^{+2.5}_{-6.5}$ deg (errors are given at 90 per cent), which is consistent with 7 deg $\leq \alpha \leq 14$ deg determined by [D'Avanzo et al.](#page-5-23) [\(2006\)](#page-5-23) by directly using the 1σ limits to the radial velocity curves and mass ratio (we note that our 68 per cent constraint is $\alpha = 12.5 \frac{+1.5}{-3}$ deg. Therefore, even for per cent constraint is $\alpha = 12.5 - 3$) deg. Therefore, even
if this measurement allows for smaller accretion disc opening angles, it is not significantly different from the outburst value presented here.

5 CONCLUSIONS

We have presented time-resolved spectroscopy of Aql X-1 in outburst with an unprecedented orbital phase coverage. We resolved Bowen blend narrow components and proved that the Bowen technique is able to trace the orbital motion of the companion star when ample phase coverage is available. We used new generation Doppler mapping to determine *K*em from N III $4640.64/4641.84$ Å emission line. This, together with K_2 and q values from near-infrared spectroscopy, allowed us to directly measure the elusive accretion disc opening angle in outburst $(\alpha = 15.5 \frac{+2.5}{-5} \text{ deg})$, the large value of which is in agreement with accretion disc models that take into account X-ray irradiation.

ACKNOWLEDGEMENTS

We are thankful to the anonymous referee for providing useful comments that improved the manuscript. Based on data from the GTC Public Archive at CAB (INTA-CSIC), developed in the framework of the Spanish Virtual Observatory project supported by the Spanish MINECO through grants AYA 2011-24052 and AYA2014-55216. The system is maintained by the Data Archive Unit of the CAB (INTA-CSIC). DMS acknowledges Fundación La Caixa for the financial support received in the form of a PhD contract. TMD is supported by RYC-2015-18148. MOLLY software developed by T. R. Marsh is gratefully acknowledged.
