ABSTRACT

We investigate the saturation of particle acceleration in relativistic reconnection using two-dimensional particle-in-cell simulations at various magnetizations σ . We find that the particle energy spectrum produced in reconnection quickly saturates as a hard power law that cuts off at $\gamma \approx 4\sigma$, confirming previous work. Using particle tracing, we find that particle acceleration by the reconnection electric field in X-points determines the shape of the particle energy spectrum. By analyzing the current sheet structure, we show that physical cause of saturation is the spontaneous formation of secondary magnetic islands that can disrupt particle acceleration. By comparing the size of acceleration regions to the typical distance between disruptive islands, we show that the maximum Lorentz factor produced in reconnection is $\gamma \approx 5\sigma$, which is very close to what we find in our particle energy spectra. We also show that the dynamic range in Lorentz factor of the power law spectrum in reconnection is ≤ 40 . The hardness of the power law combined with its narrow dynamic range implies that relativistic reconnection is capable of producing the hard narrowband flares observed in the Crab Nebula but has difficulty producing the softer broadband prompt GRB emission.

Key words: magnetic reconnection – acceleration of particles – relativistic processes – radiation mechanisms: non-thermal

INTRODUCTION

Magnetic reconnection is a process in which topology change in the magnetic field structure results in the rapid conversion of magnetic energy into kinetic energy. In the nonrelativistic case, this process has been directly observed on the Sun [\(Schmieder et al.](#page-11-0) [2015\)](#page-11-0) and in the Earth's magnetosphere [\(Milan et al.](#page-11-1) [2017\)](#page-11-1). In the relativistic reconnection regime (see [Kagan et al.](#page-11-2) [\(2015\)](#page-11-2) for a review), where the ratio of the magnetic energy to the total enthalpy of the particles (the magnetization σ) is much larger than 1, efficient particle acceleration in reconnection has been used to explain high-energy nonthermal emission from pulsar wind nebulae (PWN) [\(Kirk & Skjæraasen](#page-11-3) [2003;](#page-11-3) [Sironi & Spitkovsky](#page-11-4) [2011;](#page-11-4) Pétri [2012;](#page-11-5) [Uzdensky et al.](#page-11-6) [2011;](#page-11-6) [Cerutti et al.](#page-11-7) [2012,](#page-11-7) [2013\)](#page-11-8), active galactic nucleus (AGN) jets [\(Giannios et al.](#page-11-9) [2009;](#page-11-9) [Giannios](#page-11-10) [2013;](#page-11-10) [Nalewajko et al.](#page-11-11) [2011;](#page-11-11) [Narayan & Piran](#page-11-12) [2012;](#page-11-12) [Petropoulou et al.](#page-11-13) [2016\)](#page-11-13), and the prompt phase of gammaray bursts (GRBs) [\(Thompson](#page-11-14) [1994;](#page-11-14) [Lyutikov & Blandford](#page-11-15) [2003;](#page-11-15) [Giannios & Spruit](#page-11-16) [2005;](#page-11-16) [Lyutikov](#page-11-17) [2006;](#page-11-17) [Zhang & Yan](#page-11-18) [2011;](#page-11-18) [McKinney & Uzdensky](#page-11-19) [2012;](#page-11-19) [Zhang & Zhang](#page-11-20) [2014;](#page-11-20) [Be-](#page-10-0)

[niamini & Piran](#page-10-0) [2013;](#page-10-0) [Beniamini & Granot](#page-10-1) [2016;](#page-10-1) [Beniamini](#page-10-2) [& Giannios](#page-10-2) [2017\)](#page-10-2).

Particle-in-cell (PIC) simulations are the most common method for probing the acceleration of particles in plasmas, including acceleration in relativistic reconnection. In general, the physics of reconnection as revealed by PIC simulations is similar in two and three dimensions [\(Sironi & Spitkovsky](#page-11-21) [2014;](#page-11-21) [Guo et al.](#page-11-22) [2014;](#page-11-22) [Werner & Uzdensky](#page-11-23) [2017\)](#page-11-23) unless the initial reconnection structure is inherently three-dimensional. This justifies the use of two-dimensional simulations which reduce computational cost and increase the system sizes that can be simulated. These simulations generally focus on the pair plasma case which is both realistic and easy to simulate. In the limit for which all species are relativistic after undergoing reconnection, these pair plasma simulations capture the physics of electron-ion plasmas as well [\(Guo et al.](#page-11-24) [2016b;](#page-11-24) [Werner et al.](#page-11-25) [2016a\)](#page-11-25). The PIC simulations have shown that relativistic reconnection can produce power law energy spectra of the form $dN/d\gamma \propto \gamma^{-p}$ and accelerate particles officiently to high energies (Zenitari ℓ , Hoshino 2001, 2005 efficiently to high energies [\(Zenitani & Hoshino](#page-11-26) [2001,](#page-11-26) [2005,](#page-11-27) [2007;](#page-11-28) [Zenitani & Hesse](#page-11-29) [2008;](#page-11-29) [Jaroschek et al.](#page-11-30) [2008;](#page-11-30) [Bessho](#page-10-3) [& Bhattacharjee](#page-10-3) [2005,](#page-10-3) [2007,](#page-10-4) [2012;](#page-10-5) [Daughton & Karimabadi](#page-11-31) [2007;](#page-11-31) [Lyubarsky & Liverts](#page-11-32) [2008;](#page-11-32) [Liu et al.](#page-11-33) [2011;](#page-11-33) [Cerutti et al.](#page-11-7)

[?] [E-mail:kagandan@post.bgu.ac.il](#page-10-0)

[2012,](#page-11-7) [2013,](#page-11-8) [2014;](#page-11-34) [Werner et al.](#page-11-35) [2016b;](#page-11-35) [Sironi & Spitkovsky](#page-11-21) [2014;](#page-11-21) [Sironi et al.](#page-11-36) [2016;](#page-11-36) [Guo et al.](#page-11-22) [2014,](#page-11-22) [2015,](#page-11-37) [2016a;](#page-11-38) [Liu](#page-11-39) [et al.](#page-11-39) [2015;](#page-11-39) [Yuan et al.](#page-11-40) [2016;](#page-11-40) [Lyutikov et al.](#page-11-41) [2016;](#page-11-41) [Kagan](#page-11-42) [et al.](#page-11-42) [2016\)](#page-11-42).

While these results indicate that reconnection produces efficient particle acceleration, there are several difficulties in understanding how it occurs. First, it is unclear what is the dominant acceleration mechanism in reconnection. The simplest and most fundamental acceleration mechanism is linear acceleration by the reconnection electric field. However, other possible mechanisms also exist, many of which were reviewed by [Oka et al.](#page-11-43) [\(2010\)](#page-11-43). In various studies, "antireconnection" between colliding islands [\(Oka et al.](#page-11-43) [2010;](#page-11-43) [Sironi & Spitkovsky](#page-11-21) [2014\)](#page-11-21), curvature drift acceleration [\(Guo](#page-11-22) [et al.](#page-11-22) [2014,](#page-11-22) [2015\)](#page-11-37), and island contraction [\(Drake et al.](#page-11-44) [2006\)](#page-11-44) were found to dominate the particle acceleration process in reconnection.

The energy spectra produced by particle acceleration in reconnection also have several puzzling properties. The power law index is not universal but varies significantly with the magnetization σ from $p > 2$ at low σ to $p \sim 1$ at high σ[\(Sironi & Spitkovsky](#page-11-21) [2014;](#page-11-21) [Werner et al.](#page-11-35) [2016b;](#page-11-35) [Guo et al.](#page-11-22) [2014,](#page-11-22) [2015;](#page-11-37) [Lyutikov et al.](#page-11-41) [2016;](#page-11-41) [Kagan et al.](#page-11-42) [2016\)](#page-11-42). In contrast, PIC simulations of relativistic shocks show that a first-order Fermi process produces a power law spectrum with an approximately universal index of $p \approx 2.2$ [\(Sironi](#page-11-45) [et al.](#page-11-45) [2015\)](#page-11-45). This indicates that the power law produced in reconnection results not from a self-similar acceleration process but self-consistently from another physical constraint.

An additional feature of the power law energy spectra in reconnection is that $1 < p < 2$ for large σ . As a result, the total energy in a logarithmic interval, proportional to immediately indicates that this power law must have finite $\gamma^2 dN/d\gamma$, is dominated by the highest-energy particles. This extent to satisfy energy conservation. Indeed, [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35) have found that for large σ a cutoff to the power law occurs at $\gamma_f \approx 4\sigma$ independent of σ . However, the variation in p with σ makes it uncertain how energy conservation constraints are satisfied by this cutoff.

This paper investigates these questions about the causes of particle acceleration in reconnection and the properties and saturation of the particle energy spectrum resulting from that acceleration. We carry out two-dimensional PIC simulations of pair plasmas at many values of σ . We then calculate the properties of the particle energy spectrum, confirming that saturation occurs. We trace particles to show that acceleration by the reconnection electric field in Xpoints is the dominant particle acceleration mechanism in these simulations. Combining these results, we suggest that the saturation is caused by the spontaneous formation of secondary magnetic islands, at whose edges the magnetic field is strong enough to deflect the particles. By analysing the structure of the current sheet during reconnection, we show that this hypothesis correctly predicts both the presence of saturation and the energy at which this saturation occurs.

Our paper is organized as follows. In Section [2,](#page-1-0) we discuss our simulation methods. In Section [3,](#page-2-0) we present our results. In Section 4, we summarize the implications of our results for reconnection models of radiation from high-energy astrophysical systems. Finally, in Section [5,](#page-10-6) we discuss the conclusions of our research.

2 METHODOLOGY

We use the particle-in-cell (PIC) method to carry out our simulations. This method evolves the discretized exact equations of electrodynamics (the mean-field Maxwell's Equations and the Lorentz Force Law), allowing us to precisely probe the full physics of particle acceleration, limited only by the accuracy of the discretization. In the PIC method discretization is carried out by using macroparticles to represent many individual particles and tracking fields only on the vertices of a grid. We implement the PIC simulations using the Tristan-MP code [\(Spitkovsky](#page-11-46) [2008\)](#page-11-46), which uses current filtering to greatly reduce noise even at relatively small macroparticle densities.

Our initial conditions are very similar to those in [Werner](#page-11-35) [et al.](#page-11-35) [\(2016b\)](#page-11-35). This allows us to verify their results and directly probe the physics responsible for their conclusions regarding the saturation of reconnection. The spatial domain is rectangular with $0 \le x \le L_x$, $0 \le y \le L_y$, and the boundary conditions are periodic in all directions. The initial configuration contains two relativistic Harris current sheets [\(Harris](#page-11-47) [1962;](#page-11-47) [Kirk & Skjæraasen](#page-11-3) [2003\)](#page-11-3) without guide field at $x = L_x/4$ and $x = 3L_x/4$ with equal and opposite currents. This configuration is susceptible to the growth of reconnection from thermal noise. Each current sheet has a magnetic field given by

$$
\mathbf{B} = B_0 \tanh\left(\frac{x - x_0}{\Delta}\right)(\pm \hat{\mathbf{y}}),\tag{1}
$$

where Δ is the half-thickness of each current sheet and x_0 is its center. The sign in \pm is positive for the vicinity of the current sheet at $x_0 = L_x/4$ and negative near the current sheet at $x_0 = 3L_x/4$.

The density profile of the particles consists of a specially varying, drifting current population with maximum density n_0 centered at each current sheet, plus a background population of stationary particles of density *n*^b :

$$
n = n_0 \text{ sech}^2 \left(\frac{x - x_0}{\Delta}\right) + n_b. \tag{2}
$$

We define densities including both species.

Our primary goal in our simulations is the probe the saturation of particle acceleration as a function of σ , the magnetization in the background plasma

$$
\sigma \equiv \frac{B_0^2}{4\pi m n_b c^2 h},\tag{3}
$$

where $h = \langle \gamma \rangle + P/(mnc^2)$ is the average enthalpy of back-
ground particles ground particles.

We carry out simulations for $\sigma = 3$, 10, 30, 100, 200, and 500, which gives us enough resolution to explore the dependence of parameters on σ . We name the simulations with Sx, where *x* is the value of σ for the simulation.

The stationary populations of both species begin in relatively cold relativistic Maxwellians at temperature T_b = $0.05mc^2$. We always choose $n_0 = 16n_b$. To ensure pressure

balance across the current sheet, the temperature T_0 of the particles in the current sheet must be given by

$$
n_0 T_0 = n_\text{b} T_\text{b} \left(\frac{\sigma h}{T_b} \right) = \sigma n_\text{b} h. \tag{4}
$$

Since our background particles are cold, we find $T_0 \approx$ $\sigma n_b/n_0$. Therefore, we initiate all particles in the drifting population at temperature $T_0 = \sigma/16$.

2.1 Length and time scales

The particle acceleration process occurs at a rate proportional to the magnetic field B_0 . In order to compare results at different values of σ , it is advantageous to use simulation parameters for which the rate of particle acceleration is the same in each simulation. This can be done by normalizing all length scales to the product σr_L , where $r_L = mc^2/(qB_0)$ is
the Larmor radius of particles moving at mildly relativistic the Larmor radius of particles moving at mildly relativistic speed in the background plasma. Our results will show that most aspects of the particle acceleration process do not vary with σ when quantities are normalized in this way.

We set our grid spacing as $\sigma r_L/32$ for most values of σ (σr_L /64 for the simulation with σ = 500) and the width Δ of the current sheet to $\Delta = (5/32)\sigma r_L$ for all values of σ. Simulations with larger $\Delta = (5/16)\sigma r_L$ indicate that our results do not depend on ∆. We find that our simulations are well resolved with respect to the size of these small scales, with no significant differences in particle acceleration physics even for grid spacings as small as $\sigma r_L/128$ (with the same relative current sheet sizes).

[Werner et al.](#page-11-35) [\(2016b\)](#page-11-35) found that saturation in relativistic reconnection required that simulations have current sheet lengths larger than $40\sigma r_L$. The overall length scale of our simulations is typically $(L_x, L_y) = (320 \sigma r_L, 320 \sigma r_L)$ (half as large for $\sigma = 500$. All runs are carried out for a time of at least $180\sigma r_L/c$ ($100\sigma r_L/c$ for Simulation S500), which is more than long enough for us to observe saturation. We carry out an additional simulation for $\sigma = 100$ with twice the length and time scales to verify that long-term saturation is indeed occurring.

To ensure sufficient resolution in density to capture the physics of reconnection, we use a density of 8 macroparticles/cell/species throughout the plasma. Tests of the code [\(Kagan et al.](#page-11-42) [2016\)](#page-11-42) show that the physics of reconnection and the evolution of the current sheet is similar for macroparticle densities up to 50 macroparticles/cell/species.

3 RESULTS

We find that the evolution of reconnection is similar to that found in other 2D simulations, including that of [Werner](#page-11-35) [et al.](#page-11-35) [\(2016b\)](#page-11-35). The tearing instability produces small-scale reconnection regions and magnetic islands, which merge with time. In the meantime, fast particle acceleration occurs. We will first find a phenomenological fit to the particle energy spectrum and then use it to constrain the characteristics of the saturation of particle acceleration in Section [3.1.](#page-2-1) We then investigate the properties of particle acceleration in the current sheet using test particle simulations in Section [3.2.](#page-4-0)

Table 1. Fits of simulations at saturation ($\tau \approx 84$)

Run ^a	\boldsymbol{v}	γ_i	γ_f	r ^b	$f_{\rm acc}^{\rm b, c}$	$\langle \gamma \rangle_{\rm acc}^{\rm d}$	$\langle \gamma \rangle_{\rm pl}^{\rm e}$	f_{int}^1

eThe average Lorentz factor predicted for accelerated particles based on our power law fits and Equation [\(6\)](#page-3-0).

fThe fraction of the particle kinetic energy in intermediate particles (those in the interval $1.8 < \gamma < \gamma_i$).

Figure 1. The evolution of the normalized particle energy spectrum $\gamma^2 dN/d\gamma = \gamma^2 f$ with the normalized time $\tau = ct/(\sigma r_L)$ for Simulation \$30. Successive spectra are approximately logarithmic Simulation S30. Successive spectra are approximately logarithmically spaced. The spectrum at the time of saturation $\tau_s \approx 84$ is shown using a thicker line. Note that our energy spectra here and in other plots do not include the contribution of the hot population of particles that began the simulation in the current sheet.

Finally, we analyze the properties of the current sheet and how they physically explain saturation in Section [3.3.](#page-6-0)

3.1 Fitting of Particle Spectra

Figure [1](#page-2-2) shows the evolution of the overall particle energy spectrum with normalized time $\tau = ct/(\sigma r_L)$ for $\sigma = 30$. Because successive spectra are logarithmically spaced, this plot provides clear evidence that saturation of the particle energy spectrum occurs near the time $\tau \approx 100$. Our later analysis based on a phenomenological fit to the spectrum indicates that the time of saturation is approximately $\tau_s \approx 84$ for all values of σ . This is in rough agreement with the results of [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35) that $L_{\text{min}} = 40 \sigma r_L$ is the minimum length scale required for saturation. It corresponds to two light-crossing times for a current sheet of that length.

4 D. Kagan, E. Nakar, and T. Piran

3.1.1 Saturation of the power law

To constrain the properties of this saturation more precisely, we fit the high-energy spectrum for simulations with all values of σ . Qualitatively, it is clear from the Figure [1](#page-2-2) that a thermal spectrum is present at low energies that fully cuts off at approximately $\gamma = 1.8$. Then, an approximate power law begins at a location γ_i and ends with a possibly exponential cutoff at location γ_f .

We make a phenomenological fit to the portion of the spectrum that begins at γ_i (the start of the power law) with the function

$$
N(\gamma) = A \left(\frac{\gamma}{\gamma_i}\right)^{-P} e^{-(\gamma/\gamma_f)^{\zeta}}.
$$
 (5)

This allows us to probe the properties of the power law and of the high-energy cutoff. The fitting of ζ allows us to compare our results with those of [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35), whose cutoff fitting function was the product of an exponential with $\zeta = 1$ and one with $\zeta = 2$. The value of γ_i where we begin fitting must be input to the fitting function, so we do fits for various values of this parameter and compare them. We select values for γ_i that are as small as possible without significantly worsening the fit.

Our fits show that saturation occurs at approximately the same time for all values of σ , which is at normalized saturation time $\tau_s \approx 84$. The only fitting parameter that does not saturate at this time is ζ , the shape of the high-energy cutoff. Table 1 shows the fitting parameters averaged over several inputs near this time of saturation, while Figure [2](#page-3-1) visually shows the particle energy spectra (solid lines) and the fits (dotted lines) to those spectra. The evolution of *p* with σ is generally consistent with that found by [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35) both qualitatively and quantitatively. *p* decreases monotonically with σ to an approximate asymptote at $p \approx$ 1.2, with $p > 2$ only for $\sigma = 3$. We also confirm their findings with respect to γ_f , which is indeed approximately 4σ for most values of σ . An exception to this is the case $\sigma = 3$ for most values of σ . An exception to this is the case $\sigma = 3$, for which in any case we do not have enough dynamic range to obtain a good power law fit.

The fraction f_{acc} of the particle energy in the power law at the saturation time $\tau_s \approx 84$ is also indicated in Table 1. The table indicates that the power law particle population already has > 90% of the particle energy at saturation for $\sigma > 10$. Even for Simulation S3, $f_{\text{acc}} > 0.7$ at $2\tau_{\text{s}}$, which is a very short time on macroscopic scales. Thus, energy from the power law population will dominate the radiation produced in reconnection, as generally assumed in models of this process.

Reconnection is an efficient process, as can be seen from the fact that the magnetization in the current sheet is of order unity (see Figure 3 of [Kagan et al.](#page-11-42) [\(2016\)](#page-11-42) for an example showing this). We therefore expect that particles that experience full acceleration in the current sheet will receive an average energy of $\langle \gamma \rangle \approx \sigma$. Table 1 shows that $\langle \gamma \rangle \geq 0.6\sigma$ in all cases.

We now check how well our power law fits represent the overall energetics of the accelerated particles. For a power law

Figure 2. The normalized particle energy spectrum per logarithmic bin $\gamma^2 dN/d\gamma = \gamma^2 f$ at the time of saturation $\tau_s \approx 84$ for each value of σ . The calculated fits above γ_i for each value of σ are shown using dashed lines.

with index *p* beginning at γ_i and ending at γ_f , the average
particle energy is given by particle energy is given by

$$
\langle \gamma \rangle_{\text{pl}} = \left(\frac{1-p}{2-p}\right) \frac{\gamma_f^{2-p} - \gamma_i^{2-p}}{\gamma_f^{1-p} - \gamma_i^{1-p}}.\tag{6}
$$

We note that the commonly used approximation in which the γ_f term is dropped from the denominator and the γ_i term from the numerator is highly inaccurate for $p < 2$. Table 1 shows that the power law represents the overall energetics very well, within $\pm 10\%$, although it typically overestimates the average energy slightly.

We now discuss the uncertainties in our fits. The fit has a significant dependence on the choice of error model, but the resulting variation is not overwhelming so long as the fractional error in the distribution decreases as $N(\gamma)$ increases. In the reported fits, we assume that errors in the spectrum are Gaussian in logarithmic space, proportional to $1/\sqrt{\gamma N(\gamma)}$.
Hencertainties in the choice of error model and the choice Uncertainties in the choice of error model and the choice of γ_i dwarf the calculated error for most of the parameters, imposing a significant uncertainty of at least ± 0.1 in the power law index p and of $\pm 20\%$ in the location of the cutoff γ_i . The cutoff exponent ζ is very sensitive to the error model
(but insensitive to γ_i), with approximate uncertainty ± 0.2 .
The fitting uncertainties are significantly greater for the runs γ_i . The cutoff exponent ζ is very sensitive to the error model The fitting uncertainties are significantly greater for the runs with $\sigma = 3$ and $\sigma = 500$. In the earlier case, the shortness of the power law portion of the spectrum makes it difficult to estimate the parameters of the fit, while in the latter case the shape of the spectrum appears to be less well described by our fitting function. These uncertainties and the trend in their magnitudes are roughly consistent with those found by [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35).

3.1.2 The lower limit of the power law and the intermediate population

The value of γ_i , the lower limit of the power law, is not
reported by Warner et al. (2016b). But it is crucial to un reported by [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35). But it is crucial to understanding the particle energy spectrum produced in relativistic reconnection. This is well illustrated by Figure [2,](#page-3-1) which compares the fits of particle spectra at saturation for all values of σ . While $\gamma_i \approx 2$ for low σ , it increases significantly at larger values of σ , reaching an approximate value of $\sigma/10$ for Simulations S30, S100, and S200. The low value of $\gamma_i = 36 \approx 500/13.5$ for Simulation 500 is not too surprising given the high uncertainty in the fit for this value of σ .

The coupled saturation of both *p* and γ_i/σ at large σ is not a coincidence. Let us assume that *p* is constant, and $\gamma_i = a\sigma$ and $\gamma_f = b\sigma$ (with *a* and *b* being constants). Then Equation [\(6\)](#page-3-0) becomes $\langle \gamma \rangle_{\text{pl}} = k\sigma$, where

$$
k = \left(\frac{1-p}{2-p}\right) \frac{b^{2-p} - a^{2-p}}{b^{1-p} - a^{1-p}},\tag{7}
$$

is a constant. Thus, the coupled saturation of p and γ_i combined with the already present saturation of γ_f ensures that the average energy of the power law is a constant proportional to σ , as expected for an efficient reconnection process.

The fact that γ_i is far above the end of the thermal
ibution at $\gamma = 1.8$ at high σ implies the presence of a distribution at $\gamma = 1.8$ at high σ implies the presence of a significant population of particles in the interval $1.8 < \gamma < \gamma_i$.
These particles are nother unaccelerated like the background These particles are neither unaccelerated like the background plasma nor fully accelerated to $\langle \gamma \rangle \sim \sigma$. We do not detect any significant difference between the locations in the current sheet of the intermediate particles and of the highest energy particles. This indicates that the intermediate particles go through the current sheet but receive little energy during the reconnection process.

The intermediate part of the spectrum as shown in Figure 2 can be approximated as a power law with $p \sim 2$. although the shape of the spectrum changes with σ . Thus, it is possible that at very high σ 1000 the intermediate component of the spectrum expands or disappears. Table 1 shows that for $\sigma > 3$ these particles have $f_{\text{int}} \approx 0.05$ of the particle kinetic energy at the time of saturation. The variation in this number with σ is not systematic, and may result from uncertainties in the value of γ_i . f_{int} does not change
significantly following saturation indicating that this part of significantly following saturation, indicating that this part of the spectrum has also reached a steady state. We leave the investigation of the detailed properties of these intermediate particles to future work.

The values for γ_i shown in Table 1 imply that $\gamma_f/\gamma_i \approx 40$ at large σ . This is a very narrow range and restricts the dynamic range of particle acceleration in reconnection. We discuss the implications of this result and the other properties of our fits for reconnection models of radiation from highenergy systems in Section [4.](#page-9-0)

3.1.3 Analysis of the high-energy cutoff

Figure [3](#page-4-1) shows how ζ depends on time for all values of σ except σ ⁼ ⁵⁰⁰. At the time of saturation, ζ [≈] ².⁴ for Simulation S30 and $\zeta \approx 2.1$ for all other simulations with σ > 3. This is roughly consistent with the results of [Werner](#page-11-35) [et al.](#page-11-35) [\(2016b\)](#page-11-35), who found that at small system sizes the highenergy cutoff was well described with a cutoff corresponding to $\zeta = 2$. After τ_s , ζ decreases monotonically with time. At $\tau = 2\tau_s$, $\zeta \approx 1.3$ for Simulations S100 and S200, $\zeta \approx 1.6$ for Simulation S10, and $\zeta \approx 1.7$ for Simulation S30.

We have carried out some simulations at larger box size $L_x = L_y = 500 \sigma r_L$ to further investigate the evolution of ζ .

Figure 3. The evolution of ζ with normalized time τ for all values of σ except σ = 500, for which the simulation was not run for a long enough time to probe its evolution well beyond the saturation time of the other parameters. Data points are shown only for times at which a good fit to Equation [\(5\)](#page-3-2) could be found. The saturation time $\tau_s \approx 84$ is indicated using the dot-dashed line.

They indicate that at late times the value of ζ continues to decrease, reaching approximately $\zeta \approx 1.25$ for $\sigma = 30$ and $\zeta \approx 1.15$ for $\sigma = 100$ at $\tau = 4\tau_s$. Comparing these results with the evolution in Figure [3](#page-4-1) indicates that the monotonic decrease in ζ slows at late times, but we do not see a clear asymptote in this evolution. Our results are roughly consistent with a cutoff at very late times that is asymptotically a simple exponential $\zeta = 1.0$, as suggested by the results of [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35) for large reconnection systems. However, truly understanding the character of the high-energy cutoff will require future simulations with enough computer resources to probe the evolution of the particle energy spectrum over temporal and spatial scales larger than our simulations by an order of magnitude.

3.2 Analysis of particle acceleration

In order to find why the saturation of the power law at $\gamma_f \approx 4\sigma$ is occurring in our simulations (and those of [Werner](#page-11-35) [et al.](#page-11-35) [\(2016b\)](#page-11-35)), we must first identify the primary acceleration process in the simulations. There are two methods for assigning significance to acceleration mechanisms. The first is an arithmetic measure, which compares the difference in Lorentz factor $\gamma_{\rm after}$ – $\gamma_{\rm before}$ before and after each acceleration process. The second is a logarithmic measure, which instead compares the ratios $\gamma_{\rm after}/\gamma_{\rm before}$ for each process. The latter is the more important measure because acceleration can occur over several orders of magnitude and thus the logarithmically dominant process determines the shape of the spectrum.

To investigate the primary acceleration processes before and after saturation, we trace particles entering acceleration regions in the simulation with $\sigma = 30$ at $ct/\sigma r_L \approx 35$ before saturation and at $ct/\sigma r_L \approx 140$ after saturation. We initiate the particle tracing before and after saturation by duplicating particles flowing into X-points at these times and adding spread to their momenta and location. We then trace the

Figure 4. The current sheet structure throughout the simulation with $\sigma = 30$ displayed using the mean Lorentz factor $\langle \gamma \rangle$ at times $\tau \approx 35$ before saturation (top) and at $\tau \approx 140$ after saturation (bottom). The shaded boxes show the locations of the reconnection regions centered at $(x_0, y_0) = (240, 263.3)\sigma r_L$ before saturation and $(x_0, y_0) = (240, 110.75)\sigma r_L$ after saturation where we use test particles to probe the physics of particle accelerations. The edges of the boxes show the locations of particle injection, which are at $x_0 \pm 3\sigma r_L$ with a spread of $2\sigma r_L$. We repeat these boxes to the right of the figure for clarity.

particles for a period of $\tau \approx 70$ (105) for the pre-saturation (post-saturation) tracing.

Figure [4](#page-5-0) shows the structure of the simulation at these times, with the reconnection regions for which particle tracing is done highlighted with boxes and the initial locations of the traced particles entering the current sheet shaded in grey. From the figure, it is clear that the number of secondary islands in reconnection regions is increasing with time: there are no such islands in our chosen pre-saturation reconnection region, while there are between 2 and 9 islands of varying sizes in the post-saturation reconnection region (depending on the size needed for structures to be considered significant). Based on our more detailed study of current sheet structure in Section [3.3](#page-6-0) we find that there are 3 significant islands in this X-point that can deflect high-energy particles above $\gamma = 4\sigma$. The length of the primary reconnection regions has also increased approximately linearly with time, from *D* = 6.25σ*r*_L at *ct*/σ*r*_L ≈ 35 before saturation to *D* = 30σ*r*_L at $ct/\sigma r_L \approx 140$ after saturation.

Figure [5](#page-5-1) shows particle acceleration histories for two typical particles before and two other typical particles after saturation. It is clear from these figures that most of

Figure 5. The particle acceleration history for two typical particles in the pre-saturation particle tracing beginning at $\tau \approx 35$ (top) and two other typical particles in the post-saturation particle tracing beginning at $\tau \approx 140$ (bottom) in Simulation S30. The particles are labeled with different colors as particles A (black), B (orange), C(green), and D (blue) The majority of the acceleration for all particles clearly occurs in a single rapid acceleration episode, consistent with X-point acceleration. This rapid acceleration phase is bounded with red diamonds.

the energy gain for these particles occurs in a single, linear acceleration episode. For Particles C (green) and D (blue) post-saturation and Particle A (black) pre-saturation, it is clear that this acceleration takes place in the shaded X-point where the particle was injected. Even Particle B (orange) in the pre-saturation run is accelerated in an X-point. The late time at which its acceleration begins is due to the fact that this X-point is not the one shaded in Figure [4](#page-5-0) but the one just above it.

We now consider the contribution of other acceleration mechanisms. Particle C (green) in the in the post-saturation run oscillates at late times as it reflects off of concentrations of B_x . This acceleration is clearly due to a Fermi process associated with either island contraction or curvature drift acceleration, as the acceleration per cycle increases with γ . However, this acceleration process increases the energy of the particle by a factor of only 2.

To confirm that these acceleration histories are indeed typical of the particle acceleration, we identify the rapid acceleration phase for each particle. This is done by selecting the period of monotonic increase in γ during which it increases by the greatest factor. Table 2 shows the averaged

properties of the traced particles during the rapid acceleration phase for both the pre- and post- saturation tracing periods. We find that the particle energy at the end of this rapid acceleration phase is 13.7 (12.4) in the pre- (post-) saturation tracing. In both cases, this is more than 2/3 of the average energy $\langle \gamma \rangle$ = 18.4 of all accelerated particles throughout the simulation with $\sigma = 30$ shown in Table 1. This rapid acceleration also dominates the total acceleration experienced by the traced particles in the X-point, taking up more than 90% (60%) of the acceleration before (after) saturation. Furthermore, more than 80% of particles in both traces begin the rapid acceleration phase of acceleration at γ < 2, indicating that this phase is typically the first strong acceleration phase. This result favors X-point acceleration (independent of γ), over Fermi-type acceleration in which the energy gain is proportional to γ .

Logarithmically, X-point acceleration is even more dominant. X-point acceleration typically increases the particle energy by a factor of at least ¹².4, while all other mechanisms combined produce at most an increase by a factor of ∼ 18.4/12.4 ≈ 1.48. Thus, X-point acceleration clearly determines the shape of the spectrum in our simulations.

Our results indicate that X-point acceleration by the reconnection electric field is indeed the dominant particle acceleration mechanism, in both the arithmetic and especially the logarithmic sense. Many studies find that alternative mechanisms are important arithmetically [\(Sironi &](#page-11-21) [Spitkovsky](#page-11-21) [2014;](#page-11-21) [Guo et al.](#page-11-22) [2014,](#page-11-22) [2015\)](#page-11-37). But in the more important logarithmic sense, those studies usually^{[1](#page-6-1)} still find that X-point acceleration is dominant [\(Sironi & Spitkovsky](#page-11-21) [2014;](#page-11-21) [Guo et al.](#page-11-37) [2015\)](#page-11-37). We note that this conclusion may change on extremely large scales not currently accessible to

1 In the study of [Guo et al.](#page-11-22) [\(2014\)](#page-11-22) it is unclear whether X-point acceleration or a first-order Fermi process involving curvature drift is logarithmically dominant because some details of the acceleration process are not shown. But later work from the same researchers [\(Guo et al.](#page-11-37) [2015\)](#page-11-37) confirms that X-point acceleration is logarithmically dominant in their simulations.

MNRAS **000**,

? (0000)

simulations, because acceleration during the many generations of island mergers that occur on such scales may become more energetically important than in current simulations.

3.3 Effects of current sheet structure on the particle acceleration process

3.3.1 Conditions for the disruption of particle acceleration

In the previous section, we showed that the primary particle acceleration mechanism is acceleration by the electric field in the X-point. The energy equation for particles accelerated electromagnetically is given by

$$
mc^2 \frac{d\gamma}{dt} = q\mathbf{E} \cdot \mathbf{v}.
$$
 (8)

Particle acceleration in the X-point therefore requires that the particle's momentum is (anti)- aligned with the electric field in the reconnection region, but a particle can be deflected when it encounters a magnetic island of sufficient size and magnetic field strength, disrupting the acceleration process. But since the deflection actually occurs at the edge of the island (or equivalently the adjacent X-point), we characterize both X-points and islands in a unified way, referring to them generically as current sheet structures (CSS).

We approximately estimate that deflection by the strong magnetic field at the edge of an island (or equivalently, Xpoint) will occur if the particle is strongly affected by the magnetic field B_c at the edge of a CSS before it can escape from the structure. The time required for escape is just $D_c/\langle v_v \rangle$, where D_c is the length of the current sheet structure in the y direction and $\langle v_y \rangle$ is the average velocity of the particle in the y direction as it crosses the structure. To estimate $\langle v_{y} \rangle$, we calculate the average velocity $\langle v_{y} \rangle_{r}/c$ for our test particles in Simulation S30 with $\sigma = 30$ during their rapid acceleration phases in X-points. We show in Table 2 that $\langle v_v \rangle_r/c \approx 0.50$ on average before saturation and $\langle v_v \rangle_r/c \approx 0.72$ afterwards, which is already quite large. Particles passing through a region of high magnetic field at the edge of a CSS will have an even larger velocity in that direction because the magnitude of v_y increases monotonically during the rapid acceleration phase. Therefore, we set $\langle v_v \rangle = c$ in this part of the analysis.

We estimate the time required for the particle to be deflected as the time for the direction of the particle's momentum to change by an angle of $\pi/2$. When the particle is deflected that much, its momentum in the y direction is close to 0 (because the particle's momentum was originally mostly in the y direction) and it is no longer able to escape. This time is

$$
\frac{\gamma mc}{4qB_{\rm c}} = \frac{\gamma}{4} \frac{B_0}{B_{\rm c}} \frac{r_{\rm L}}{c},\tag{9}
$$

where we have used the definition of r_L in the second part of the expression.

We can now parameterize each CSS using the characteristic Lorentz factor γ_c for which the escape and deflection times are equal, given by

$$
\gamma_{\rm c} = 4\sigma \frac{D_{\rm c}}{\sigma r_{\rm L}} \frac{B_{\rm c}}{B_0}.\tag{10}
$$

Figure 6. A schematic figure comparing the typical trajectories of a particle entering a magnetic island with $\gamma \ll \gamma_c$ (red) and with $\gamma \gg \gamma_c$ (blue). The red particle is quickly deflected by the strong magnetic field at the edge of the island (or equivalently, the X-point) and is then trapped in the island. In contrast, the blue particle is basically unaffected by the magnetic field. The oscillations prior to entering the island are Speiser orbit trajectories characteristic of particle motion in X-points. Note that before entering the island, the largest component of the particles' momentum is in the $\pm z$ direction (not shown) due to acceleration by the electric field.

This equation shows that larger CSS with higher magnetic field also have higher characteristic Lorentz factors.

We schematically show in Figure [6](#page-7-0) how the deflection process works in the case of a magnetic island. The blue particle with $\gamma \gg \gamma_c$ is unaffected by the magnetic island and can undergo further acceleration in another X-point. In contrast, the red particle with $\gamma \ll \gamma_c$ is strongly deflected and then trapped in the island. As a result, it can no longer undergo significant acceleration. The comparison shows that particles only "see" current sheet structures with $\gamma_c > \gamma$. We show in Section [3.3.3](#page-8-0) how this affects the saturation of particle acceleration.

3.3.2 Current sheet analysis

We can now investigate the structure of the current sheet to find D_c and B_c for each structure. We first find the maxima and minima of the reconnected field $|B_x|$ over the length

Figure 7. The identification of current sheet structures using our algorithm. The colors show the local magnetic field normalized to the background field B_0 in the Simulation S30 at the time $\tau \approx 140$ of post-saturation tracing. We focus on a region centered at the middle location of particle injection $(x_0, y_0) = (240, 110.75)\sigma r_L$ at that time. The locations ymin of current sheet structures are shown to the right of the main figure. The size of these symbols corresponds to which of two ranges of γ_c (shown to the right of the figure) the CSS corresponds to. X-points are labeled with an X and magnetic islands with a filled circle. They are differentiated by finding whether the structure corresponds to a maximum (island) or a minimum (X-point) in number density as well, although this identification is uncertain near the edges of the primary X-point at $|y - y_0| > 17 \sigma r_L$.

of the current sheet. Each of the minima corresponds to the center of a CSS, while maxima correspond to the edges of a magnetic island or X-point. We hierarchically pair the maxima and minima in order to associate each location of large deflection with a CSS. For each pair we can calculate $D_c = 2(y_{\text{max}} - y_{\text{min}})$ and $B_c = (B_{x,\text{max}} - B_{x,\text{min}})/2$. The factor of 2 in the expression for *D*c arises because the size of the structure is approximately the distance between two maxima (e.g., from one side of a magnetic island to another) or two minima (from an X-point to an island), not that between a maximum and a minimum. The factor of $1/2$ in the expression for *B*c arises because we estimate that the average magnetic field in the structure is around half of the maximum field. Finally, we can calculate γ_c using D_c , B_c , and Equation [\(10\)](#page-6-2).

Figure 7 shows the locations y_{min} for highly significant CSS with $\gamma_c > \sigma$ at the beginning of post-saturation particle tracing for Simulation S30. The minima calculated using our algorithm clearly correspond to minima of B_0 . These CSS typically be identified as X-points or magnetic islands from inspection or by reference to the simulation's density

Figure 8. The number of CSS N_s at each value of γ_c/σ summed over 3 outputs near the time of saturation $\tau_s \approx 84$. We multiply the number of structures by 2 for Simulation S500, because the normalized system size in that simulation was half of that found in the other simulations. It is clear that the distribution does not depend strongly on σ for $\sigma > 3$.

structure (as discussed in the figure caption). Note, however, that this identification has no effect on our results, which are based on generic properties of CSS.

Figure [8](#page-8-1) shows *N*s, the number of CSS with each value of γ_c in all of the simulations at the time of saturation $\tau_s \approx 84$. It is clear that the distribution of γ_c/σ does not depend significantly on σ for $\sigma > 3$. There are many small CSS with $\gamma_c/\sigma \sim 0.1$, but the number of such structures quickly declines with increasing γ_c , leveling out at approximately $\gamma_c = 4\sigma$. Because increased particle acceleration no longer reduces the number of disruptive CSS encountered beyond this point, our result suggests that saturation of particle acceleration may occur near $\gamma \approx 4\sigma$. We return to this argument in Section [3.3.3.](#page-8-0)

3.3.3 Current sheet structures and the saturation of particle acceleration

We now consider the maximum energy that can be reached by a particle accelerated in a CSS. Assuming that $\mathbf{E} \cdot \mathbf{v} \approx Ec$ is approximately constant over a typical particle's trajectory, the typical Lorentz factor γ_t reached by a particle accelerated in single X-point is approximately

$$
\gamma_t = \frac{qE}{mc} \frac{D_c}{v_y}.
$$
\n(11)

This would give the correct final Lorentz factor if particles were accelerated in only one structure. But particles do not finish their acceleration unless they encounter a CSS with $\gamma_c > \gamma$. Thus, the size of the acceleration region actually encountered by a particle depends on the particle energy. The typical size of acceleration regions for particles with $\gamma \sim \gamma_c$ can be estimated as $\langle D \rangle(\gamma_c)$, defined as the median distance between CSS with structure parameter larger than γ_c . We normalize this quantity to σr_L in our calculations, as we do with all length scales in this paper.

Figure [9](#page-8-2) shows how this parameter varies with γ_c . It is clear that the distance between CSS increases slowly and

Figure 9. The median distance $\langle D \rangle / \sigma r_L$ between CSS with parameter larger than γ_c for all simulations. This distance is clearly independent of σ . For low γ_c this distance grows as $\gamma_c^{1/3}$, but it levels out at higher γ_c .

Figure 10. The ratio $\gamma_{\text{max}}/\gamma_c$ as a function of γ_c . When the ratio falls below 1 (shown with the dashed line), particle acceleration above γ is no longer possible due to the intervention of significant CSS.

monotonically with γ_c approximately as $\gamma_c^{1/3}$ at low γ_c , level-
ing off somewhat at higher γ_c (D)(πr , is basically independent ing off somewhat at higher γ_c . $\langle D \rangle / \sigma r_L$ is basically independent of σ for $\sigma > 3$ just as M is We note that $10\sigma r$ is the dent of σ for $\sigma > 3$, just as N_s is. We note that $10\sigma r$ _L is the approximate size of CSS predicted by [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35) based on a heuristic argument using the results of [Larrabee](#page-11-48) [et al.](#page-11-48) [\(2003\)](#page-11-48) and [Kirk & Skjæraasen](#page-11-3) [\(2003\)](#page-11-3). Here, we confirm that this result is approximately correct for $\gamma_{\rm c}\approx 4\sigma$ and somewhat low for $\gamma_c > 10\sigma$.

Using this parameter, we find an implicit equation for the maximum Lorentz factor γ_{max} that can be reached by particles in CSS with parameter γ_c or greater:

$$
\gamma_{\text{max}}(\gamma_{\text{c}}) = \frac{qE}{mc} \frac{\langle D \rangle(\gamma_{\text{c}})}{\langle v_{\text{y}} \rangle}.
$$
 (12)

Rearranging this equation using the definition of r_L yields

$$
\frac{\gamma_{\text{max}}(\gamma_{\text{c}})}{\sigma} = \frac{cE}{\langle v_{\text{y}}\rangle B_0} \frac{\langle D\rangle(\gamma_{\text{c}})}{\sigma r_{\text{L}}}.
$$
\n(13)

10 D. Kagan, E. Nakar, and T. Piran

We assume that E/B_0 is not significantly dependent on σ because reconnection rate has no dependence on σ [\(Kagan](#page-11-42) [et al.](#page-11-42) [2016\)](#page-11-42). We also assume that $c/\langle v_v \rangle$ does not depend significantly on σ because the bulk outflow momentum from reconnection regions is independent of σ [\(Melzani et al.](#page-11-49) [2014;](#page-11-49) [Kagan et al.](#page-11-42) [2016\)](#page-11-42). We use parameters from our particle tracing in Simulation S30 (Table 2) during the rapid phase of acceleration to estimate these values, choosing $E/B_0 = 0.25$ and $\langle v_v \rangle/c = 0.5$ based on the pre-saturation averages. Note that the product $cE/\langle v_v \rangle B_0$ is very similar if we instead use the post-saturation averages. For our chosen parameters, Equation [\(13\)](#page-8-3) reduces to

$$
\frac{\gamma_{\text{max}}(\gamma_{\text{c}})}{\sigma} = 0.5 \frac{\langle D \rangle (\gamma_{\text{c}})}{\sigma r_{\text{L}}}.
$$
\n(14)

Because $\langle D \rangle / \sigma r_L$ is independent of σ as seen in Figure [9,](#page-8-2) this equation indicates that $\gamma_{\text{max}} \propto \sigma$. Thus, the spontaneous formation of CSS with a separation proportional to σr_L provides a physical explanation for the saturation of the power law in our fits.

While Equation (14) is still implicit, it is clear that there are two regimes for γ_{max} depending on the ratio $\gamma_{\text{max}}/\gamma_c$. If $\gamma_{\text{max}} > \gamma_{\text{c}}$, particle acceleration in X-points with parameter of at least γ_c tends to result in the particle reaching high enough energy to be unaffected by a significant number of large CSS. This makes further acceleration more probable. In contrast, if $\gamma_{\text{max}} < \gamma_c$ particles will not accelerate enough to reduce their susceptibility to deflection by CSS. As a result, we expect that such particles will not accelerate beyond γ_{max} . This will produce a cutoff at $\gamma_{\text{max}} = \gamma_c$.

In Figure [10,](#page-8-4) we plot the ratio $\gamma_{\text{max}}/\gamma_c$ as a function of γ_c . The figure shows that $\gamma_{\text{max}}/\gamma_c$ decreases monotonically with γ_c approximately as $\gamma_c^{-2/3}$. Figure [10](#page-8-4) shows that $\gamma_{\text{max}} = \gamma_c$ at around $\gamma_c \approx 5\pi$, which is close to the location of the cutoff around $\gamma_c \approx 5\sigma$, which is close to the location of the cutoff that we find in fits of the power law particle energy spectrum.

Figure [9](#page-8-2) shows that value of $\gamma_{\text{max}} = \langle D \rangle / 2 \sigma r_L$ is typically around 30 σ for $\gamma_c = 100\sigma$. Because particles accelerating in large X-points with $\gamma_c \gg 4\sigma$ cannot reach higher Lorentz factors than γ_{max} , we expect almost no particles to reach above $\gamma = 30\sigma$, which is less than a factor of 10 higher than the cutoff. This indicates that the cutoff should be sharp, consistent with an exponential or super-exponential. Thus, our current sheet analysis has correctly predicted the existence and the location at $\gamma \approx 4 - 5\sigma$ of a sharp highenergy cutoff of the power law in the particle energy spectrum produced in relativistic reconnection.

It has commonly been thought that because current sheet evolution produces larger and larger primary X-points and magnetic islands, the properties of the particle energy spectrum in reconnection are determined by global dynamics. But we have shown that spontaneous tearing in large X-points continually produces magnetic islands with a characteristic size of $\sim \sigma r_L$, which implies that the maximum $\gamma \sim \sigma$. Our detailed analysis gives a more precise cutoff at $\gamma \approx 4\sigma$. Thus, the small-scale properties of the current sheet can never be ignored in investigating reconnection even though the global dynamics dominate the overall structure. Constraints from this small-scale structure have significant effects on reconnection models of astrophysical emission, as we show in the next section.

4 APPLICATION TO ASTROPHYSICAL **SOURCES**

We now discuss the implications of our results in Section 3.1 for the application of relativistic reconnection to observed radiation from high-energy astrophysical sources. We note that these conclusions may be unreliable if new acceleration mechanisms become important in very large scale systems. In addition, the application of our results to ion-electron plasmas still needs to be confirmed. In this section, we assume that our conclusions scale to very large scales found in astrophysical systems and that our pair-plasma results apply to any ionelectron plasmas that may be present in such systems..

We have shown in Section 3.1.1 that the power law index found in reconnection falls in the range $1.15 < p < 2.3$. The power law index of synchrotron radiation resulting from particles in the power law is typically either −*p*/2 (if cooling is fast) or $-(p-1)/2$ (if cooling is slow) [\(Sari et al.](#page-11-50) [1998\)](#page-11-50). This corresponds to a range of flux per logarithmic interval $\nu F_V \propto \nu^{-0.15} - \nu^{0.9}$. Thus, reconnection produces nearly flat or rising logarithmic radiation spectra. In Section 3.1.2, we have shown that the extent of the power law in the particle energy spectrum is quite narrow: $\gamma_f/\gamma_i \leq 40$. The corresponding maximum dynamic range of the high-energy synchrotron spectrum emitted by the particles is $\approx 40^2 = 1600$.

This narrow range can be expanded if significant relativistic bulk flows or variations in the magnetic field are present because the energy at the synchrotron peak is proportional to *B*Γ. Ultrarelativistic bulk flows with $\Gamma \gg 1$ are rarely produced in relativistic reconnection [\(Melzani et al.](#page-11-49) [2014;](#page-11-49) [Guo et al.](#page-11-22) [2014;](#page-11-22) [Kagan et al.](#page-11-42) [2016\)](#page-11-42), although they may occur for some initial conditions [\(Sironi et al.](#page-11-36) [2016\)](#page-11-36). The variation in *B* in the outskirts of magnetic islands where particles emit is also relatively small, typically no more than a factor of a few (as can be seen in Figure 7). Overall, we estimate that *B*Γ does not vary by more than a factor of 5 for particles in a given reconnection region. Variability in the central source or resulting from global instabilities may also be a source of variation in *B*Γ. If we roughly estimate that the variation in *B*Γ from these sources is similar to the variation in the location of the spectral peak, we can estimate the size of this effect for any given source.

We now consider whether these properties of reconnection are consistent with various observed astrophysical systems. We first consider the flares in the Crab's PWN [\(Tavani](#page-11-51) [et al.](#page-11-51) [2011;](#page-11-51) [Abdo et al.](#page-10-7) [2011;](#page-10-7) [Striani et al.](#page-11-52) [2011;](#page-11-52) [Buehler](#page-11-53) [et al.](#page-11-53) [2012;](#page-11-53) [Mayer et al.](#page-11-54) [2013\)](#page-11-54), which extend for around 1.5 decades in frequency below the peak of the distribution, with a sharp cutoff above it. It is possible that the power law extends a bit further at low energies where it is swamped by the quiescent spectrum, but this dynamic range is still easily consistent with reconnection. The flare spectra near the peak frequency are nearly flat in vF_v at the peak time of the flares. Therefore, the reconnection model with a relatively low σ works well for the Crab flares.

The TeV flares in AGN [\(Aharonian et al.](#page-10-8) [2007,](#page-10-8) [2009;](#page-10-9) [Albert et al.](#page-10-10) [2007;](#page-10-10) [Tavecchio et al.](#page-11-55) [2013;](#page-11-55) [Cologna et al.](#page-11-56) [2017\)](#page-11-56) have a power law spectrum with some curvature that extends for around 2 decades in frequency. This range can easily be produced by reconnection. The intrinsic power law spectra of Fermi-LAT blazars have hard power law indices in the range $vF_v \propto v^{-0.65} - v^{-0.15}$ [\(Singal et al.](#page-11-57) [2012\)](#page-11-57). Flaring galaxies have

quiescent spectra consistent with these values, but the flaring spectra are typically harder [\(Abramowski et al.](#page-10-11) [2012;](#page-10-11) [Albert](#page-10-12) [et al.](#page-10-12) [2008;](#page-10-12) [Cologna et al.](#page-11-56) [2017\)](#page-11-56). Thus, most TeV flares are consistent with being produced in reconnection at low σ , or even at moderate σ in extraordinary cases.

Finally, we consider the prompt phase of gamma-ray bursts. In many GRBs in the Fermi catalog, the combined GBM and LAT data are consistent with a single power law component over a large frequency range. In GRB 0901003, the prompt emission observed by Fermi appears to constitute a single power law from a peak at ∼ 400 keV in the GBM instrument all the way up to ∼2.8 GeV as observed in the LAT instrument [\(Zhang et al.](#page-11-58) [2011\)](#page-11-58). The peak of the energy spectrum varied by a factor of only 1.5 during the burst, so variation in *B*Γ likely cannot expand the power law range of reconnection (which is less than 1600) enough to explain the observed dynamic range of 7000 for the GRB. While this GRB is an extreme case, many other GRBs observed in the LAT band have a directly observed dynamic range of around 1000-3000 in frequency with no strong evidence of a cutoff beyond that range [\(Ackermann et al.](#page-10-13) [2013\)](#page-10-13). It not easy to explain such GRBs in a reconnection model.

Additional evidence against the direct application of reconnection to prompt GRB emission comes from spectral slopes. Fits to the high-energy portion of the spectrum of gamma-ray burst range from $vF_v \propto v^{-2.8} - v^{-0.6}$ [\(Gruber &](#page-11-59) Goldstein 2014), significantly softer than in reconnection even [Goldstein](#page-11-59) [2014\)](#page-11-59), significantly softer than in reconnection even at low σ . Thus, it seems difficult for relativistic reconnection to produce the nonthermal emission seen in the prompt phase of GRBs. In summary, it appears that relativistic reconnection is clearly applicable to the Crab flares and to TeV flares in AGN, and has difficulty accounting for the prompt GRB emission.

5 CONCLUSIONS

In this paper, we investigated the saturation of the highenergy power law spectrum in reconnection using particlein-cell simulations at various magnetizations σ . We used particle tracing to identify the dominant particle acceleration mechanism as direct acceleration by the reconnection electric field in X-points. We then analyzed the structure of the current sheets in our simulations to show that the spontaneous formation of secondary islands and X-points (referred to as CSS, current sheet structures) was responsible for saturation.

Our conclusions are as follows:

• The high-energy part of the particle energy spectrum produced by reconnection can be fit with a hard power law followed by a super-exponential cutoff.

• The high-energy power law in the particle particle energy spectrum saturates at $\gamma_f \approx 4\sigma$ This saturation occurs at the normalized time $\tau \approx 84$, consistent with the saturation at $L = 40 \sigma r_L$ found by [Werner et al.](#page-11-35) [\(2016b\)](#page-11-35).

• The ratio γ_f/γ_i , where γ_i is the minimum energy of the were law approaches ≈ 40 at large σ power law, approaches ≈ 40 at large σ .

• Our particle tracing reveals that X-points are responsible for the majority of particle acceleration, especially in a logarithmic sense. The average energy of particles after a single episode of rapid acceleration in the X-point is at least 70% of the average energy of all accelerated particles after saturation.

Physics of saturation in reconnection 11

• We find that the saturation of particle acceleration in reconnection is due to the spontaneous production of magnetic islands within large X-points. At the edges of the magnetic islands, strong magnetic fields are present that can deflect particles and end particle acceleration. We characterize current sheet structures (CSS) including both X-points and magnetic islands in a unified way by the maximum Lorentz factor γ_c of particles that the adjacent strong magnetic fields can deflect.

• The distribution of γ_c/σ is largely independent of σ . It declines quickly at small γ_c but plateaus at $\gamma_c \approx 4\sigma$. This is consistent with saturation of the power law at $\gamma_f \approx 4\sigma$.

• We calculate an implicit equation for the maximum acceleration possible in CSS as a function of their typical size and γ_c parameter. We find that particles entering the current sheet can be accelerated to a maximum energy of approximately 5σ before they are deflected by an encounter with a significant CSS and their acceleration is stopped. This is very close to the location of the high energy cutoff we find in our fits.

• Our results indicate that the fundamental spatial scale for particle acceleration is of order σr_L . Because secondary islands and X-points are constantly produced at this scale, it remains important even at late times when primary islands and X-points are much larger than σr_L ,

• Our simulations predict that particles accelerated in reconnection will produce synchrotron spectra that are hard power laws with index $vF_v \approx v^0$ and a narrow frequency
range of ≈ 1600 TeV ACN flare spectra and Crab PWN range of ∼ 1600. TeV AGN flare spectra and Crab PWN flare spectra, which are hard and have narrow frequency ranges, can easily be produced by reconnection. In contrast, the relatively soft and broad power laws present in prompt GRB emission are difficult to produce in reconnection.
