Abstract

The DArk Matter Particle Explorer (DAMPE), a space-based high precision cosmic ray detector, has just reported the new measurement of the total electron plus positron energy spectrum up to 4.6 TeV. A notable feature in the spectrum is the spectral break at ∼ 0.9 TeV, with the spectral index softening from −3.1 to −3.9. Such a feature is very similar to the knee at the cosmic nuclei energy spectrum. In this work we propose that the knee-like feature can be explained naturally by assuming that the electrons are accelerated at the supernova remnants (SNRs) and released when the SNRs die out with lifetime around 10^5 years. The cut-off energy of those electrons have already decreased to several TeV due to radiative cooling, which may induce the observed TeV spectral break. Another possibility is that the break is induced by a single nearby old SNR. Such a scenario may bring a large electron flux anisotropy that is observable by the future detectors. We also show that a minor part of electrons escaping during the acceleration in young and nearby SNRs are able to contribute to several TeV or higher energy region of the spectrum.

I. INTRODUCTION

The DArk Matter Particle Explorer (DAMPE), which is one of the new generation spaceborne instruments for measuring cosmic rays (CRs), has been running in orbit for nearly two years. Recently, the DAMPE Collaboration published their first result of the high energy CR electron plus positron $(e^{-} + e^{+})$ spectrum from 25 GeV to 4.6 TeV, with the data recorded between December 27, 2015 and June 8, 2017 [\[1](#page-19-0)]. The measurement of DAMPE is very precise due to its unprecedentedly high energy resolution and strong electron/proton discrimination [\[2\]](#page-19-1). This measurement provides the direct evidence of a spectral break at \sim 0.9 TeV for the first time, which is consistent with the spectral break around 1 TeV detected indirectly by ground-based experiments, such as H.E.S.S and VERITAS [\[3](#page-19-2), [4\]](#page-19-3). The DAMPE spectrum shows another interesting feature at ~ 1.4 TeV, although it is not significant right now. Meanwhile, the uncertainties above 3 TeV are large at present, and spectral features are still possible at the high energy end.

The most notable and clear feature of the DAMPE spectrum is the break at ~ 0.9 TeV. This feature is very similar to the 'knee' of the cosmic nuclei energy spectrum, which has been observed by ground-based experiments for more than 50 years [\[5,](#page-19-4) [6\]](#page-19-5). The origin of the knee is still under debate due to the lack of direct measurement in space with clear identification of nuclei species. One naturally explain is that the knee is caused by the acceleration limit in the cosmic ray sources [\[7\]](#page-19-6). Similarly, the break feature at the electron spectrum may also be caused by the cut-off energy of electrons, which is much lower than that of nuclei because of the large radiative energy loss of the electron.

Supernova remnants (SNRs) have long been considered as the major source of galactic CRs [\[8](#page-19-7)[–10](#page-19-8)]. The electron injection of an SNR is often assumed to be happened at the birth time of the SNR [\[11,](#page-19-9) [12\]](#page-19-10). However, this is true only when the delay time (the time from birth to CR injection) of the injection is far less than the age of the SNR. In this work, we consider a more realistic injection picture for SNRs. CRs are largely released from an SNR when the SNR dies as a CR factory at an age of $\sim 10^5$ yr [\[13\]](#page-19-11). Meanwhile, the maximum energy of electrons in a mature SNR should decrease with time, due to significant radiative cooling. As we will show, an evolution time of $\sim 10^5$ yr corresponds to a cut-off energy of ∼ TeV for electrons, which can explain the TeV break detected by DAMPE.

On the other hand, spectral features in the electron spectrum are often expected in the

TeV region, which could be produced by young and nearby CR sources [\[14,](#page-19-12) [15](#page-19-13)]. The final released population mentioned above can hardly account for remarkable spectral features at such high energy. However, if a minor part of electrons can escape from the SNRs during the acceleration process, the young and nearby SNRs may contribute such a high energy component. We will show below that the spectral index of this population of electrons can be very hard, which is necessary for a distinctive spectral structure in high energies.

In this work, we use the CR electrons released at the final stage of SNRs to explain the DAMPE result, and also consider the contribution from the CR electrons released during the acceleration process. Besides, CR positrons contribute $\sim 10\%$ of the total $e^- + e^+$ flux, which have been measured by space-borne detectors with the magnetic spectrometer, such as PAMELA and AMS-02 [\[16,](#page-19-14) [17](#page-19-15)]. The 'positron excess' in cosmic rays is one of the most important findings in CR researches. Thus we attempt to explain the DAMPE $e^- + e^+$ spectrum and the positron fraction $(e^+/(e^- + e^+))$ of AMS-02 [\[17\]](#page-19-15) simultaneously to obtain a complete picture. We consider pulsar wind nebulae (PWNe) as the sources of high energy positrons. Note that the e^{\pm} injection spectrum of a PWN could have a rapid drop due to the cooling effect. This mechanism may account for the tentative feature at 1.4 TeV of the DAMPE spectrum, if this feature is actually edge-like.

This paper is organized as follows. In Sec. [II,](#page-2-0) we introduce the propagation of CR electrons and positrons (e^{\pm}) after their injection into the interstellar medium (ISM), and show the calculation of the e^{\pm} spectrum at the Earth. In Sec. [III,](#page-4-0) we describe the picture of electron escape for SNRs, and also introduce the positron sources. In Sec. [IV,](#page-10-0) the fitting results are presented and analyzed. Then we discuss a possible scenario to reproduce the TeV spectral break by a single nearby source in Sec. [V.](#page-13-0) Finally, we conclude in Sec. [VI.](#page-15-0)

II. PROPAGATION OF GALACTIC ELECTRONS AND POSITRONS

The propagation process of e^{\pm} can be described by the diffusion equation with consideration of the radiative cooling during their journey:

$$
\frac{\partial N}{\partial t} - \nabla(D\nabla N) - \frac{\partial}{\partial E}(bN) = Q, \qquad (1)
$$

where N is the differential number density of e^{\pm} , D denotes the diffusion coefficient, b is the energy-loss rate, and the source function of e^{\pm} is denoted by Q. The data of DAMPE

is above 20 GeV, where convection or reacceleration has little effect on $e^- + e^+$ spectrum [\[18\]](#page-20-0), so the relevant terms are not included in Eq. [\(1\)](#page-2-1). The propagation zone is set as a cylindrical slab, with a radius of 20 kpc and a half thickness of z_h . The diffusion coefficient is usually assumed to be $D(E) = \beta D_0 (R/\text{1 GV})^{\delta}$, where D_0 and δ are both constants, β is the velocity of particles in the unit of light speed, and R is the rigidity of e^{\pm} . We adopt the propagation parameters given by the DR2 model (the revised diffusion reacceleration model) in Ref. [\[19\]](#page-20-1): $D_0 = (2.08 \pm 0.28) \times 10^{28}$ cm² s⁻¹, $\delta = 0.500 \pm 0.012$, and $z_h = 5.02 \pm 0.86$ kpc. This DR2 model is the best performing model in Ref. [\[19](#page-20-1)] when fitting to the latest B/C data of AMS-02 [\[20\]](#page-20-2). The energy-loss rate has the form of $b(E) = b_0(E)E^2$, where $b_0(E)$ is decided by synchrotron and inverse Compton radiation of e^{\pm} . We set the interstellar magnetic field in the Galaxy to be 1 μ G to get the synchrotron term [\[11](#page-19-9), [21](#page-20-3)]. The inverse Compton term refers to the calculation of [\[22](#page-20-4)], in which a relativistic correction to the scattering cross-section is considered.

The general solution of Eq. [\(1\)](#page-2-1) can be obtained by the method of Green's function [\[23\]](#page-20-5), which is written as

$$
N(E,\boldsymbol{r},t)=\iiint dE_0 dr_0 dt_0 Q(E_0,\boldsymbol{r}_0,t_0)G(E,\boldsymbol{r},t;E_0,\boldsymbol{r}_0,t_0).
$$
\n(2)

The infinite three-dimensional solution can be a good approximation for high energy case $[15, 24]$ $[15, 24]$, which takes the form of

$$
G(E, \mathbf{r}, t; E_0, \mathbf{r}_0, t_0) = \frac{1}{(\pi \lambda^2)^{3/2} b(E)} \exp \left[-\frac{(\mathbf{r} - \mathbf{r}_0)^2}{\lambda^2} \right] \delta(t - t_0 - \tau) , \tag{3}
$$

where

$$
\tau = \int_{E}^{E_0} \frac{dE'}{b(E')} \simeq \frac{1}{b_0} \left(\frac{1}{E} - \frac{1}{E_0} \right)
$$
(4)

and

$$
\lambda^2 = \int_E^{E_0} \frac{D(E')}{b(E')} dE' \simeq \frac{D_0 \left[1 - (E/E_0)^{1-\delta}\right]}{b_0 (1-\delta) E^{1-\delta}}.
$$
\n(5)

For a point source with burst-like injection, the source function is $Q(E, \mathbf{r}, t) = Q(E)\delta(\mathbf{r} - \mathbf{r})$ r_s)δ(t – t_s). Setting the location of the Earth as $r = 0$ and the present time as $t = 0$, and substituting this source function expression into Eq. [\(2\)](#page-3-0), we obtain the spectrum contributed by a source with distance r and age t :

$$
I(E,r,t) = \frac{c}{4\pi} N(E,t,r) = \frac{c}{4\pi^{5/2}\lambda^3} \frac{b(E^*)}{b(E)} \exp\left(-\frac{r^2}{\lambda^2}\right) Q(E^*),\tag{6}
$$

where $E^* = E/(1-b_0Et)$. As to a point source with continuous particle injection, the source function is written as $Q(E, \mathbf{r}, t) = Q(E, t)\delta(\mathbf{r} - \mathbf{r_s})$. Similarly, we get the spectrum in this case:

$$
I(E,r,t) = \int_{t_{\min}}^{t_{\max}} \frac{c}{4\pi^{5/2}\lambda^3} \frac{b(E^*)}{b(E)} \exp\left(-\frac{r^2}{\lambda^2}\right) Q(E^*, t_0) dt_0, \qquad (7)
$$

where t_{max} is the smaller one between the age t and $1/(b_0E)$, and we set t_{min} to be r/c since Eq. [\(1\)](#page-2-1) does not reject superluminal case.

III. GALACTIC SOURCES OF ELECTRONS AND POSITRONS

A. An Electron Escaping Scenario of SNRs

Particles can be boosted to very high energies via the first-order Fermi acceleration in the shock wave of an SNR [\[25](#page-20-7)[–29\]](#page-20-8). Accelerated CR particles are trapped in the SNR for $\sim 10^5$ years until the shock dissolves into the ISM. However, adiabatic energy losses during the expansion of the SNR prevents the released CRs to reach the high energies as observed, thus the additional particle escape process during the acceleration is required [\[30\]](#page-20-9). Hence CR particles injected from SNRs can be divided into two populations: CRs escaping from the upstream region during the Sedov phase, and CRs released in the final stage of SNRs [\[13](#page-19-11), [31](#page-20-10)]. In this work, we adopt the above picture for the electron injection of SNRs to explain the DAMPE data.

1. Electron Spectra of SNRs

To obtain the injection spectrum, we apply the result of Ref. [\[32](#page-20-11)], in which the method of asymptotic solution is used to get analytical expressions for electron spectra in SNRs. Under the assumption that the energy losses of electrons are dominated by the synchrotron radiation, the electron momentum distribution in the very high energy range at the shock can be solved analytically from the transport equation as

$$
f_0(p) = \sqrt{b(p)/p} \exp\left[-\frac{\gamma^2}{u_1^2} \left(1 + \sqrt{\kappa}\right)^2 \int_0^p \frac{b(p')D(p')}{p'^2} dp'\right],\tag{8}
$$

where $b(p)$ is the downstream synchrotron energy loss rate, $D(p)$ is the diffusion coefficient in the downstream, $\gamma = 3\sigma/(\sigma - 1)$ with σ denoting the shock compression ratio, u_1 denotes

the upstream shock speed, and κ is the ratio of the magnetic field of the upstream to that of the downstream. In the case of nominal Bohm diffusion with $D(p) = pc^2/3eB$, where e is the electric charge and B is the downstream magnetic field, it can be inferred from Eq. [\(8\)](#page-4-1) that

$$
f_0(p) \propto p^{1/2} \exp(-p^2/p_c^2), \qquad (9)
$$

where the cut-off momentum is written as

$$
p_c = 4.3 \,\text{TeV/c} \left(\frac{u_1}{300 \,\text{km s}^{-1}}\right) \left(\frac{B}{30 \,\mu\text{G}}\right)^{-1/2},\tag{10}
$$

if we take the standard compression factor $\sigma = 4$ and $\kappa = 1/\sqrt{11}$ as in Ref. [\[32\]](#page-20-11). In the low energy region, the energy losses can be neglected, and the transport equation reduces to the simplest diffusion-convection equation. Then $f_0(p)$ can be expressed by the well-known form $f_0(p) \propto p^{-4}$ for $\sigma = 4$.

In the high energy cut-off region, both the spatially integrated spectrua in the upstream $F_1(p)$ and downstream $F_2(p)$ have the relations with $f_0(p)$ as $\propto p^{-1}f_0(p)$, and subsequently $\propto p^{-1/2} \exp(-p^2/p_c^2)$ [\[32](#page-20-11)]. While in the low energy part, the momentum distribution of the upstream is $f_1(x,p) = f_0(p) \exp(u_1x/D_1)$ (x = 0 for the shock front and x < 0 for the upstream region), which means $F_1(p) \propto p^{-3}$ under the Bohm diffusion. Then the downstream integrated spectrum is approximately given by $F_2(p) \propto p^{-5}$, which can be derived from the boundary condition at the shock front [\[32](#page-20-11)]. The integrated spectra change gradually from the single power-law form to the form of $p^{-1/2} \exp(-p^2/p_c^2)$ when p tends to be p_c . Since in the cut-off region the exponential term overwhelms the $p^{-1/2}$ term, we can approximate the integrated spectra in the whole energy range by

$$
F_1(p) \propto p^{-3} \exp(-p^2/p_c^2), \qquad (11)
$$

and

$$
F_2(p) \propto p^{-5} \exp(-p^2/p_c^2). \tag{12}
$$

2. Electrons Released at the Final Stage

As we have described above, electrons injected by SNRs may consist of a final released component (population A hereafter) and a component escaping during the acceleration (population B hereafter). We assume all the SNRs dissolve into the ISM and massively release

their electrons in a same evolution time of t_{end} (the typical age of Sedov phase of an SNR is $\sim 5 \times 10^4$ yr [\[33\]](#page-20-12), which means $t_{\text{end}} \gtrsim 5 \times 10^4$ yr). This indicates that the population A can only be contributed by SNRs older than t_{end} , and thus the injection time of a source with an age of t is $t_0 = t - t_{\text{end}}$. We use the smooth radial distribution of Ref. [\[34\]](#page-20-13) for all the SNRs with $t > t_{\text{end}}$ to calculate the spectrum of the population A.

For smooth distributed sources with the continuous injection, the observed spectrum can also be derived by Eq. [\(2\)](#page-3-0):

$$
I(E) = \int_0^{\frac{1}{b_0 E}} dt_0 \int_0^{r_{\text{max}}} dr_0 \int_0^{2\pi} d\varphi_0 \frac{c}{4\pi^{5/2} \lambda^3} \frac{b(E^*)}{b(E)} \exp\left(-\frac{r_0^2}{\lambda^2}\right) f \rho(r_0, \varphi_0) r_0 Q(E^*), \quad (13)
$$

where $f = 4$ century⁻¹ galaxy⁻¹ is the explosion rate of SNR in the Galaxy, $\rho(r,\varphi)$ is the normalized distribution centered on the solar system, $E^* = E/(1 - b_0 E t_0)$, and $r_{\text{max}} =$ $\min\{20 \text{ kpc}, ct_0\}$. The population A should be a mixture of upstream and downstream electrons, so according to Eq. [\(11\)](#page-5-0) and Eq. [\(12\)](#page-5-1), we write the injection spectrum of the population A as

$$
Q(E) = Q_{0,\text{A}}(E/1 \,\text{GeV})^{-\gamma_{\text{A}}} \exp(-E^2/E_c^2),\tag{14}
$$

where $Q_{0,A}$ is the normalization, γ_A is the power-law index, and E_c denotes the cut-off energy which is decided by Eq. [\(10\)](#page-5-2). For the integrated spectra of the upstream and downstream, we have $\gamma_A = 1$ and $\gamma_A = 3$ respectively. However, the population A should be dominated by the downstream electrons, so γ_A should be between 2 and 3.

For an SNR which has gone through the free expansion phase, the shock velocity can be expressed as

$$
u_1 = 3.9 \times 10^8 \,\mathrm{cm} \,\mathrm{s}^{-1} \, E_{51}^{1/3} n_{\rm ISM}^{-1/3} \left(\frac{t_{\rm evo}}{10^3 \,\mathrm{yr}}\right)^{-3/5} \tag{15}
$$

for $t_{\text{evo}} < 4 \times 10^4 E_{51}^{4/17} n_{\text{ISM}}^{-9/17}$ yr, and

$$
u_1 = 2.3 \times 10^7 \,\mathrm{cm} \,\mathrm{s}^{-1} \, E_{51}^{11/51} n_{\mathrm{ISM}}^{-4/17} \left(\frac{t_{\mathrm{evo}}}{10^5 \,\mathrm{yr}}\right)^{-2/3} \tag{16}
$$

for $t_{\text{evo}} > 4 \times 10^4 E_{51}^{4/17} n_{\text{ISM}}^{-9/17}$ yr, where t_{evo} is the evolution time of the SNR, E_{51} is the initial energy of SN ejecta in units of 10^{51} erg, and n_{ISM} is the number density of ISM in units of 1 cm⁻³ [\[33](#page-20-12)]. Here we take the typical value $E_{51} = n_{ISM} = 1$ for them. If we assume a typical magnetic field of 10 μ G for the SNR environment, then we have the magnetic field in the downstream as $B = 30 \mu$ G for $\kappa = 1/\sqrt{11}$. Then for an SNR stepping into the radiative phase, the cut-off energy E_c is simply determined by t_{evo} through Eq. [\(10\)](#page-5-2) and

TABLE I. The name, distance, and age of SNRs within 1 kpc included by the Green's catalog. One can refer to Ref. [\[12\]](#page-19-10) and references therein for parameters of these sources. For parameters given in the form of interval in Ref. [\[12](#page-19-10)], we take the mean values here.

Eq. [\(16\)](#page-6-0). Taking the typical lifetime of SNRs as $t_{\text{end}} = 10^5$ yr, the corresponding $E_c(t_{\text{end}})$ is 3.2 TeV, and the break in the observed spectrum should begin at lower energy due to cooling of electrons in the propagation. Such a behavior is consistent with the TeV break in the DAMPE data. In the following fitting procedure, we set $Q_{0,A}$, γ_A , and t_{end} as the free parameters of the population A.

3. Electrons Escaping during the Acceleration

The population B are accelerated electrons that are not advected to the downstream, but escape from the upstream of the shock of an SNR. Obviously, the injection of the population B should be a continuous process for each SNR. For those SNRs with age $t > t_{\text{end}}$, the injections last from t to $t - t_{\text{end}}$, while for a source younger than t_{end} , the injection should last from t to now. The arrival spectrum of an SNR with continuous injection can be calculate with Eq. [\(7\)](#page-4-2). For $t > t_{\text{end}}$, $t_{\text{max}} = \min\{t, 1/b_0 E\}$ and $t_{\text{min}} = \max\{t - t_{\text{end}}$, $r/c\};$ while for $t < t_{\text{end}}$, t_{max} and t_{min} are defined as in Sec. [II.](#page-2-0) The injection spectrum can be expressed as

$$
Q(E, t_0) = \dot{Q}_{0,\text{B}}(E/1 \,\text{GeV})^{-1} \exp\{-E^2/[E_c(t - t_0)]^2\},\tag{17}
$$

where t_0 is the injection time, $\dot{Q}_{0,B}$ is the constant rate of injection, which has the unit of $\mathrm{GeV^{-1}\;s^{-1}}$.

Eq. [\(11\)](#page-5-0) indicates that the integrated spectrum in the upstream takes the form of \propto E^{-1} in the low energy part. We adopt this hard spectrum as the power-law term of the injection spectrum of the population B, as shown in Eq. [\(17\)](#page-7-0). We have mentioned in Sec. [III A 2](#page-5-3) that the momentum distribution of the upstream takes the form of $f_1(x, p) =$ $f_0(p) \exp[u_1x/D_1(p)]$ in the low energy region, which implies a harder spectrum for a farther distance from the shock front. This is because the diffusion scale is larger for electrons with higher energy. If one believes a larger diffusion scale equals to a larger chance of escape, the injection spectrum should be even harder than $\propto E^{-1}$. We do not intend to investigate the specific mechanisms of particle escape in the present work, but discuss a scenario of free escape in Appendix [A.](#page-16-0)

The cut-off energy for a continuous injection SNR is time dependent, which can be inferred from Eq. [\(10\)](#page-5-2), Eq. [\(15\)](#page-6-1), and Eq. [\(16\)](#page-6-0). The assumptions about E_0 , n_{ISM} , and B are kept the same with those in Sec. [III A 2.](#page-5-3) For an SNR with an age of t , when it releases electrons at t_0 , it has evolved for a time of $t_{\text{evo}} = t - t_0$. Thus the cut-off energy should be $E_c(t - t_0)$.

We treat $\dot{Q}_{0,B}$ as a free parameter. For old sources contributing to the population B, their contributions are submerged in the population A. This means that their $\dot{Q}_{0,B}$ cannot be restrict by the data. On the other hand, the high energy end of DAMPE still reserves the possibility of spectral features above ∼ 3 TeV. Such features can be produced by young and nearby sources contributing to the population B, so we only focus on this kind of SNRs. SNRs within 1 kpc included by the Green's catalog [\[35\]](#page-20-14) are displayed in Table [I.](#page-7-1) All of them are younger than $\sim 5 \times 10^4$ yr. We choose them as the sources of the population B, and assume that they share a common $\dot{Q}_{0,B}$ in the following fitting procedure.

B. Positrons

Although SNRs are expected to mainly account for the features of the $e^- + e^+$ spectrum of DAMPE, extra positron sources are needed to explain the 'positron excess' observed by PAMELA and AMS-02. In this work, we use a single powerful pulsar as the high energy e^{\pm} source, and test two different known pulsars. Besides, the calculation of the secondary positrons is also briefly mentioned.

1. Pulsars

Electron/positron pairs are produced in the strong magnetic field of pulsars through the electromagnetic cascade [\[36](#page-20-15)]. The details of the injection spectrum of pulsars is described in Appendix [B.](#page-18-0) In this work, the injection spectrum of a pulsar can be determined by three parameters: the conversion efficiency from the total spin-down energy of the pulsar to injected electrons or positrons, η_{pwn} , the spectral index of its PWN, γ_{pwn} , and the cut-off energy of its PWN, $E_{c,\text{pwn}}$.

Firstly, we adopt PSR J0940-5428 to be the single source of the positron excess. The reason of choosing this pulsar is given in Appendix [B.](#page-18-0) PSR J0940-5428 is a Vela-like pulsar [\[37](#page-20-16)] with a distance of 0.38 kpc, an age of 4.2×10^4 yr, and a spin-down energy of 1.34×10^{49} erg. It is also detected as a γ -ray pulsar [\[38\]](#page-21-0). There is no further information about its injection spectrum provided by observations. So in the following model discussions, we set all the parameters of the injection spectrum of PSR J0940-5428, i.e., $\eta_{\text{pwn}}, \gamma_{\text{pwn}},$ and $E_{\text{c,pwn}}$ as free variables. As we assume a continuous injection for pulsars, the spectrum at the Earth should be calculated by Eq. [\(7\)](#page-4-2).

Geminga pulsar is expected to be a significant e^{\pm} contributor [\[39](#page-21-1)[–41\]](#page-21-2), which is nearby $(r = 0.25$ kpc) and relatively old $(t = 3.42 \times 10^5 \text{ yr})$ with a large enough spin-down energy of 1.23×10^{49} erg. We consider Geminga as an alternative single positron source, and set its conversion efficiency η_{pwn} and power-law index γ_{pwn} as free parameters. The cut-off energy E_c is fixed to be 50 TeV, which is consistent with the observation of HAWC along with Milagro [\[42](#page-21-3), [43](#page-21-4)].

Recently, there are arresting discussions about Geminga, focusing on whether its injected e^{\pm} can really reach the Earth [\[44](#page-21-5), [45](#page-21-6)]. The spatial profile of γ -ray around Geminga implies a much slower diffusion of e^{\pm} in this region than that in the ISM [\[44](#page-21-5)]. However, if this slowdiffuse region is fairly small, Geminga may still contribute considerably to the observed $e^- + e^+$ spectrum [\[45](#page-21-6)].

2. Secondary Positrons

Secondary positrons produced by the inelastic collision between CR nuclei and ISM are treated as the background of the exotic positron spectrum. We use the method of [\[18](#page-20-0)] to

obtain the spectrum of secondary e^{\pm} . The only difference is that we adopt the intensities of incident H and He given by Ref. [\[12\]](#page-19-10). Besides, a rescaling parameter c_e is introduced for the secondary component in the following fitting procedure, considering the uncertainties in the calculation.

IV. EXPLANATION OF THE DAMPE DATA AND FITTING TO THE MODEL PARAMETERS

In this section, we show our explanation of the DAMPE data and fitting results of the model parameters. Here we repeat again all the components needed to account for the total e^{\pm} spectrum: the population A and population B electrons from SNRs, a single pulsar as e^{\pm} source, and secondary e^{\pm} . The common free parameters are $Q_{0,\text{A}}$, γ_{A} , t_{end} , and c_{e} which are determined by the fitting to the DAMPE $e^- + e^+$ and AMS-02 $e^+/(e^- + e^+)$ data. We seek the best-fit model parameters by minimizing chi-squared statics^{[1](#page-10-1)} between model predictions and the experimental data. The best-fit parameters of these models are compiled in Table [II.](#page-11-0)

Figs. [1](#page-12-0) and [2](#page-13-1) show the fitting results compared with the DAMPE and AMS-02 data. As expected, the TeV break of the DAMPE $e^- + e^+$ spectrum can be well reproduced in all cases, owing to the cut-off energy of the population A of SNRs. The best-fit t_{end} varies from $\sim 9 \times 10^4$ yr to $\sim 1.4 \times 10^5$ yr, which is quite reasonable for the final release time of particles in SNRs. The corresponding cut-off energies of injection spectra of the population A vary from 3.5 TeV to 2.5 TeV.

In Figs. [1](#page-12-0) and [2](#page-13-1) we take the pulsar PSR J0940-5428 and Geminga as the single positron source respectively. As shown in the figures, the $e^- + e^+$ spectra of PSR J0940-5428 and Geminga are significantly different in the TeV region, which can be attributed to the differences between their t and E_c . The spectral break of Geminga around 1 TeV is due to its old age: under the assumption of Eq. [B1,](#page-18-1) most spin-down energy of the pulsar is released in the form of e^{\pm} in the early age of Geminga, and the high energy part of the e^{\pm} has been effectively cooled by now. On the other hand, the very high Ec ensures the spectrum of Geminga to extend to tens of TeV, which is contributed by the e^{\pm} injected at the later age of Geminga. This indicates that no significant contribution from the population B is needed

Single pulsar		J0940		Geminga
With Pop B?		No.	Yes	Yes
Parameters	Bounds Best-fit Best-fit Best-fit			
$Q_{0,A}$ [10 ⁵⁰ GeV ⁻¹] [0.1, 10.0]		2.60	2.61	2.66
γ_A	$[2.0, 3.0]$ 2.497		2.498	2.501
t_{end} [10 ⁵ yr]	[0.4, 5.0]	0.94	0.89	1.44
$\dot{Q}_{0,B}$ [10 ³³ GeV ⁻¹ s ⁻¹] [0.0, 10.0]			1.72	0.19
η_{pwn}	[0.0, 2.0]	1.29	1.21	1.26
$\gamma_{\rm{pwn}}$	[1.0, 2.7]	2.54	2.52	1.96
$E_{c, \text{pwn}}$ [TeV]	[0.8, 10.0]	3.24	2.37	
$c_{\rm e}$	[0.5, 2.0]	1.41	1.42	0.5
χ^2 /d.o.f		0.72	0.71	0.81

TABLE II. Best-fit parameters for three cases. The reduced chi-square of each model is also shown, and 'd.o.f' is the abbreviation of degree of freedom. As described in Sec. [III B 1,](#page-9-0) the cut-off energy of Geminga is fixed at 50 TeV, so its best-fit value of $E_{\rm c,pwn}$ is blank.

to prevent a fast spectral cut-off at the high energy end of DAMPE, as shown in Fig. [2.](#page-13-1)

In comparison, since PSR J0940-5428 is a much younger source, the plenty of high energy e^{\pm} released in its early age are still energetic now. The fitting result requires a large cut-off energy of ∼ 3 TeV to suppress the spectrum at high energies and produce the break feature at \sim TeV. In this case, the values of $E^3 I(E)$ for the population A and the single pulsar descend in several TeV. Therefore the total $e^- + e^+$ spectrum quickly rolls off at higher energies, as shown in the left panel of Fig. [1.](#page-12-0) If we expect an additional spectral feature in the TeV region, the population B of SNRs is needed. The best-fit injection rate of the population B is $\dot{Q}_{0,\text{B}} = 1.72 \times 10^{33} \text{ GeV}^{-1} \text{ s}^{-1}$, corresponding to a total injection energy of $\sim 10^{46}$ erg for an SNR with an age of 10^4 yr (like Vela). Since the typical kinetic energy of SN ejecta is 10^{51} erg, only a fraction of $\sim 10^{-5}$ of the total energy is required to deliver to the population B.

We notice that the conversion efficiencies of the total spin-down energy to positrons are larger than 1 for the two single pulsar cases. However, this is not a crucial problem. On the one hand, the spin-down time scale τ_0 is quite uncertain, which is important for the

FIG. 1. Results of the fitting to the DAMPE $e^- + e^+$ and AMS-02 $e^+/(e^- + e^+)$ data, with PSR J0940-5428 as the single positron source in the high energy region. Left panels: the electron plus positron spectrum. Right panels: the positron fraction. The results in the bottom panels include the population B of SNRs, while the results in the top panels do not. In the legends, 'TOT' stands for the total $e^- + e^+$ flux (or $e^+/(e^- + e^+)$) of all the sources, the population A of SNRs are abbreviated to 'Pop A', the population B are abbreviated to 'Pop B', while 'J0940' stands for PSR J0940-5428.

estimation of the spin-down energy. On the other hand, the single pulsar model is definitely a simplified picture. In the realistic case, e^{\pm} should be contributed by more pulsars, which may alleviate the demand for a large η_{pwn} .

The fitting requires a reasonable γ_pwn of 1.96 for Geminga, while the best-fit γ_pwn for PSR J0940-5428 is ∼ 2.5. In fact, among all the identified PWNe with measurements of radio spectral indices, only DA 495 has an electron spectral index larger than 2.5 (to be specific, 2.74)[\[46](#page-21-7), [47\]](#page-21-8). The requirement of such a soft injection spectrum for PSR J0940-5428 in the fitting is attributed to its younger age and farther distance, compared with those of

FIG. 2. Same as Fig. [1,](#page-12-0) but for the case of Geminga as the high energy positron source.

Geminga. In general, a source with a large r and small t yields a hard e^{\pm} spectrum at the Earth, which cannot well fit the $e^+/(e^-+e^+)$ fraction of AMS-02. If the source accommodates the $e^+/(e^- + e^+)$ data at low energies, the hard positron spectrum would cause a deviation from the AMS-02 data above \sim 300 GeV. Hence a large γ_{pwn} and soft injection spectrum are required for PSR J0940-5428 as the single source to explain the positron observation.

Finally, we briefly discuss the tentative spectral feature around 1.4 TeV. If this feature is a sharp peak, a mono-energetic electron injection at 1.4 TeV from a nearby source is required, such as dark matter annihilation in a subhalo. However, if there exists some unclear uncertainties, the spectral feature would not be a strictly peak. For instance, if the count number at ∼ 1.2 TeV is underestimated, the actual spectral feature should be edge-like around 1.4 TeV. We have described above that the spectrum of Geminga breaks around ∼ 1.2 TeV due to cooling effect, which can create an edge-like feature at the TeV region, as shown in Fig. [2.](#page-13-1) The precise property of this tentative spectral feature should be tested with larger statistics of further results of DAMPE.

V. A POWERFUL NEARBY SNR AS THE DOMINANT HIGH ENERGY ELEC-TRON SOURCE

In the previous sections, the population A is assumed to be contributed by smoothly distributed sources. In fact, electrons with $E > 1$ TeV may be mainly contributed by sources with $r < 1.5$ kpc and $t_0 < 3 \times 10^5$ yr due to the radiative cooling of the travelling electrons. This condition can be derived by the criteria given in Appendix B of Ref. [\[15\]](#page-19-13). For $t_{\text{end}} \simeq 10^5$ yr, among observed SNRs, only the Monogem Ring (MR) and Loop I can satisfy this condition. Other observed SNRs within 1.5 kpc are too young to contribute to the population A. In this section, we show the scenario in which a powerful nearby SNR dominantly accounts for the TeV spectrum of the population A, and choose MR as an example. We take the distance of MR to be $r_{\rm mr} = 300$ pc [\[48](#page-21-9)], and set its age to be $t_{\rm mr} = 1.1 \times 10^5$ yr, which is same as its associated pulsar PSR B0656+14 [\[49](#page-21-10)].

To calculate the electron spectrum, we consider the population A contributed by MR and a smooth distributed SNR background. We adopt the framework in Ref. [\[24](#page-20-6)], but with the electron injection introduced in the present work. The injection age of MR is $t_{\rm mr} - t_{\rm end}$; the cut-off energy of its injection spectrum $E_c(t_{\text{end}})$ is estimated by Eq. [\(10\)](#page-5-2) and [\(16\)](#page-6-0). The spectral index of MR γ_{mr} and total energy of injected electrons W_{mr} are both assumed to be free. Then we perform the fitting to the DAMPE $e^- + e^+$ spectrum and the positron fraction of AMS-02 again, adopting Geminga as the single high energy positron source. The population B of SNRs is not included here. The fitting result is presented in the left panel of Fig. [3;](#page-15-1) the best-fit parameters can be found in the caption. The positron fraction is similar to that in the right panel of Fig. [2,](#page-13-1) and thus is not shown here.

Similar to the result in Fig. [2,](#page-13-1) this scenario can also well fit the DAMPE data. The bestfit spectral index $\gamma_{\rm mr}=2.1$ and total injection energy $W_{\rm mr}=8.8\times 10^{48}$ erg are reasonable for an SNR. The spectral shape at ∼ 1 TeV in the model is mainly determined by the properties of MR and Geminga. Thus the TeV break of DAMPE can be coincidentally generated by one or few powerful nearby sources, as indicated by the previous works [\[12,](#page-19-10) [24,](#page-20-6) [51](#page-21-11)].

Meanwhile, nearby sources with young injection ages can produce significant anisotropy of $e^- + e^+$, as the dipole anisotropy of a burst-like point source can be roughly estimated by $3r/(2ct_0)$ [\[52\]](#page-21-12). The detection of the anisotropy may help to ascertain the contribution of high energy $e^- + e^+$ [\[40](#page-21-13), [53](#page-21-14), [54\]](#page-21-15). Since the injection age of MR is only 2×10^4 yr, we show the case that MR dominates the $e^- + e^+$ anisotropy of the model in the right panel Fig. [3.](#page-15-1) We compare the predicted anisotropy with the upper limits given by the seven years detection of Fermi-LAT [\[50\]](#page-21-16). The anisotropy produced by MR almost hits the upper limits of Fermi-LAT. Future instruments with larger acceptance and stronger electron/proton discrimination, like HERD [\[55\]](#page-21-17), will provide further judgement to a scenario discussed in this section. An expectation of the sensitivity of HERD with three years measurement is shown in the right panel of Fig. [3;](#page-15-1) one may refer to Ref. [\[54\]](#page-21-15) for the estimation of the sensitivity.

FIG. 3. Left panel: The $e^- + e^+$ spectrum of the model where the population A are contributed by a nearby source MR and a smooth distributed SNR background (labeled with 'BKG Pop A'). The best-fit parameters are: $\gamma_{\rm mr} = 2.1$, $W_{\rm mr} = 8.8 \times 10^{48}$ erg, $Q_{0,A} = 1.92 \times 10^{50}$ GeV⁻¹, $\gamma_A = 2.36$, $t_{\text{end}} = 9 \times 10^4$ yr, $\gamma_{\text{pwn}} = 1.93$, $\eta_{\text{pwn}} = 1.23$, and $c_e = 0.57$. Right panel: the corresponding anisotropy spectrum, assuming that the MR contribution is dominant. The anisotropy is calculated by $3r_{\text{mr}}/[2c(t_{\text{mr}} - t_{\text{end}})]$ multiplying the relative flux of MR. The two groups upper limits (UL) of Fermi-LAT are given by the two different analysis methods in Ref. [\[50](#page-21-16)]. An expectation of the sensitivity of HERD is also shown.

VI. CONCLUSION

In this work, we apply an electron escaping scenario of SNRs to explain the DAMPE $e^- + e^+$ spectrum. In this scenario, most accelerated electrons are released at the final stage of the evolution of SNRs, while a minor part of electrons may escape during their acceleration process. The similar scenario has already been utilized in the researches of CR protons. We also explain the $e^+/(e^- + e^+)$ fraction measured by AMS-02 at the same time, using a single powerful pulsar as the primary high energy positron source. The main conclusions are presented as follows.

- 1. The spectral break at ∼ 0.9 TeV can be naturally explained by the final released electrons of smoothly distributed SNRs, which escape at an age of $\sim 10^5$ yr.
- 2. The break can also be mainly induced by a single nearby old SNR, this case will be hopefully tested by future measurements of the anisotropy of $e^- + e^+$ flux with future instruments, such as HERD.
- 3. A minor part of electrons escaping during the evolution of nearby SNRs are able to contribute to the TeV region significantly, owing to the hard spectral index of the injection spectrum.
- 4. The single pulsar, such as Geminga, can be a dominant source of high energy CR positrons. The sharp drop at ~ 1 TeV of the e^{\pm} spectrum from Geminga can induce an edge-like feature at the $e^- + e^+$ spectrum, which may account for the tentative feature of the DAMPE data at ∼1.4 TeV.

ACKNOWLEDGMENTS

We thank Qiang Yuan for very helpful discussions. This work is supported by the National Key Program for Research and Development (No. 2016YFA0400200) and by the National Natural Science Foundation of China under Grants No. 11475189, 11475191.

Appendix A: Electrons Injected from a Free-escape Boundary

To describe the injection of electrons during the acceleration, we impose the free boundary condition of $f(-x_b) = 0$ at a position $-x_b$ in the upstream of the SNR shock [\[30](#page-20-9)]. At low energies, the distribution of electrons in the upstream can be simply described by the diffusion-convection equation. The solution is expressed as

$$
f(x,p) = f_0(p) \frac{\exp(u_1 x/D_1) - \exp(-u_1 x_b/D_1)}{1 - \exp(-u_1 x_b/D_1)}.
$$
 (A1)

Then we can get the escape flux $F_{\text{esc}} = D_1 \partial f / \partial x |_{x_b}$ in the whole energy range as

$$
F_{\rm esc} = \frac{u_1 f_0(p)}{\exp(u_1 x_b/D_1) - 1},
$$
\n(A2)

where $f_0(p) \propto p^{-4} \exp(-p^2/p_c^2)$. The free-escape boundary is placed at $x_b = cR_{sh}$, where R_{sh} is the radius of the SNR and c is a constant [\[13](#page-19-11)]. The radius R_{sh} is derived by Eq. [\(15\)](#page-6-1) and Eq. [\(16\)](#page-6-0), and the injection spectrum should be proportional to $F_{\text{esc}}R_{sh}^2$. Here we take c to be 0.01. For a larger c, particles escaping from the free-escape boundary are required to be much more energetic than the cut-off energy due to radiative cooling. This means that few particles could escape for a larger c.

FIG. 4. The electron spectrum of the population B contributed by a complete group of SNRs with a free-escape boundary (solid line), compared with the spectrum of the population B shown in the top left panel of Fig. [1](#page-12-0) (dashed line).

In the main text, the sources of the population B consist of only young and nearby SNRs. Here we would like to build a complete group of the sources of the population B. Taking the birth rate of SNe of 4 century[−]¹ galaxy[−]¹ and the radial distribution of SNRs given in Ref. [\[34\]](#page-20-13), we generate 4×10^5 SNRs randomly with the age from 0 to 10^7 yr (SNRs older than 10^7) yr can hardly contribute to the energy range in which we are interested). We calculate the injection spectra for all the sources, and use Eq. [\(7\)](#page-4-2) to obtain the observed spectrum at the Earth. The final spectrum generated with this method is drawn in Fig. [4,](#page-17-0) compared with the spectrum of the population B shown in the top left panel of Fig. [1.](#page-12-0) The normalization of the generated injection spectrum has been adjusted to produce a comparable flux with that shown in Fig. [1.](#page-12-0)

Although the contributions of distant or/and old SNRs to the population B are included, the model described in this section generates a similar spectral shape with that predicted by the model in Sec. [III A 3,](#page-7-2) where only young and nearby sources are considered and the integrated upstream spectrum is adopted as the injection spectrum. This is because that the injection spectra from SNRs with a free-escape boundary described in this section are much harder.

Appendix B: The Injection Spectrum of Pulsars

Pulsars convert their spin-down energy partially to relativistic winds of e^{\pm} pairs. The young or middle aged pulsar may be surrounded by an observable PWN (see Ref. [\[56](#page-21-18)] and references therein). Particles injected into the PWN are constrained in a period of time until the crush of the PWN, and then escape into the ISM [\[57](#page-22-0)]. Thus the injection spectrum of e^{\pm} should be the spectrum from the PWN, rather than that from the pulsar itself [\[58\]](#page-22-1). The particle acceleration and escape processes in PWNe are much more complicated than those in SNRs. Here we simply assume that the injection process has the same time dependency with the spin-down luminosity of pulsars (i.e., $\propto (1 + t/\tau_0)^{-2}$ [\[59\]](#page-22-2)), and the e^{\pm} injection spectrum of PWNe takes the form of

$$
Q(E, t_0) = C \left[1 + (t - t_0) / \tau_0 \right]^{-2} \left(E / 1 \,\text{GeV} \right)^{-\gamma} \exp(-E / E_c) \,, \tag{B1}
$$

where C is the normalization, t is the age of a pulsar, and t_0 denotes the injection time. Meanwhile, Q can be related to the total spin-down energy released by a pulsar by

$$
\int_{E_{\min}}^{\infty} dE \int_{r/c}^{t} dt_0 Q(E, t_0) E = \eta W_{\mathbf{p}},
$$
\n(B2)

where $W_{\rm p}$ is the spin-down energy, η represents the conversion efficiency to injected positrons, r is the distance of the pulsar, and E_{min} is set to be 0.1 GeV. We integrate the spin-down luminosity \dot{E} with time to get the spin-down energy

$$
W_{\rm p} = \dot{E} t \left(1 + \frac{t}{\tau_0} \right),\tag{B3}
$$

where τ_0 is the initial spin-down timescale of the pulsar, which has a typical value of 10 kyr [\[41\]](#page-21-2). E and t of known pulsars are given by the ATNF catalog [\[60](#page-22-3)], so for each pulsar we can perform an estimation to W_p . Then the injection spectrum of a pulsar is determined by three parameters: η , γ , and E_c .

So far, the ATNF catalog has collected 2573 pulsars. We gave a rank of all these pulsars by their potential of contribution to the arrival e^{\pm} spectrum in Ref. [\[54\]](#page-21-15). One may refer to Ref. [\[54\]](#page-21-15) for the rule of this rank. Vela pulsar and PSR J0940-5428 are much more powerful in e^{\pm} spectrum than other pulsars. So if we intend to reproduce the positron excess by a single pulsar, these two sources may require the smallest η . However, as we have described above, e^{\pm} may not be injected from a PWN until the crush of the PWN. It may take thousands of years for the reverse shock of an SNR to propagate backward and collide with its PWN [\[61,](#page-22-4) [62](#page-22-5)]. Since Vela pulsar has an age of 1.1×10^4 years, an injection delay of thousands of years may push it to contribute in higher energy region of e^{\pm} spectrum. While for PSR J0940-5428, which is 4.2×10^4 years old, the injection delay may have less influence. Therefore, we choose PSR J0940-5428 as the single positron source in this work.
