ABSTRACT

Using a suite of isolated L_* galaxy simulations we show that global depletion times and star-forming gas mass fractions in simulated galaxies exhibit systematic and well-defined trends as a function of the local star formation efficiency per freefall time, ϵ_{ff} , strength of stellar feedback, and star formation threshold. We demonstrate that these trends can be reproduced and explained by a simple physical model of global star formation in galaxies. Our model is based on mass conservation and the idea of gas cycling between star-forming and non-star-forming states on certain characteristic time scales under the influence of dynamical and feedback processes. Both the simulation results and our model predictions exhibit two limiting regimes with rather different dependencies of global galactic properties on the local parameters. When ϵ_{ff} is small and feedback is inefficient, the total star-forming mass fraction, f_{sf} , is independent of ϵ_{ff} and the global depletion time, τ_{dep} , scales inversely with ϵ_{ff} . When ϵ_{ff} is large or feedback is very efficient, these trends are reversed: $f_{\text{sf}} \propto \epsilon_{\text{ff}}^{-1}$ and τ_{dep} is independent of ϵ_{ff} but scales linearly with the feedback strength. We also compare our results to the observed depletion times and mass fractions of star-forming and molecular gas and show that they provide complementary constraints on ϵ_{ff} and the feedback strength. We show that useful constraints on ϵ_{ff} can also be obtained using measurements of the depletion time and its scatter on different spatial scales.

1. INTRODUCTION

Understanding how galaxies build up their stellar component is a key to understanding galaxy evolution. Formation of stars in galaxies is a complex multi-scale process, as stars are formed from gravitationally bound gaseous cores on sub-parsec scales, while the formation of such cores is aided by bulk gas motions of the interstellar medium (ISM) on hundreds of parsec scales. Despite this complexity, the star formation rate (SFR) per unit gas mass on kiloparsec- and larger scales appears to be surprisingly universal: the gas depletion time, $\tau_{\text{dep}} = M_{\text{g}}/\dot{M}_*$, has a characteristic value and exhibits a relatively small scatter (see, e.g., Kennicutt & Evans 2012, for a review). This universality is manifested in the tight Kennicutt-Schmidt relation (Schmidt 1959; Kennicutt 1989, 1998) between the surface densities of gas and the star formation rate.

Existence of such a tight relation implies that the small-scale star formation, averaged over all individual star-forming regions, is closely related to the total gas mass in galaxies. Numerical simulations and semi-analytic models of galaxy evolution show that this gas mass is controlled by 1) the net galactic gas supply rate, determined by the rates of inflow and outflow, and 2) the star formation rate or, alternatively, the global depletion time. During the last decade, our understanding of inflows and feedback-driven outflows has improved dramatically, although qualitative and quantitative details of the relevant physical processes are still subject of an active

and lively debate (see, e.g., Somerville & Davé 2015; Naab & Ostriker 2017, for recent reviews). Likewise, understanding global star formation rates and depletion times requires insight into the interplay between ISM gas flows and local star formation and feedback processes. Understanding of this interplay can be greatly aided with numerical simulations of galaxies, as we will illustrate in this paper.

Modeling of local star formation and feedback processes in galaxy simulations is admittedly rather crude. With some variations and few exceptions, star formation prescriptions usually follow ideas introduced for the first generation of simulations (Katz 1992; Cen & Ostriker 1992): star formation occurs only in star-forming gas, defined using some conditions, e.g., that gas density (temperature) is larger (smaller) than some threshold, that gas within some region is gravitationally bound, that gas is in molecular phase, etc. (see, e.g., Hopkins et al. 2013a). Star-forming gas is then converted into stellar particles using a stochastic Poisson process with the rate

$$\dot{\rho}_* = \frac{\rho}{t_*}, \quad (1)$$

where ρ is the density of the gas that is deemed to be star-forming according to the adopted criteria, and t_* is its local depletion time. In most recent studies, this time is parametrized as $t_* = t_{\text{ff}}/\epsilon_{\text{ff}}$, where ϵ_{ff} is the star formation efficiency per freefall time, $t_{\text{ff}} \equiv \sqrt{3\pi/32G\rho}$. Likewise, the stellar feedback is modeled by simply injecting thermal and kinetic energy and momentum into gas resolution elements adjacent to a young star particle (e.g., Hopkins et al. 2011, 2017b; Agertz et al. 2013; Simpson et al. 2015) or using a subgrid prescription with a specific model of ISM on scales below resolution (e.g., Yepes et al. 1997; Springel & Hernquist 2003; Braun & Schmidt 2012).

Despite a rather simplistic modeling of star formation and feedback on scales close to the spatial resolution, modern galaxy formation simulations generally predict τ_{dep} and the

* semenov@uchicago.edu

Kennicutt-Schmidt relation on kiloparsec- and larger scales in a reasonable agreement with observations (e.g., Governato et al. 2010; Stinson et al. 2013; Hopkins et al. 2014, 2017a; Agertz & Kravtsov 2015, 2016; Grand et al. 2017; Orr et al. 2017). Although in certain regimes the normalization and slope of the Kennicutt-Schmidt relation on galactic scales simply reflect the adopted value of t_* on small scales (Equation 1) and its assumed density dependence (Schaye & Dalla Vecchia 2008; Gnedin et al. 2014), in other regimes there is no direct connection between t_* and the global Kennicutt-Schmidt relation (Hopkins et al. 2017a; Orr et al. 2017; Semenov et al. 2017). The fact that simulations in the latter regime still result in the global depletion time scale close to the observed values is non-trivial. This agreement indicates that such simulations can be used to shed light on the physical processes connecting local parameters of star formation and feedback to the global star formation in galaxies.

This connection and associated processes are the focus of this paper and our goal is to extend and make sense of the results of other recent studies of this issue (cf., e.g., Hopkins et al. 2011, 2017a; Agertz et al. 2013; Agertz & Kravtsov 2015; Benincasa et al. 2016; Li et al. 2017a,b). We use a suite of isolated L_* -sized galaxy simulations with systematically varied ϵ_{ff} value, the star formation threshold, and the feedback strength to show that the global depletion time and the star-forming gas mass fraction in simulated galaxies exhibit systematic and well-defined trends as a function of these parameters. We also demonstrate that these trends can be reproduced both qualitatively and quantitatively with a physical model presented in Semenov et al. (2017, hereafter Paper I) that explains the origin of long gas depletion times in galaxies.

Our model is based on the mass conservation equations relating the star-forming and non-star-forming components of the ISM and the idea of gas cycling between these components on certain characteristic time scales under the influence of dynamical and feedback processes (such gas cycling was also envisioned by Madore 2010; Kruijssen & Longmore 2014; Elmegreen 2015). Our model explicitly relates the global depletion time to the parameters of local star formation and feedback.

The success of this relatively simple framework in explaining the long depletion time scale of observed galaxies (Paper I) and in reproducing the trends exhibited in the simulations presented in this paper and other recent studies (see Section 6) implies that conversion of gas into stars in galaxies is a result of dynamic gas cycling between the star-forming and non-star-forming states on short time scales. The long time scale of gas depletion is partly due to the low efficiency of star formation in star-forming regions and partly due to rather short lifetime of these regions limited by stellar feedback. The combination of these factors results in gas going through many cycles before complete conversion into stars.

We will discuss how the trends identified in simulations and our analytic model can be used to guide the choice of star formation and feedback parameters in high-resolution galaxy simulations. In particular, we will show that both the global depletion times and the star-forming gas mass fractions of observed galaxies should be used on kiloparsec- and larger scales, while the measurements of the depletion time and its scatter on smaller spatial scales provide additional constraints on the local efficiency of star formation.

The paper is organized as follows. In Section 2, we describe our simulation suite and the adopted star formation and

feedback prescriptions. In Section 3, we present the trends of the global depletion times, star-forming mass fractions, and freefall times in star-forming gas with the parameters of the star formation and feedback prescriptions used in simulations. In Section 4, we summarize the model for global star formation presented in Paper I and show that it can reproduce the trends in our simulation results both qualitatively and quantitatively. In Section 5, we compare our simulation results and model predictions to the observed star-forming properties of real galaxies and identify a combination of the star formation efficiency and the feedback strength that satisfies all considered observational constraints. In Section 6, we compare our predictions to the results of previous recent studies and interpret their results in the context of our model. Finally, in Section 7, we summarize our results and conclusions.

2. SIMULATIONS

2.1. Methods overview

To understand the connection between local and global star formation, we explore the effects of local star formation and feedback parameters in a suite of L_* -sized isolated galaxy simulations performed with the adaptive mesh refinement gas-dynamics and N -body code ART (Kravtsov 1999; Kravtsov et al. 2002; Rudd et al. 2008; Gnedin & Kravtsov 2011). In this section, we briefly summarize the adopted initial conditions and subgrid models and for details, refer the reader to Section 3 of Paper I.

Our simulations start from the initial conditions of the AGORA code comparison project (Kim et al. 2016), in which an L_* -sized exponential galactic disk with a stellar bulge is embedded into a dark matter halo. The disk scale height and radius are $h_d \approx 340$ pc and $r_d = 10 h_d$, and its total mass is $M_d \approx 4.3 \times 10^{10} M_\odot$, 20% of which are in the gaseous disk and the rest is in the initial population of old stellar particles. The stellar bulge has a Hernquist (1990) density profile, with the scale radius of $a = h_d$ and the total mass of $M_{*,b} \approx 4.3 \times 10^9 M_\odot$. The dark matter halo is initialized with a Navarro-Frenk-White profile (Navarro et al. 1996, 1997) with the characteristic circular velocity of $v_{c,200} = 150$ km s⁻¹ and the concentration of $c = 10$. In our simulations, we adaptively resolve cells whose gas mass exceeds $\sim 8300 M_\odot$ and reach the maximum resolution of $\Delta = 40$ pc.

For cooling and heating, we adopt Gnedin & Hollon (2012) model assuming constant metallicity of $Z = Z_\odot$ and the background radiation field with the photodissociation rate of 10^{-10} s⁻¹ (Stecher & Williams 1967). Molecular gas shielding is modeled using a prescription calibrated against radiative transfer ISM simulations (the ‘‘L1a’’ model in Safranek-Shrader et al. 2017). In each computational cell, we dynamically follow unresolved turbulence using the ‘‘shear-improved’’ model of Schmidt et al. (2014), which implementation in the ART code is discussed in Semenov et al. (2016). Subgrid turbulence dynamically acts on resolved gas motions and its distribution allows us to predict velocity dispersions in star-forming regions which we account for in our star formation prescription (Section 2.2).

Analysis of time evolution shows that all our simulations exhibit a short, $\lesssim 300$ Myr, initial transient stage, after which the simulated galaxy settles into a quasi-equilibrium state with approximately constant global galaxy parameters, such as gas depletion time, τ_{dep} (see, e.g., Figure 1 below). Thus, in our subsequent analysis we average the equilibrium values of the parameters of interest between 300 and 600 Myr, as this time

interval is sufficiently long to average out the temporal variability of such quantities, but it is also shorter than τ_{dep} , and hence the galaxy maintains the approximate equilibrium over this time interval. The only exceptions are the runs without feedback and with high local star formation efficiency of $\epsilon_{\text{ff}} \geq 10\%$, in which τ_{dep} is very short and the total gas mass decreases appreciably between 300 and 600 Myr. The equilibrium assumption is also violated for the central region in simulations with $\epsilon_{\text{ff}} \leq 0.1\%$, where the central density keeps increasing due to continuous accretion. However, outside the central 1 kpc the total gas mass and the value of τ_{dep} remain approximately constant, and therefore we exclude gas in the central 1 kpc region when computing quantities in our analysis.

To explore gas flows between different states in the ISM, we use passive gas-tracer particles which are exchanged between adjacent computational cells stochastically, with the probability proportional to the gas mass flux between the cells, as proposed by Genel et al. (2013). These tracer particles are initialized proportionally to the local gas density after 400 Myr of disk evolution. By this point, all initial transients have dissipated away and ISM gas distribution became stationary. Using tracer particles, we average this distribution between 400 and 600 Myr and measure at each step the instantaneous contribution of each tracer into gas fluxes as the second-order time-derivatives between the previous and subsequent snapshots. To accurately track these gas fluxes, we output positions, densities and subgrid velocity dispersion for each gas tracer every 1 Myr. To account for gas consumption, whenever a stellar particle is formed, relative weights of all tracers inside the host cell are decreased correspondingly.

We note, that the analysis presented in this paper differs from Paper I in our implementation of gas tracers: we now use stochastic tracer particles instead of classical velocity tracers and also initialize these particles proportionally to gas density rather than uniformly as in Paper I. Both these changes allow us to follow the evolution of gas distribution more accurately. We checked, however, that all the conclusions of Paper I remain valid after these changes.

2.2. Star formation and feedback

As our goal is to explore the effects of star formation and feedback model parameters, we adopt a usual parametrization of the local star formation rate with a star formation efficiency per freefall time, ϵ_{ff} :

$$\dot{\rho}_{\star} = \epsilon_{\text{ff}} \frac{\rho}{t_{\text{ff}}}, \quad (2)$$

and systematically vary ϵ_{ff} as will be explained at the end of this section. We allow star formation to occur only in the gas that satisfies a chosen criterion. To explore the effects of such a criterion, we adopt thresholds in either the gas virial parameter, $\alpha_{\text{vir,sf}}$, or the density, n_{sf} , and also vary the values of α_{vir} and n_{sf} .

As our fiducial star formation criterion, we adopt a threshold in α_{vir} and define all gas with $\alpha_{\text{vir}} < \alpha_{\text{vir,sf}}$ as star-forming. For a computational cell with a side Δ , the local virial parameter is defined as for a uniform sphere of radius $R = \Delta/2$ (Bertoldi & McKee 1992):

$$\alpha_{\text{vir}} \equiv \frac{5\sigma_{\text{tot}}^2 R}{3GM} \approx 9.35 \frac{(\sigma_{\text{tot}}/10 \text{ km s}^{-1})^2}{(n/100 \text{ cm}^{-3})(\Delta/40 \text{ pc})^2}, \quad (3)$$

where $\sigma_{\text{tot}} = \sqrt{\sigma_{\text{t}}^2 + c_{\text{s}}^2}$ is the total subgrid velocity dispersion

due to turbulent and thermal motions, and subgrid turbulent velocities, σ_{t} , are dynamically modeled in each cell following Schmidt et al. (2014).

The choice of the star formation threshold in α_{vir} is motivated by theoretical models of star formation in turbulent giant molecular clouds (GMCs), which generically predict an exponential increase of ϵ_{ff} with decreasing α_{vir} (see Padoan et al. 2014, for a review). We set our fiducial values of parameters to $\epsilon_{\text{ff}} = 1\%$ and $\alpha_{\text{vir,sf}} = 10$ as supported by the observed efficiencies and virial parameters of star-forming GMCs (e.g., Evans et al. 2009, 2014; Heiderman et al. 2010; Lada et al. 2010, 2012; Lee et al. 2016; Vutisalchavakul et al. 2016; Miville-Deschênes et al. 2017) and also consistent with the results of high-resolution GMC simulations (e.g., Padoan et al. 2012, 2017), which show a sharp increase of ϵ_{ff} below $\alpha_{\text{vir}} \sim 10$. Note also, that the threshold in α_{vir} is equivalent to a threshold in the local Jeans length that accounts for both the thermal and turbulent pressure support: $\lambda_{\text{J}} = \sigma_{\text{tot}} \sqrt{\pi/G\rho} = \pi\Delta \sqrt{\alpha_{\text{vir}}/5}$, and thus $\alpha_{\text{vir,sf}} = 10$ implies that gas becomes star-forming when the local Jeans length is resolved by less than $\lambda_{\text{J}}/\Delta \approx 4.5$ cells.

In galaxy simulations that do not track subgrid turbulence, the GMC-scale α_{vir} is not readily available due to insufficient resolution. Instead, such simulations often adopt a star formation threshold in gas density, n , and define star-forming gas as the gas with $n > n_{\text{sf}}$. To show that our conclusions remain valid for such a threshold, we explore models with varied density-based threshold in addition to our fiducial α_{vir} -based threshold.

The feedback from young stars is implemented by injection of thermal energy and radial momentum generated during supernova (SN) remnant expansion in a non-uniform medium in the amounts calibrated against simulations by Martizzi et al. (2015). The total number of SNe exploded in a single stellar particle is computed assuming the Chabrier (2003) initial mass function. To mimic the effects of pre-SNe feedback, such as radiation pressure and winds from massive young stars, the momentum injection commences at the moment when a stellar particle is created and continues for 40 Myr.

The explicit injection of the generated radial momentum allows to partially resolve the overcooling problem and efficiently couple the feedback energy to resolved gas dynamics, which explains the growing popularity of the method (e.g., Simpson et al. 2015; Grisdale et al. 2017; Hopkins et al. 2017b). However, the injected momentum is still partially lost due to advection errors (see, e.g., Agertz et al. 2013), and to compensate for this loss, we boost the momentum predicted by Martizzi et al. (2015) by a factor of 5. This value is motivated by our idealized tests of a stellar particle exploding in a uniform medium with additional translational motion at velocity 200 km s^{-1} , which is comparable to the rotational velocity of the simulated galaxy. Such fiducial boosting factor also absorbs uncertainties related to SNe clustering (Gentry et al. 2017) and the total energy of a single SN. To explore the effects of the feedback strength on the global depletion times, in addition to this fiducial boosting, we multiply the injected momentum by a factor b , which is systematically varied.

In the end, in our simulations, star formation and feedback are parametrized by three numbers: the star formation efficiency, ϵ_{ff} , the star formation threshold, $\alpha_{\text{vir,sf}}$ or n_{sf} , and the feedback boost factor, b , which we vary in order to explore their effects on the global star formation. To assess the effect of the local star formation efficiency, we vary ϵ_{ff} from 0.01%

FIG. 1.— Evolution of the global depletion time, τ_{dep} , and the star-forming mass fraction, f_{sf} , in the simulations with varying ϵ_{ff} at the fiducial feedback strength ($b = 1$) and star formation threshold ($\alpha_{\text{vir,sf}} = 10$). To compare different runs at the same temporal resolution, all curves are smoothed using a Gaussian filter with a width of 30 Myr. All quantities are measured in a cylindrical volume centered at the disk center with the $|z| < 2$ kpc and $1 < R < 20$ kpc.

to 100%, i.e., by four orders of magnitude around our fiducial value of $\epsilon_{\text{ff}} = 1\%$. To explore the effects of the star-forming gas definition, we vary $\alpha_{\text{vir,sf}}$ between 10 and 100, and n_{sf} between 10 cm^{-3} and 100 cm^{-3} . We do not consider $\alpha_{\text{vir,sf}} < 10$ and $n_{\text{sf}} > 100 \text{ cm}^{-3}$ because gas with such densities and virial parameters is not fully resolved in our simulations. Finally, in order to explore the effect of the feedback strength, in addition to the fiducial case of $b = 1$, we also consider the 5 times stronger feedback ($b = 5$), the 5 times weaker feedback ($b = 0.2$), and the case of no feedback at all ($b = 0$). Such wide variation of model parameters allow us to explore the connection between the subgrid-scale and the global star formation in the simulated galaxy.

3. EFFECTS OF STAR FORMATION AND FEEDBACK PARAMETERS ON GLOBAL STAR FORMATION

The analysis presented in this section focuses on the quantities that characterize the global star formation of the simulated galaxy: the global gas depletion time,

$$\tau_{\text{dep}} \equiv \frac{M_{\text{g}}}{\dot{M}_{\star}}, \quad (4)$$

as well as the mass fraction of star-forming gas, $f_{\text{sf}} = M_{\text{sf}}/M_{\text{g}}$, and the mean freefall time of star-forming gas¹, $\tau_{\text{ff}} = \langle 1/t_{\text{ff}} \rangle_{\text{sf}}^{-1}$. These quantities are closely interrelated. For example, the global depletion time can be expressed as

$$\tau_{\text{dep}} \equiv \frac{M_{\text{g}}}{\dot{M}_{\star}} = \frac{M_{\text{sf}}}{\dot{M}_{\star}} \frac{M_{\text{g}}}{M_{\text{sf}}} = \frac{\tau_{\text{ff}}}{\epsilon_{\text{ff}} f_{\text{sf}}}, \quad (5)$$

because by definition $\dot{M}_{\star} = \epsilon_{\text{ff}} M_{\text{sf}} / \tau_{\text{ff}}$.

¹ We define the average freefall time by analogy with Equation (2): $\dot{M}_{\star} = \epsilon_{\text{ff}} M_{\text{sf}} / \tau_{\text{ff}}$, and thus τ_{ff} relates to the local t_{ff} via $\epsilon_{\text{ff}} / \tau_{\text{ff}} = \dot{M}_{\star} / M_{\text{sf}} = \int (\epsilon_{\text{ff}} / t_{\text{ff}}) \rho dV / \int \rho dV = \epsilon_{\text{ff}} \langle 1/t_{\text{ff}} \rangle_{\text{sf}}$, where the integrals are taken over all star-forming gas.

FIG. 2.— Dependence of the equilibrium τ_{dep} and f_{sf} values on the ϵ_{ff} value in our simulations with the fiducial feedback strength ($b = 1$) and star formation threshold ($\alpha_{\text{vir,sf}} = 10$). The values of τ_{dep} and f_{sf} are time-averaged between 300 and 600 Myr with error bars indicating 5th and 95th percentiles over this time interval. The choice of the averaging interval is explained in Section 2.1. The figure illustrates qualitatively different behavior of τ_{dep} and f_{sf} at low and high ϵ_{ff} .

Below, we describe the trends of τ_{dep} , f_{sf} , and τ_{ff} with the main parameters of the star formation and feedback prescriptions in our L_{\star} -sized galaxy simulations: efficiency ϵ_{ff} , the feedback strength parameter b , and the star formation threshold $\alpha_{\text{vir,sf}}$ or n_{sf} . The efficiency ϵ_{ff} affects local star formation in the most direct way, while the feedback strength b affects the *integral* local star formation efficiency by controlling the time that gas spends in the star-forming state. The interplay between star formation and feedback also affects the overall distribution of gas in a galaxy. For a given distribution, the star formation thresholds control the mass fraction, f_{sf} , and the mean density of star-forming gas, and thus its mean freefall time, τ_{ff} .

Figure 1 shows the evolution of τ_{dep} and f_{sf} in simulations with varying ϵ_{ff} at the fixed fiducial feedback strength ($b = 1$) and the star formation threshold ($\alpha_{\text{vir,sf}} = 10$). After initial transient stage, τ_{dep} and f_{sf} become approximately constant in time at values that depend on the choice of ϵ_{ff} . To explore this dependence on ϵ_{ff} , we average the equilibrium values of τ_{dep} and f_{sf} between 300 and 600 Myr² and show them in Figure 2 with error bars indicating temporal variability around the average. Gray lines in this figure show the predictions of our model that will be described and discussed in Section 4.

Figure 2 clearly shows that the dependence of τ_{dep} and f_{sf} on ϵ_{ff} is qualitatively different when ϵ_{ff} is low and when it is high. When ϵ_{ff} is low, $\leq 0.01\%$, τ_{dep} scales as $\epsilon_{\text{ff}}^{-1}$, whereas the star-forming mass fraction remains independent of ϵ_{ff} . When ϵ_{ff} is high, $\epsilon_{\text{ff}} \geq 1\%$, the trends are reversed: τ_{dep} is independent of ϵ_{ff} , whereas f_{sf} scales as $\epsilon_{\text{ff}}^{-1}$. Such independence of τ_{dep} of ϵ_{ff} has been referred to as *self-regulation* in the literature.

In the top left panels of Figure 3, we explore the equilibrium values of τ_{dep} and f_{sf} as a function of both ϵ_{ff} and the feedback boosting factor, b . In the bottom panel, we also show variation of τ_{ff} with varying ϵ_{ff} and b . As before, the error bars indicate

² The choice of this time interval is explained in Section 2.1.

FIG. 3.— Equilibrium values of τ_{dep} , f_{sf} , and τ_{ff} , in simulations with varying ϵ_{ff} and different feedback strengths (b , left column) and star formation thresholds set in virial parameter ($\alpha_{\text{vir}} < \alpha_{\text{vir,sf}}$, middle columns) and gas density ($n > n_{\text{sf}}$, right column). The feedback strength is varied at the fiducial threshold value ($\alpha_{\text{vir,sf}} = 10$), whereas the threshold is varied at the fiducial feedback strength ($b = 1$). Points indicate the values of τ_{dep} , f_{sf} , and τ_{ff} time-averaged between 300 and 600 Myr with error bars indicating 5th and 95th percentiles over this time interval. To avoid overlap, points for $\epsilon_{\text{ff}} = 0.1\%$, 1% , and 10% are slightly shifted horizontally around the actually used values of b , $\alpha_{\text{vir,sf}}$, and n_{sf} . Lines show our analytical model detailed in Section 4 and summarized in Appendix A.

temporal variability around the average and lines show the predictions of our model that will be detailed in Section 4.

The figure shows that at any fixed b , the dependence of τ_{dep} and f_{sf} on ϵ_{ff} is qualitatively similar to the fiducial case discussed above, and the limiting regimes of low and high ϵ_{ff} exist at all b . However, for stronger feedback, the transition to the high- ϵ_{ff} regime occurs at smaller ϵ_{ff} , and the resulting depletion time increases almost linearly with b : $\tau_{\text{dep}} \sim (6 \text{ Gyr}) b^{0.75}$. The bottom left panel also shows that despite wide variation of ϵ_{ff} and b , the value of τ_{ff} varies only mildly, from $\tau_{\text{ff}} \sim 3 \text{ Myr}$ at low ϵ_{ff} to $\tau_{\text{ff}} \sim 5\text{--}6 \text{ Myr}$ at high ϵ_{ff} .

The middle column of panels in Figure 3 shows the variation of τ_{dep} , f_{sf} , and τ_{ff} in the runs with different ϵ_{ff} and values of the adopted star formation threshold: $\alpha_{\text{vir,sf}} = 10, 30, \text{ and } 100$. Again, for every value of $\alpha_{\text{vir,sf}}$, the dependence on ϵ_{ff} is qualitatively similar to the fiducial case. In the high- ϵ_{ff} regime, τ_{dep} decreases at higher $\alpha_{\text{vir,sf}}$, i.e., when the threshold becomes less stringent and makes more gas eligible to star formation. At a less stringent threshold, f_{sf} and τ_{ff} both increase and this increase is stronger in the high- ϵ_{ff} regime. In the right panels of Figure 3, the star formation threshold is set in the gas density rather than in α_{vir} , and the behavior of τ_{dep} , f_{sf} , and τ_{ff} remains qualitatively the same, but the direction of all trends is opposite since the density-based threshold becomes less stringent at smaller n_{sf} .

The presented results show that the key global star formation properties of our simulated galaxies change systematically with changing parameters of the local star formation and feedback. The trends are well defined and exhibit distinct be-

havior in the low- ϵ_{ff} and high- ϵ_{ff} regimes. In the latter, the global star formation rate and the gas depletion time become insensitive to the variation of ϵ_{ff} , while the mass fraction of the star-forming gas, f_{sf} , is inversely proportional to ϵ_{ff} . In the low- ϵ_{ff} regime, the trends are reversed: τ_{dep} scales inversely with ϵ_{ff} , while f_{sf} is almost insensitive to it. The dependence of τ_{dep} on the feedback strength parameter b is the opposite to the dependence on ϵ_{ff} : in the low- ϵ_{ff} regime, τ_{dep} is insensitive to b , while in the high- ϵ_{ff} regime τ_{dep} exhibits a close-to-linear scaling with b .

4. ANALYTIC MODEL FOR GLOBAL STAR FORMATION IN GALAXIES

As solid lines in Figures 2 and 3 show, the trends of τ_{dep} , f_{sf} , and τ_{ff} are well described by a physical model of gas cycling in the interstellar medium formulated in Paper I. This model is based on the basic mass conservation between different parts of the interstellar gas. In this section, we summarize the main equations of our model and its predictions for the global gas depletion time and the star-forming gas mass fraction. We then discuss the qualitative predictions of the model for the trends of τ_{dep} , f_{sf} , and τ_{ff} in simulations and provide a physical interpretation of these trends. We then show that with a minimal calibration, our model can reproduce these trends *quantitatively*. For convenience, the meaning of quantities used in our model are summarized in Table 1 (Appendix A).

4.1. Description of the model

Figure 4 illustrates our model for τ_{dep} , f_{sf} , and τ_{ff} using the distribution of gas in our fiducial simulation in the plane of gas density, n , and total velocity dispersion that includes both the thermal and subgrid turbulent motions, $\sigma_{\text{tot}} = \sqrt{c_s^2 + \sigma_t^2}$. The values of τ_{dep} , f_{sf} , and τ_{ff} are defined by the distribution of star-forming gas, which resides below the adopted star formation threshold, $\alpha_{\text{vir}} < \alpha_{\text{vir,sf}} = 10$, shown with the dotted line in the figure. This distribution of star-forming gas is shaped by gas motions in the $n - \sigma_{\text{tot}}$ plane, and its total mass, $M_{\text{sf}} = f_{\text{sf}} M_{\text{g}}$, changes due to the gas consumption at a rate \dot{M}_{\star} and the net gas flux through the star formation threshold, which in general can be decomposed into a positive and a negative components, F_+ and F_- :

$$\dot{M}_{\text{sf}} = F_+ - F_- - \dot{M}_{\star}. \quad (6)$$

As the local dynamical time scales of processes controlling F_+ and F_- are short compared to the global time scales, such as rotation period or gas consumption time, isolated galaxies settle into a quasi-equilibrium state.³ In this state, $\dot{M}_{\text{sf}} \approx 0$ over a suitably short time interval, and, therefore, the global SFR is balanced by the net inflow of the star-forming gas, $\dot{M}_{\star} \approx F_+ - F_-$. As was shown in Paper I, in normal star-forming galaxies the small net flux required by the observed small SFRs results from the near cancellation of F_+ and F_- , both of which are much larger than the resulting net mass flux. The total positive flux, F_+ , results from a combined effect of gravity, cooling, compression in ISM turbulence, etc., while the negative flux is due to the dispersal of star-forming regions by stellar feedback, $F_{-\text{fb}}$, and dynamical processes like the turbulent shear, the differential rotation, and the expansion behind spiral arms, $F_{-\text{d}}$: $F_- = F_{-\text{fb}} + F_{-\text{d}}$.

The global depletion time and the star-forming mass fraction can be related to the parameters of star formation and feedback if the terms in the above equation are parametrized as

$$F_+ \equiv \frac{(1 - f_{\text{sf}}) M_{\text{g}}}{\tau_+}, \quad (7)$$

$$F_{-\text{fb}} \equiv \frac{f_{\text{sf}} M_{\text{g}}}{\tau_{-\text{fb}}} = \xi \dot{M}_{\star}, \quad (8)$$

$$F_{-\text{d}} \equiv \frac{f_{\text{sf}} M_{\text{g}}}{\tau_{-\text{d}}}, \quad (9)$$

$$\dot{M}_{\star} \equiv \frac{f_{\text{sf}} M_{\text{g}}}{\tau_{\star}}. \quad (10)$$

In these expressions, the adopted star formation prescription determines the average consumption time in the star-forming gas, τ_{\star} , which in our case is equal to $\tau_{\text{ff}}/\epsilon_{\text{ff}}$, and the strength of the stellar feedback is reflected in the parameter ξ , which is analogous to the usual feedback mass-loading factor, but is defined on the scale of star-forming regions. The final expressions for the global depletion time and the star-forming fraction follow from Equation (6) after the substitution of Equa-

³ An assumption of the quasi-equilibrium is not required in general. As was shown in Paper I, the out-of-equilibrium state of a galaxy (or a given ISM patch) results in an extra term in the final expression for τ_{dep} , which contributes to the scatter of the depletion time.

FIG. 4.— Illustration of the analytical model of Paper I using the gas distribution from our fiducial simulation in the plane of the gas density, n , and the total subgrid velocity dispersion, $\sigma_{\text{tot}} = \sqrt{c_s^2 + \sigma_{\text{turb}}^2}$. The contours enclose 68%, 95%, and 99% of the ISM gas mass. The star-forming gas in this diagram resides below the star formation threshold, $\alpha_{\text{vir}} < \alpha_{\text{vir,sf}} = 10$ (Equation 3), shown by the dotted line. Thick blue and red arrows illustrate the total positive and negative gas mass fluxes through the star formation threshold, while the thick black arrow illustrates gas conversion into stars at a rate \dot{M}_{\star} .

tions (7–10):

$$\tau_{\text{dep}} = N_c \tau_+ + \tau_{\star}, \quad (11)$$

$$f_{\text{sf}} = \frac{\tau_{\star}}{\tau_{\text{dep}}} = \left(N_c \frac{\tau_+}{\tau_{\star}} + 1 \right)^{-1}, \quad (12)$$

where N_c in the steady state with $\dot{M}_{\text{sf}} \approx 0$ is given by

$$N_c \approx 1 + \xi + \frac{\tau_{\star}}{\tau_{-\text{d}}}. \quad (13)$$

Equations (11–13) explicitly connect τ_{dep} and f_{sf} to the parameters of subgrid models for star formation (via τ_{\star}) and feedback (via ξ) and their physical interpretation is clear. In the ISM, gas is gradually converted into stars as individual gas parcels frequently cycle between the non-star-forming and actively star-forming states. On average, a given gas parcel transits from the non-star-forming to the star-forming state on a dynamical time scale, τ_+ , determined by a mix of processes such as ISM turbulence, gravity, cooling, etc.

In order to be converted into stars, a gas parcel needs to spend one average depletion time of *star-forming gas* in the star-forming state: $\tau_{\star} \equiv M_{\text{sf}}/\dot{M}_{\star} = \langle 1/t_{\star} \rangle_{\text{sf}}^{-1}$. However, before the gas parcel is converted into stars, it can be removed back into the non-star-forming state by efficient feedback or dynamical processes, and then this gas parcel has to start the cycle from the beginning. Overall, if star-forming stages on average last for t_{sf} , then $N_c = \tau_+/t_{\text{sf}}$ such replenishment-expulsion cycles are required to convert all gas into stars. The global depletion time can be expressed by Equation (11), where the first and the second terms in the sum correspond to the total times in the non-star-forming and the star-forming states, respectively. The star-forming mass fraction is then given by the ratio of the time spent in the star-forming state to the total depletion time, as expressed by Equation (12). In a steady state with the constant total star-forming gas mass, the number of transitions, N_c , is controlled by the stellar feedback and the dynamical processes that destroy star-forming re-

FIG. 5.— Effect of ϵ_{ff} on the spatial gas distribution and the gas distribution in the phase space of the gas density, n , and the total subgrid velocity dispersion, σ_{tot} . The adopted value for ϵ_{ff} changes from left to right: 0.01%, 1%, and 100%. *Top row* of panels shows the mid-plane density slices at $t = 500$ Myr, with black contour indicating cold dense gas, $n > 10 \text{ cm}^{-3}$, and green contour indicating star-forming regions, $\alpha_{\text{vir}} < \alpha_{\text{vir,sf}} = 10$. *Bottom row* of panels shows $n - \sigma_{\text{tot}}$ diagrams colored with the mass-weighted temperature in each bin. The distribution is time-averaged between 400 and 600 Myr using gas-tracer particles at $R > 1$ kpc (see Section 2.1). Black contours indicate 68%, 95%, and 99% of resulting gas tracers PDF. Thin red arrows throughout the diagram show the average net flux of gas tracers, while the thick blue and red arrows in the corner of each panel illustrate magnitudes and directions of the average positive and negative gas fluxes measured at the point indicated with a cross. All arrows can be directly compared to each other because their normalization is the same: the arrow extent corresponds to the distance that a tracer traverses over 5 Myr. Star-forming gas in each $n - \sigma_{\text{tot}}$ diagram resides below the thick dotted line, which corresponds to the star formation threshold of $\alpha_{\text{vir,sf}} = 10$. Thin dotted lines parallel to the star formation threshold show constant values of $\alpha_{\text{vir}} = 1000, 100, \text{ and } 1$ (from left to right).

regions, and thereby define the average duration of star-forming stages (Equation 13).

As was shown in Figures 2 and 3 and as we will discuss in more detail below, Equations (11–13) can predict the trends of τ_{dep} and f_{sf} observed in our simulations (Section 3) with varied star formation efficiency ϵ_{ff} , star formation threshold, and feedback strength b . We note, that the latter is closely related to the ξ parameter of the model. Both these parameters reflect the strength of feedback per unit stellar mass formed and its efficacy in dispersing star-forming regions. However, these parameters are not identical: b is a relative strength of the momentum injection in our implementation of feedback, while $\xi = F_{\text{-,fb}}/\dot{M}_{\star}$ is an average “mass-loading factor” which characterizes the efficacy of gas removal from star-forming regions by feedback. We also note, that in equations for τ_{dep} and f_{sf} , the average freefall time in the star-forming gas, τ_{ff} , is a model parameter, but, as we will show in Section 4.2.4 and Appendix A, its trends with simulation parameters discussed in Section 3 can also be understood using our model predictions.

For our subsequent discussion, it is convenient to combine Equations (11) and (13) and rearrange terms in the resulting equation as

$$\tau_{\text{dep}} = (1 + \xi)\tau_{+} + \left(1 + \frac{\tau_{+}}{\tau_{-,d}}\right) \frac{\tau_{\text{ff}}}{\epsilon_{\text{ff}}}, \quad (14)$$

where we have substituted $\tau_{*} = \tau_{\text{ff}}/\epsilon_{\text{ff}}$. Similarly, using Equation (12), the star-forming mass fraction can be expressed as

$$f_{\text{sf}} = \left[(1 + \xi)\tau_{+} \frac{\epsilon_{\text{ff}}}{\tau_{\text{ff}}} + 1 + \frac{\tau_{+}}{\tau_{-,d}} \right]^{-1}. \quad (15)$$

Equation (14) readily shows that the global depletion time is a sum of two terms, one of which may dominate depending on the parameters. For example, the first term, $(1 + \xi)\tau_{+}$, will dominate when feedback is sufficiently strong, i.e. ξ is large, or star formation efficiency ϵ_{ff} is sufficiently high so that the second term, $(1 + \tau_{+}/\tau_{-,d})\tau_{\text{ff}}/\epsilon_{\text{ff}}$, is subdominant. Conversely, the second term may dominate if feedback is inefficient or ϵ_{ff} is low. In these two regimes, the dependence of depletion time on the parameters of star formation and feedback will be qualitatively different. Specifically, when the first term in the equation dominates, τ_{dep} is insensitive to ϵ_{ff} and scales with feedback strength ξ . Conversely, when the second term dominates, τ_{dep} scales as $\epsilon_{\text{ff}}^{-1}$ and is independent of feedback strength.

Physically, these two regimes reflect the dominance of different negative terms in Equation (6) and thus different mechanisms that limit lifetimes of star-forming regions. In the first regime, $\tau_{\text{dep}} \approx (1 + \xi)\tau_{+}$ and the lifetime of gas in star-forming state is limited by feedback and star formation itself. We, therefore, will refer to this case as the “*self-regulation regime*,” because this was the term used to indicate insensi-

tivity of τ_{dep} to ϵ_{ff} in previous studies. In the second regime, $\tau_{\text{dep}} \approx (1 + \tau_+ / \tau_{-,d}) \tau_{\text{ff}} / \epsilon_{\text{ff}}$ and star-forming gas lifetime is limited by dynamical processes dispersing star-forming regions, such as turbulent shear, differential rotation, expansion behind spiral arms, operating on timescale $\tau_{-,d}$. We will refer to this case as the “*dynamics-regulation regime*,” as star formation passively reflects the distribution of ISM gas regulated by gas dynamics, rather than actively shaping it by gas consumption and associated feedback.

In the next section, we will consider dynamics- and self-regulation regimes in more detail. We will illustrate these regimes using our simulations with the fiducial feedback strength and star formation threshold but varying ϵ_{ff} from a low value of 0.01%, corresponding to the dynamics-regulation regime, to a high value of 100%, corresponding to the self-regulation regime. As Figure 5 shows, in different regimes, the quasi-equilibrium ISM gas distribution is qualitatively different. The figure shows the mid-plane density slices and $n - \sigma_{\text{tot}}$ diagrams (like the one in Figure 4) colored according to the average gas temperature with arrows indicating average gas fluxes. In all cases, small net fluxes result from the near cancellation of strong positive and negative fluxes, F_+ and F_- , whose typical magnitudes are shown with the thick blue and red arrows in the lower right corner of each diagram. Depending on the ϵ_{ff} value, the negative flux can be dominated by either $F_{-,d}$ or $F_{-,fb}$, which in turn results in qualitatively different behavior of Equation (14).

4.2. Predictions for trends of τ_{dep} , f_{sf} , and τ_{ff}

4.2.1. Interpretation of scalings in the dynamics-regulation regime

As discussed above, dynamics-regulation occurs when ϵ_{ff} or ξ are small so that the second term on the right hand side of Equation (14) dominates. In this case, τ_{dep} scales inversely with ϵ_{ff} :

$$\tau_{\text{dep}} \approx \left(1 + \frac{\tau_+}{\tau_{-,d}}\right) \frac{\tau_{\text{ff}}}{\epsilon_{\text{ff}}}. \quad (16)$$

The star-forming mass fraction, on the other hand, remains independent of ϵ_{ff} because according to Equation (15),

$$f_{\text{sf}} \approx \left(1 + \frac{\tau_+}{\tau_{-,d}}\right)^{-1}. \quad (17)$$

Such scalings, $\tau_{\text{dep}} \propto \epsilon_{\text{ff}}^{-1}$ and $f_{\text{sf}} \approx \text{const}$, indeed persist in our simulations with low ϵ_{ff} values (see $\epsilon_{\text{ff}} = 0.01\%$ and 0.1% in Figures 1–3).

Physically, these scalings arise because at low ϵ_{ff} and ξ the contributions of star formation, \dot{M}_* , and feedback, $F_{-,fb}$, terms to the overall mass flux balance in Equation (6) become small. As a result, the steady state is established with $F_{-,d} \approx F_+$, which yields Equations (16) and (17). In our simulated galaxy, such state is established as gas is compressed into new star-forming clumps at the same rate at which old clumps are dispersed by differential rotation and tidal torques, and neither of these processes depends on ϵ_{ff} . The interplay between compression and dynamical dispersal determines the steady-state distribution of gas in the $n - \sigma_{\text{tot}}$ diagram (the lower left panel in Figure 5), which is also insensitive to ϵ_{ff} . As a consequence, the star-forming mass fraction, f_{sf} , and the mean freefall time in star-forming gas, τ_{ff} , also do not depend on ϵ_{ff} and are determined solely by the definition of the star-forming gas. The global depletion time, however, does depend on ϵ_{ff} as is evident from Equation (16).

As $F_{-,fb}$ is subdominant in this regime, τ_{dep} , f_{sf} , and τ_{ff} are also insensitive to the feedback strength, but they do depend on the star formation threshold. Indeed, as blue lines in the left column of Figure 3 show, τ_{dep} , f_{sf} , and τ_{ff} remain approximately constant when feedback boost factor, b , is varied from 0 to 5. At the same time, when star formation threshold is varied such that more gas is included into the star-forming state, both f_{sf} and τ_{ff} increase because more low-density gas is added, while τ_{dep} decreases as additional star-forming gas increases SFR. It is worth noting, that these dependencies on star formation threshold are rather weak when the threshold encompasses significant fraction of the ISM gas, but they become stronger when the threshold selects gas only from the high-density tail of distribution, because it is this high-density gas that mostly determines τ_{dep} , f_{sf} , and τ_{ff} .

Finally, it is also worth noting that for some galaxies, or certain regions within galaxies, equilibrium may not be achievable, so that $F_+ > F_{-,d}$ or $F_+ < F_{-,d}$. In this case distribution of gas evolves and thus τ_{dep} , f_{sf} , and τ_{ff} also change with time. This occurs in the central regions of galaxies in simulations with $\epsilon_{\text{ff}} = 0.1\%$ and 0.01% , where the central gas concentration grows due to accretion and which we thus exclude from our analysis (see Section 2.1).

4.2.2. Interpretation of scalings in the self-regulation regime

Self-regulation occurs when ϵ_{ff} or ξ are sufficiently large, so that the first term on the right hand side of Equation (14) dominates and depletion time is given by

$$\tau_{\text{dep}} \approx (1 + \xi) \tau_+, \quad (18)$$

and is thus independent of ϵ_{ff} , but scales almost linearly with ξ . In this regime, the star-forming mass fraction scales inversely with ϵ_{ff} (see Equation 15):

$$f_{\text{sf}} \approx \frac{1}{(1 + \xi) \epsilon_{\text{ff}}} \frac{\tau_{\text{ff}}}{\tau_+}, \quad (19)$$

which also implies $f_{\text{sf}} \ll 1$ because $\tau_{\text{ff}} / \epsilon_{\text{ff}} \ll (1 + \xi) \tau_+$ is required for the subdominance of the terms proportional to $\epsilon_{\text{ff}}^{-1}$ in Equation (14).

The scalings of Equations (18) and (19) are consistent with the results of our simulations with large ϵ_{ff} values (Figures 1–3). The insensitivity of τ_{dep} to ϵ_{ff} and its scaling with feedback strength has also been observed in other simulations with high ϵ_{ff} and efficient feedback (e.g., Agertz & Kravtsov 2015; Hopkins et al. 2017a; Orr et al. 2017). In the literature, these phenomena are also usually referred to as “self-regulation.”

As detailed in Paper I, self-regulation occurs when gas spends most of the time in non-star-forming stages, $f_{\text{sf}} \ll 1$, and the rate of star-forming gas supply, F_+ in Equation (6), is balanced by rapid gas consumption and strong feedback-induced gas dispersal: $F_+ \approx \dot{M}_* + F_{-,fb}$. In this case, global depletion time is given by $\tau_{\text{dep}} \approx N_c \tau_+$, where N_c is the total number of cycles between non-star-forming and star-forming states (see Section 4.1). Due to large $\dot{M}_* + F_{-,fb} \propto (1 + \xi) \epsilon_{\text{ff}}$, the duration of star-forming stages, t_{sf} , is regulated by star formation and feedback: when ϵ_{ff} or ξ are increased, lifetime of gas in the star-forming state shortens as $t_{\text{sf}} \propto [(1 + \xi) \epsilon_{\text{ff}}]^{-1}$. However, the *total* time spent in the star-forming state before complete depletion depends on ϵ_{ff} but not on ξ : $\tau_* \propto \epsilon_{\text{ff}}^{-1}$. The dependence on ϵ_{ff} thus cancels out in $N_c = \tau_* / t_{\text{sf}}$ and global depletion time becomes independent of ϵ_{ff} but maintain scaling with ξ .

Therefore, in the self-regulation regime, star formation regulates itself by controlling the timescale of star-forming regions dispersal by feedback and by conversion of gas into stars in these regions. The relative importance of these processes is determined by the feedback strength per unit of formed stars, i.e. ξ value.

When feedback is efficient, $\xi \gg 1$, as is the case in our simulations⁴ shown in Figure 5, the ISM gas distribution at high ϵ_{ff} is shaped by feedback-induced gas motions, $F_+ \approx F_{-, \text{fb}}$. Specifically, as top panels show, at $\epsilon_{\text{ff}} = 1\%$ and 100% , efficient feedback makes ISM structure flocculent and devoid of dense star-forming clumps, which are typical in the $\epsilon_{\text{ff}} = 0.01\%$ simulation. The bottom panels show that at high ϵ_{ff} , efficient feedback keeps most of the dense gas above the star formation threshold or close to it. This results in a significant decrease of f_{sf} and increase of τ_{ff} in this regime, compared to the dynamics-regulated regime.

When feedback is inefficient, $\xi \ll 1$, or even completely absent, $\xi = 0$, the gas consumption dominates at high ϵ_{ff} , $F_+ \approx \dot{M}_*$. In this regime, all available star-forming gas is rapidly converted into stars and the global depletion time is determined by the timescale on which new star-forming gas is supplied, i.e. $\tau_{\text{dep}} \sim \tau_+$. Thus, this regime is analogous to the ‘‘bottleneck’’ scenario envisioned by Saitoh et al. (2008). Our simulations with $b = 0$ and $\epsilon_{\text{ff}} \geq 10\%$ operate in this regime and because τ_+ is short, τ_{dep} is also short, so that gas is rapidly consumed and simulated galaxy cannot settle into an equilibrium state.

Dependence of τ_{dep} , f_{sf} , and τ_{ff} on the choice of the star formation threshold can also be understood as follows. As ϵ_{ff} and ξ increase, the average density of the star-forming gas decreases, which increases τ_{ff} . For the density-based threshold, the value of τ_{ff} becomes independent of ϵ_{ff} and ξ as the star-forming gas is kept at the density close to the threshold, $n \sim n_{\text{sf}}$. Larger $\alpha_{\text{vir, sf}}$ (or smaller n_{sf}) in Figure 3 results in shorter $\tau_{\text{dep}} \propto \tau_+$, because τ_+ decreases as it takes less time for gas to evolve from the typical ISM density and α_{vir} to the values of the star-forming gas. As typical densities of the star-forming gas decrease, τ_{ff} increases and thus $f_{\text{sf}} \propto \tau_{\text{ff}}/\tau_+$ (Equation 19) also increases because of both longer τ_{ff} and shorter τ_+ .

In the above discussion, the dynamical time τ_+ was assumed to be independent of ϵ_{ff} and the feedback strength. This is certainly a simplification, as τ_+ can be determined by feedback, which can limit lifetime of star-forming regions, drive large-scale turbulence in the ISM, inflate low-density hot bubbles, launch fountain-like outflows, and sweep gas into new star-forming regions. These processes are reflected in the complicated pattern of the net gas flux in the $n - \sigma_{\text{tot}}$ plane in the lower middle panel of Figure 5, which shows a prominent clockwise whirl near the star formation threshold and a counter-clockwise whirl in the lower density gas. The clockwise whirl originates from the ISM gas being swept by SNe shells, while the counter-clockwise whirl is shaped by the gas in freely expanding shells (see Section 4.2 of Paper I for a more detailed discussion). Nevertheless, we find that the dependence of τ_+ on the feedback strength variation is much weaker than the linear scalings of τ_{dep} and f_{sf} with ξ and ϵ_{ff} (see Section 4.2.4), and thus our simplification is warranted.

⁴ Our results in Section 4.2.4 and Appendix A suggest that $\xi \sim 60$ in our simulations with fiducial feedback and star formation threshold.

4.2.3. Transition between the regimes

Self-regulation or dynamics-regulation regimes occur when the first or second term in Equation (14) dominates. In Section 3, we illustrated these regimes using simulations in which ϵ_{ff} , feedback strength, and star formation threshold are varied in a wide range. The transition between the two regimes depends on all of these parameters. For example, in the left panels of Figure 3, the run with $\epsilon_{\text{ff}} = 1\%$ and weak feedback, $b = 0.2$, exhibits behavior of the dynamics-regulation regime, while galaxy in the run with the same ϵ_{ff} but with much stronger feedback, $b = 5$, is in the self-regulation regime. Similarly, from the middle and right panels of the figure, when $\epsilon_{\text{ff}} = 1\%$ and threshold defines a significant fraction of gas as star-forming (e.g., $\alpha_{\text{vir, sf}} = 100$ or $n_{\text{sf}} = 10 \text{ cm}^{-3}$), simulated galaxies are in the dynamics-regulation regime. On the other hand, when threshold defines only a small fraction of gas as star-forming (e.g., $\alpha_{\text{vir, sf}} = 10$ or $n_{\text{sf}} = 100 \text{ cm}^{-3}$), galaxies are in the self-regulation regime.

Note, however, that achieving self-regulation with the threshold variation is not always possible, because the threshold affects both terms in Equation (14) and thus the value of the threshold at which the first term dominates does not always exist. For example, in the top middle panel of Figure 3, when $\epsilon_{\text{ff}} < 1\%$, depletion time bends upwards at $\alpha_{\text{vir, sf}} < 10$ and remains inversely proportional to ϵ_{ff} and therefore never reaches the self-regulation regime.

In the transition between dynamics-regulated and self-regulated regimes, the relation between our model parameters follows from the condition that the terms in Equation (14) are comparable:

$$(1 + \xi)\epsilon_{\text{ff}} \sim \left(1 + \frac{\tau_+}{\tau_{-, \text{d}}}\right) \frac{\tau_{\text{ff}}}{\tau_+}. \quad (20)$$

Notably, in this case a given galaxy has the same star-forming mass fraction independent of ϵ_{ff} or the feedback strength. Indeed, after substituting the condition (20) into Equation (15), we get

$$f_{\text{sf}} \sim \frac{1}{2} \left(1 + \frac{\tau_+}{\tau_{-, \text{d}}}\right)^{-1}, \quad (21)$$

i.e., the star-forming mass fraction at the transition is half of that in the dynamics-regulation regime (Equation 17).

4.2.4. Quantitative predictions as a function of ϵ_{ff} and feedback strength

So far, we described how the model presented above can explain the trends and regimes revealed by our simulations qualitatively. Here we will show that the model can also describe the simulation results *quantitatively*.

To predict τ_{dep} and f_{sf} in the simulations using Equations (14) and (15), we note that the unknown parameters enter these equations only in three different combinations: $(1 + \xi)\tau_+$, $\tau_+/\tau_{-, \text{d}}$, and $\tau_{\text{ff}}/\epsilon_{\text{ff}}$. These can be calibrated against a small subset of the simulations in the dynamics- and self-regulation regimes using scalings discussed in Sections 4.2.1 and 4.2.2 as a guidance. Quantitative predictions of the model with calibrated parameters for the trends of τ_{dep} and f_{sf} can then be compared to the results of other simulations, not used in the calibration.

Specifically, using two runs in the self-regulated regime with $\epsilon_{\text{ff}} = 100\%$, we measure the normalization of $(1 + \xi)\tau_+$ and its scaling with the feedback boosting factor b . Equation (18)

FIG. 6.— Comparison of our model predictions (shown with lines) for the global depletion time (τ_{dep} , top panel) and the star-forming mass fraction (f_{sf} , bottom panel) with the results of our simulations with varying ϵ_{ff} and the feedback boost factor, b , assuming the fiducial star formation threshold, $\alpha_{\text{vir,sf}} = 10$ (notation repeats that of Figure 3). To fix the model parameters, we use τ_{dep} in two high- ϵ_{ff} runs (red circled points in the top panel), which give $(1 + \xi)\tau_+ \sim (6 \text{ Gyr}) b^{0.75}$, and f_{sf} from a low- ϵ_{ff} run (the blue circled point in the bottom panel), which gives $\tau_+/\tau_{-,d} \sim 4$. As thick lines show, if we neglect variation of τ_{ff} and assume the average $\tau_{\text{ff}} = 4 \text{ Myr}$, our model correctly predicts the overall behavior of τ_{dep} and f_{sf} . As thin lines show, predictions of our model are improved if the variation of τ_{ff} is also modeled as explained in Appendix A. To avoid clutter, simulation points for $\epsilon_{\text{ff}} = 0.1\%$, 1% , and 10% are slightly shifted horizontally around the actually used values of $b = 0, 0.2, 1, \text{ and } 5$.

gives the normalization of the global depletion time in the high- ϵ_{ff} run with $b = 1$: $[(1 + \xi)\tau_+]_0 \approx \tau_{\text{dep}}(b = 1) \sim 6 \text{ Gyr}$. Adopting $(1 + \xi)\tau_+ \propto b^\beta$ for the scaling with b , the slope $\beta = \Delta \log \tau_{\text{dep}} / \Delta \log b \approx 0.75$ is measured using the second run with $b = 5$ and thus the final relation is:

$$(1 + \xi)\tau_+ \approx 6b^{0.75} \text{ Gyr}, \quad (22)$$

i.e. $(1 + \xi)\tau_+$ is long and increases almost linearly with b .

Using a simulation with $\epsilon_{\text{ff}} = 0.01\%$ (i.e., the dynamics-regulation regime) and Equation (17), we estimate the ratio of dynamical times $\tau_+/\tau_{-,d}$ from the value of star-forming mass fraction, $f_{\text{sf}} \approx 0.2$, measured in this simulation:

$$\frac{\tau_+}{\tau_{-,d}} \approx \frac{1}{f_{\text{sf}}} - 1 \sim 4, \quad (23)$$

which implies that in the absence of feedback, the star-forming gas is supplied 4 times slower than it is dispersed by dynamical effects.

Finally, the last unknown parameter is the average freefall time in the star-forming gas, τ_{ff} . In our simulations, τ_{ff} varies only mildly, from $\tau_{\text{ff}} \approx 2 - 3 \text{ Myr}$ in the dynamics-regulation regime to $\tau_{\text{ff}} \approx 5 - 6 \text{ Myr}$ in the self-regulation regime. In the simplest case, we can make predictions assuming a constant $\tau_{\text{ff}} = 4 \text{ Myr}$, which is representative of the freefall time in star-forming regions both in our simulations and in observations.

Figure 6 compares the simulation results for τ_{dep} and f_{sf} as

a function of the feedback strength, b , to the predictions of our model with constant $\tau_{\text{ff}} = 4 \text{ Myr}$ (thick lines). Of the 20 simulation results shown by points in the figure, only three were used to calibrate the four model parameters, $[(1 + \xi)\tau_+]_0$, β , $\tau_+/\tau_{-,d}$, and τ_{ff} , as described above; these simulations are shown by the large circled points. For the other 17 simulations, the lines show *predictions* of the model. Figure 6 shows that the model correctly predicts wide variation of τ_{dep} and f_{sf} with ϵ_{ff} and the feedback strength b in the entire suite of simulations.

Moreover, τ_{dep} and f_{sf} involve two independent quantities, M_* and M_{sf} , measured in the simulations. Thus, our four-parameter model calibrated using three simulations, describes well $17 \times 2 = 34$ independent data points. The fact that our model closely agrees with the simulations when we treat τ_{ff} as a fixed parameter and τ_+ as independent of ξ and ϵ_{ff} , indicates that most of the variation of τ_{dep} and f_{sf} is driven by their explicit dependence on ϵ_{ff} and ξ in Equations (14) and (15), whereas any variation of τ_{ff} and τ_+ with ϵ_{ff} and ξ is secondary.

Nevertheless, accounting for τ_{ff} variations can somewhat improve the accuracy of our model. Thin lines in Figure 6 and in the left panels of Figure 3 show our model predictions incorporating τ_{ff} variation with ϵ_{ff} and ξ values. To model this variation, we note that the increase of τ_{ff} during the transition from the dynamics- to the self-regulation regime is controlled by the total rate of the star-forming gas removal by gas consumption and feedback: $\dot{M}_* + F_{-,fb} \propto (1 + \xi)\epsilon_{\text{ff}}$. Thus, we calibrate the values of τ_{ff} in these regimes using the same three simulations as before, and interpolate τ_{ff} as a function of $(1 + \xi)\epsilon_{\text{ff}}$ for all other simulations. The details of this calibration and the adopted interpolation function are presented in Appendix A.

4.2.5. Quantitative predictions as a function of the star formation threshold

To predict how τ_{dep} , f_{sf} , and τ_{ff} depend on the star formation threshold, $\alpha_{\text{vir,sf}}$, we need to calibrate model parameters as a function of $\alpha_{\text{vir,sf}}$. Analogously to the previous section, we constrain these dependencies using runs in the limiting regimes, and use our model to predict τ_{dep} , f_{sf} , and τ_{ff} in the other simulations. Our model predictions are shown with lines in the middle column of panels in Figure 3 using calibrations done as follows.

Firstly, the dependence of $(1 + \xi)\tau_+$ and τ_{ff} in the self-regulation regime on $\alpha_{\text{vir,sf}}$ can be assessed using a run with $\epsilon_{\text{ff}} = 100\%$ and fiducial $\alpha_{\text{vir,sf}} = 10$ and an additional run with $\alpha_{\text{vir,sf}} = 100$ to obtain the following scalings:

$$(1 + \xi)\tau_+ \propto \alpha_{\text{vir,sf}}^{-0.5}, \quad (24)$$

$$\tau_{\text{ff}} \propto \alpha_{\text{vir,sf}}^{0.4}. \quad (25)$$

The scaling of $(1 + \xi)\tau_+$ is measured as the slope of τ_{dep} in the middle top panel of the figure. For the typical density of the star-forming gas \bar{n} , the freefall time is $\tau_{\text{ff}} \propto \bar{n}^{-0.5}$ and the slope of 0.4 in Equation (25) thus indicates that $\bar{n} \propto \alpha_{\text{vir,sf}}^{-0.8}$. Given that $\alpha_{\text{vir}} \propto \sigma_t^2/\bar{n}$, this means that the typical velocity dispersion in the star-forming gas scales as $\sigma_t \propto \alpha_{\text{vir,sf}}^{0.1}$.

Secondly, we note that to constrain the behavior of $\tau_+/\tau_{-,d}$ and τ_{ff} in the dynamics-regulated regime, no extra runs are needed and all the required information can be obtained directly from the simulation with $\epsilon_{\text{ff}} = 0.01\%$ and $b = 1$, which has been already used in the previous section. This is because in the dynamics-regulated regime the gas distribution in the

$n - \sigma_{\text{tot}}$ plane is not affected by star formation and feedback and thus we expect it to be the same as in the lower left panel of Figure 5. Therefore, f_{sf} — which yields $\tau_+/\tau_{-,d}$ from Equation (17) — and τ_{ff} as a function of the star formation threshold can be directly measured from this distribution. We spline $f_{\text{sf}}(\alpha_{\text{vir},\text{sf}})$ and $\tau_{\text{ff}}(\alpha_{\text{vir},\text{sf}})$ in the low- ϵ_{ff} simulation with fiducial $\alpha_{\text{vir},\text{sf}}$ and show these functions with blue lines in the bottom two panels of the middle column in Figure 3.

These two steps fix the dependencies of $(1 + \xi)\tau_+$, $\tau_+/\tau_{-,d}$, τ_{ff} on the star formation threshold, and thus we can predict how τ_{dep} , f_{sf} , and τ_{ff} depend on the threshold at different ϵ_{ff} and our predictions closely agree with the results of simulations, as shown in the middle column of panels in Figure 3. To test our model, we repeated the above steps for the simulations with the star formation threshold in the gas density rather than in α_{vir} . As the right column in Figure 3 shows, our predictions again closely agree with the results of the simulations, although the values of the parameters are of course different (see Appendix A).

4.3. Generic approach to calibrating the star formation and feedback parameters in simulations

Galaxy simulations can differ significantly in numerical methods used to handle hydrodynamics and in specific details of the implementation of star formation and feedback processes. The implementations can also be applied at different resolutions, so that the values and sometimes even the physical meaning of the parameters change. Thus, the parameter values of our model that we calibrated above should be used with caution and applied only when similar numerical techniques, resolutions, and implementations of star formation and feedback are used.

Nevertheless, the overall calibration approach can still be used in all cases to choose the values of the star formation and feedback parameters. For example, one can calibrate τ_{dep} and f_{sf} dependence on the parameters in the dynamics-regulation regime using one simulation with a very low (or even zero) value of ϵ_{ff} , as was done in Sections 4.2.4 and 4.2.5. Then, the τ_{dep} and f_{sf} behavior in the self-regulation regime can be anchored using several simulations with varying feedback strength and star formation threshold at sufficiently high ϵ_{ff} . The value of ϵ_{ff} appropriate for this second step can be chosen from the condition that the local depletion time at typical densities of the star-forming gas must be much shorter than the global depletion time, which thus implies $\epsilon_{\text{ff}} \gg \tau_{\text{ff}}/\tau_{\text{dep}}$. The appropriately high value of ϵ_{ff} will also result in f_{sf} much smaller than the f_{sf} in the simulation with low ϵ_{ff} .

5. COMPARISONS WITH OBSERVATIONS

Results presented in the previous section demonstrate that our general theoretical framework for star formation in galaxies can describe and explain the results of galaxy simulations both qualitatively and quantitatively. The model can thus be also used to interpret and explain observational results, in particular the observed long gas depletion times in galaxies, as we showed in Paper I. In this section, we use the observations to constrain the parameters of our model, in particular, the efficiency of star formation per freefall time, ϵ_{ff} . We also use the model to infer whether observed galaxies are in the dynamics- or self-regulation regime.

Specifically, we use the observed values of the depletion time of atomic+molecular and just molecular gas at different scales — from global galactic values to the scales comparable to our resolution limit of ~ 40 pc — as well as the mass

fraction of gas in star-forming regions and in the molecular phase. Comparisons and inferences from observations on different scales are presented in separate sections below. In most of the comparisons, we use observations in the Milky Way, where star formation is studied most extensively. However, whenever possible, we also use recent observations of other nearby galaxies. Note that we focus here on the inferences specific to $\sim L_*$ -sized galaxies, as our simulated galaxy model has structural parameters typical for such galaxies.

In what follows, we use the star formation rates in simulations computed differently on different scales, in ways that approximate how corresponding rates are estimated in observations. We compute the local SFR using the total mass of stellar particles younger than some age t_{sf} in the cell: $\dot{M}_{\star}^{\text{cell}} \equiv M_{\star}^{\text{cell}}(< t_{\text{sf}})/t_{\text{sf}}$, where the choice of t_{sf} is motivated by star formation indicators used in observations. In Sections 5.2.1 and 5.2.3, we compare our results with extragalactic studies which use H α and far IR indicators sensitive to the presence of massive young stars, and we thus adopt $t_{\text{sf}} = 10$ Myr (see, e.g., Table 1 in Kennicutt & Evans 2012). In Section 5.2.2 we compare with observations of individual star-forming regions, where SFR is estimated by direct counting of pre-main sequence young stellar objects, and thus we adopt $t_{\text{sf}} = 1$ Myr in this case.

To compare our results with the observed distribution of molecular gas, in each computational cell we estimate the molecular mass as $\rho_{\text{H}_2} \Delta^3 = f_{\text{H}_2}^{\text{cell}} \rho (1 - Y_{\text{He}}) \Delta^3$, assuming the helium mass fraction of $Y_{\text{He}} = 0.25$ and computing $f_{\text{H}_2}^{\text{cell}}$ using the model of Krumholz et al. (2008, 2009); McKee & Krumholz (2010): $f_{\text{H}_2}^{\text{cell}} = \max[0, (1 - 0.75s)/(1 + 0.25s)]$ with $s \approx 1.8/\tau_c$ and $\tau_c = 320(\rho\Delta/g \text{ cm}^{-2})$ at solar metallicity.

5.1. Global star formation

5.1.1. Comparison with observed τ_{dep} and f_{sf}

We start our comparisons with observations by comparing our model and simulation predictions as a function of ϵ_{ff} and the feedback strength b to the global values of the depletion time, τ_{dep} , and the mass fraction of star-forming gas, f_{sf} . To make a fair comparison, τ_{dep} and f_{sf} in observations must be defined consistently with their definition in the simulations. While τ_{dep} can be compared directly using the total gas mass and SFR, the comparison of f_{sf} is more nuanced, because one needs to choose which gas in real galaxies corresponds to the star-forming gas in simulations. Our fiducial star formation criterion, $\alpha_{\text{vir}} < \alpha_{\text{vir},\text{sf}} = 10$, is motivated by α_{vir} in observed GMCs, and it selects molecular gas with the lowest turbulent velocity dispersions on scale of our resolution, $\Delta = 40$ pc. Such a criterion also results in the average freefall time in star-forming regions of $\tau_{\text{ff}} \approx 3 - 6$ Myr, which is consistent with typical τ_{ff} values estimated for observed GMCs (see, e.g., Figure 1 in Agertz & Kravtsov 2015). In simulations with larger $\alpha_{\text{vir},\text{sf}}$, τ_{ff} becomes several times longer than observed in GMCs (see the bottom middle panel in Figure 3). Thus, we argue that our fiducial value of $\alpha_{\text{vir}} = 10$ corresponds to the definition of the star-forming regions in observations most closely, and will use the simulations with this value to constrain ϵ_{ff} . We will, however, discuss the dependence on the assumed threshold below, whenever it is relevant.

To compare our model results, we use the global depletion time and the mass fraction of the star-forming gas in the Milky Way, $\tau_{\text{dep}} \sim 5 - 10$ Gyr and $f_{\text{sf}} \sim 1.5\% - 10\%$ estimated as follows. The range of τ_{dep} follows from $M_g \sim 10^{10} M_{\odot}$

FIG. 7.— Comparison of our simulation results (points) and our model predictions (gray lines) for the star-forming mass fraction, f_{sf} , and the global depletion time, τ_{dep} , with their values in the Milky Way (green rectangle). Notation of points repeat that of Figure 3, with color indicating ϵ_{ff} and the feedback boost factor, b , increasing upwards: 0, 0.2, 1, and 5. Solid gray lines show the predictions of our model calibrated in Section 4.2.4 for the constant values of $0.2 < b < 5$ and $0.01\% < \epsilon_{\text{ff}} < 100\%$, with thicker lines corresponding to the values used in the simulations and thinner lines showing intermediate values: $b \approx 0.45, 2.2$ and $\epsilon_{\text{ff}} \approx 0.032\%, 0.32\%, 3.2\%, 32\%$. The dashed line indicates model predictions for runs without feedback ($b = 0$), assuming $\tau_+ = 100$ Myr, as motivated by the results of Paper I. The green rectangle indicates the range estimated for the Milky Way, $f_{\text{sf}} \sim 1.5\% - 10\%$ and $\tau_{\text{dep}} \sim 5 - 10$ Gyr, as explained in the text.

(e.g., Kalberla & Kerp 2009) and $\dot{M}_* \sim 1 - 2 M_{\odot} \text{ yr}^{-1}$ (e.g., Licquia & Newman 2015). The upper limit on the star-forming mass fraction follows from the assumption that all molecular gas in the Milky Way is star-forming, and thus $f_{\text{sf}} < f_{\text{H}_2} = M_{\text{H}_2}/M_{\text{g}} \sim (10^9 M_{\odot})/(10^{10} M_{\odot}) \sim 10\%$ (Heyer & Dame 2015). A conservative lower limit on f_{sf} can be estimated using the total mass in the largest star-forming GMCs in the Milky Way from Murray (2011) with sizes comparable to our resolution of 40 pc. These massive GMCs account for 33% of total SFR in the Milky Way, but have the total mass of $\approx 5 \times 10^7 M_{\odot}$. If the rest of star formation in the Milky Way were proceeding in clouds with local depletion times similar to those in the Murray (2011) sample, then the total mass of the star-forming gas would be 3 times larger, or $\approx 1.5 \times 10^8 M_{\odot}$, which would mean $f_{\text{sf}} \sim 1.5\%$. However, this estimate is a conservative lower limit, because the rest of the star-forming gas probably forms stars with lower efficiency, as it does not host bright radio sources associated with H II regions, used by Murray (2011) to identify the star-forming GMCs.

In Figure 7, the above constraints on τ_{dep} and f_{sf} in the Milky Way (green rectangle) are compared to the results of our simulations (points with error bars) and the predictions of our analytical model (gray lines). The figure shows that only $\epsilon_{\text{ff}} \sim 0.5\% - 5\%$ and $b \sim 0.3 - 2$ can satisfy the constraints on both τ_{dep} and f_{sf} simultaneously. It is important to note that this constraint on ϵ_{ff} is rather generous, due to a rather conservative lower limit estimate of f_{sf} we use for the Milky Way.

This conclusion would not change if we adopted a different star formation threshold. Figure 3 shows that $\alpha_{\text{vir},\text{sf}}$ values smaller than our fiducial $\alpha_{\text{vir},\text{sf}} = 10$ would result in even smaller f_{sf} , while even values as large as $\alpha_{\text{vir},\text{sf}} = 100$

FIG. 8.— Comparison of the simulation results (points) and our model predictions (gray lines) to the total molecular mass fraction, f_{H_2} , and the global depletion time of molecular gas, $\tau_{\text{dep,H}_2} = f_{\text{H}_2} \tau_{\text{dep}}$, in the Milky Way (green rectangle). The symbols and lines are the same as in Figure 7. Our model for f_{H_2} is explained in Appendix B. For the Milky Way, we adopt $f_{\text{H}_2} = (1.0 \pm 0.3) \times 10^9 M_{\odot}$ (Heyer & Dame 2015) and $\tau_{\text{dep,H}_2} = (10^9 M_{\odot})/(1 - 2 M_{\odot} \text{ yr}^{-1}) \sim 0.5 - 1$ Gyr (e.g., Licquia & Newman 2015).

for $\epsilon_{\text{ff}} = 100\%$ would only increase the star-forming gas mass fraction to $f_{\text{sf}} \approx 0.7\%$, while decreasing the depletion time to $\tau_{\text{dep}} \approx 2$ Gyr which is still far outside the range we estimate for the Milky Way.

Note that the figure shows that τ_{dep} and f_{sf} in the Milky Way have values close to the transition between self-regulation and dynamics-regulation regimes. Indeed, the self-regulation regime corresponds to small $f_{\text{sf}} < 0.01$ at which gray lines of constant b are horizontal, the dynamics-regulation regime is manifested by the convergence of these lines to $f_{\text{sf}} \sim 0.2$, and f_{sf} in the Milky Way lie in-between these two regimes. The conclusion that the Milky Way is in the regime intermediate between dynamics- and self-regulation regimes is also directly supported by the estimate for the second term in Equation (14), $(1 + \tau_+/\tau_{-,d})\tau_*$. Indeed, observed local depletion times in the Milky Way's GMCs are $\tau_* \sim 100 - 500$ Myr (e.g., Evans et al. 2009, 2014; Lada et al. 2010, 2012; Heiderman et al. 2010; Gutermuth et al. 2011; Schrubba et al. 2017) and the prefactor in front of τ_* is likely similar to that obtained in our simulations, $1 + \tau_+/\tau_{-,d} \sim 5$ (Equation 23), because we expect that our simulations capture dynamical time scales of star-forming gas supply and dispersal. As a result, $(1 + \tau_+/\tau_{-,d})\tau_* \sim 0.5 - 2.5$ Gyr contributes a sizable fraction to the observed global depletion time in the Milky Way, $\tau_{\text{dep,MW}} \sim 5 - 10$ Gyr, and thus the Milky Way is in the intermediate regime.

5.1.2. Comparison with the global mass fraction and the depletion time of molecular gas

Figure 8 compares the global molecular gas mass fraction, f_{H_2} , and its depletion time, $\tau_{\text{dep,H}_2}$, estimated for the Milky Way (green rectangle) to their values measured in our simulations (points with error bars) and predicted by our model (gray lines). For the Milky Way, we used $f_{\text{H}_2} = (1.0 \pm 0.3) \times 10^9 M_{\odot}$ from Heyer & Dame (2015) and estimated $\tau_{\text{dep,H}_2} = (10^9 M_{\odot})/(1 - 2 M_{\odot} \text{ yr}^{-1}) \sim 0.5 - 1$ Gyr. In the simulations, the total molecular mass, M_{H_2} , required to compute f_{H_2} and

$\tau_{\text{dep,H}_2}$, is derived as a sum of the molecular mass in each cell, computed as explained at the beginning of Section 5. The model predictions are obtained using the dependence of f_{H_2} on ϵ_{ff} and the feedback strength, calibrated at the end of Appendix B. The definition of the molecular gas depletion time is $\tau_{\text{dep,H}_2} \equiv M_{\text{H}_2}/\dot{M}_* = (M_{\text{H}_2}/M_g)(M_g/\dot{M}_*) = f_{\text{H}_2}\tau_{\text{dep}}$, with τ_{dep} given by Equation (14).

The figure shows that f_{H_2} and $\tau_{\text{dep,H}_2}$ within the observed range can be obtained only in the simulations with $\epsilon_{\text{ff}} \sim 0.5\% - 5\%$ and $b \sim 0.2 - 3$. Note that this range of parameters is similar to the range constrained by the observed f_{sf} and τ_{dep} in the previous section. This consistency between different constraints indicates that in our simulations with $\epsilon_{\text{ff}} \sim 1\%$ and $b \sim 1$, the overall distribution of the ISM gas in different phases is captured correctly.

Typical values of f_{H_2} estimated in other L_* -sized galaxies are usually even larger than the Milky Way value (e.g., $\sim 10 - 30\%$ in Leroy et al. 2008). According to Figure 8, such f_{H_2} , together with somewhat longer depletion times ($\tau_{\text{dep,H}_2} \sim 1 - 3$ Gyr in Bigiel et al. 2008, 2011; Leroy et al. 2013; Utomo et al. 2017), favors small values of ϵ_{ff} . Our model, calibrated on a specific simulation of an L_* -sized galaxy, does not predict values $f_{\text{H}_2} > 20\%$. However, according to our model, the values of $f_{\text{H}_2} > 20\%$ observed in molecular-rich galaxies can be due to a smaller ratio of dynamical time scales $\tau_+/\tau_{-,d}$ in such galaxies as compared to the value of $\tau_+/\tau_{-,d} \sim 4$ in our simulated galaxy, which sets the upper limit of $f_{\text{H}_2} \sim 20\%$ in the dynamics-regulation regime (Equation 17).

Figure 8 also illustrates three interesting differences in the behavior of f_{H_2} and $\tau_{\text{dep,H}_2}$ as compared to that of f_{sf} and τ_{dep} in the previous section: 1) the range of f_{H_2} variation is substantially narrower than that of f_{sf} , 2) in contrast to τ_{dep} , $\tau_{\text{dep,H}_2}$ does depend on ϵ_{ff} even in the self-regulation regime, and 3) the temporal variation of $\tau_{\text{dep,H}_2}$ (shown with vertical error bars) is much smaller than that of τ_{dep} . The range of f_{H_2} variation is narrow because even at high ϵ_{ff} and b , feedback cannot efficiently clear the non-star-forming molecular gas that piles up above the star formation threshold. When τ_{dep} is independent of ϵ_{ff} , the sensitivity of $\tau_{\text{dep,H}_2}$ to ϵ_{ff} originates from the weak sensitivity of f_{H_2} to ϵ_{ff} : $\tau_{\text{dep,H}_2} = f_{\text{H}_2}\tau_{\text{dep}}$, and its temporal variation is small because f_{H_2} anticorrelates with τ_{ff} , as both respond to the dispersal of the dense gas by feedback, and this anticorrelation mitigates the variation of $\tau_{\text{dep,H}_2} \propto f_{\text{H}_2}\tau_{\text{ff}}$. Note that all these effects are due to the definition of the star-forming gas being different from the molecular gas and its corollary of the existence of the non-star-forming molecular gas.

5.2. The depletion times of the molecular gas on sub-galactic scales

5.2.1. $\tau_{\text{dep,H}_2}$ on kiloparsec scales

During the past two decades star formation, the distribution of the molecular gas, and its depletion time $\tau_{\text{dep,H}_2} = \Sigma_{\text{H}_2}/\dot{\Sigma}_*$, have been studied observationally down to kiloparsec scales in dozens of nearby galaxies (e.g., Wong & Blitz 2002; Bigiel et al. 2008, 2011; Leroy et al. 2013; Bolatto et al. 2017; Utomo et al. 2017). These observational studies show that typical observed values of $\tau_{\text{dep,H}_2} \sim 2$ Gyr have a factor of ~ 2 scatter and are independent of the local kiloparsec-scale molecular gas surface density, Σ_{H_2} . In the Milky Way, values of kiloparsec-scale $\tau_{\text{dep,H}_2}$ are somewhat shorter and span a range of $\tau_{\text{dep,H}_2} \sim 0.5 - 2$ Gyr, (estimated from Figure 7 in Kennicutt & Evans 2012).

FIG. 9.— Comparison of the molecular gas depletion time, $\tau_{\text{dep,H}_2}$, averaged on kiloparsec scale in our simulations (squares with vertical bands), to the observed range shown with horizontal color bands. The blue band indicates the range of $\tau_{\text{dep,H}_2} = 1.64$ Gyr with a factor of 2.1 scatter as derived by Bolatto et al. (2017), and is also consistent with previous studies of, e.g., Bigiel et al. (2008, 2011); Leroy et al. (2013). The green band indicates the range of kiloparsec scale $\tau_{\text{dep,H}_2}$ in the Milky Way, estimated from the profiles of Σ_{H_2} and Σ_{H_2} in Figure 7 in Kennicutt & Evans (2012). In simulations, $\tau_{\text{dep,H}_2}$ is averaged using 10 simulation snapshots between 410 and 500 Myr. Squares indicate the mass-weighted averages $\langle 1/\tau_{\text{dep,H}_2} \rangle^{-1}$ and vertical stripes show the range of the running median for gas with $\Sigma_{\text{H}_2} > 1 M_{\odot} \text{pc}^{-2}$. For presentation purposes, the simulation points are slightly shifted horizontally around the actually used values of $b = 0.2, 1, \text{ and } 5$. Colored lines show the predictions of our model for the global depletion time of the molecular gas (see Sections 5.1.2).

In Figure 9, we compare these values of $\tau_{\text{dep,H}_2}$ (colored bands) to the results of our simulations (squares with vertical stripes) and our model predictions (thin lines). As the figure shows, the results of our fiducial simulation with $\epsilon_{\text{ff}} = 1\%$ and $b = 1$ agree well with the typical values of $\tau_{\text{dep,H}_2}$ inferred in observations. However, the simulations with, e.g., $\epsilon_{\text{ff}} \sim 100\%$ and $b \sim 5$ also agree with the observed range of $\tau_{\text{dep,H}_2}$, because the dependence of $\tau_{\text{dep,H}_2}$ on these parameters (and especially on ϵ_{ff}) is relatively weak. Similarly to the global star-forming gas and molecular gas mass fractions considered above in Section 5.1.2, the parameters will be constrained much better when estimates of the molecular gas fraction become available on subgalactic scales in more and more galaxies (e.g., Wong et al. 2013; Leroy et al. 2016, 2017).

To make the comparison presented in Figure 9, in the simulations we compute $\tau_{\text{dep,H}_2} = \Sigma_{\text{H}_2}/\dot{\Sigma}_*$, where Σ_{H_2} and $\dot{\Sigma}_*$ are measured by first projecting the local densities of the molecular gas and SFR perpendicular to the disk plane, and then smoothing the resulting surface densities using a Gaussian filter with a width of 1 kpc. Squares in Figure 9 show the mass-weighted averages $\langle 1/\tau_{\text{dep,H}_2} \rangle^{-1}$ on kiloparsec scale, which are equivalent to the global depletion times of the molecular gas⁵ and these averages are well approximated by our model (colored lines). A vertical band around each square indicates variation of the running median of $\tau_{\text{dep,H}_2}$ in bins of Σ_{H_2} at surface densities of $\Sigma_{\text{H}_2} > 1 M_{\odot} \text{pc}^{-2}$. This variation is rather small, because our simulations produce constant $\tau_{\text{dep,H}_2}$, even though a density-dependent depletion time is adopted on sub-grid scale: $\tau_* \propto \tau_{\text{ff}} \propto \rho^{-0.5}$. Such independence of $\tau_{\text{dep,H}_2}$ of

⁵ By definition, $\langle 1/\tau_{\text{dep,H}_2} \rangle^{-1} \equiv [\int dA (\Sigma_{\text{H}_2}/\tau_{\text{dep,H}_2}) / \int dA \Sigma_{\text{H}_2}]^{-1} = \int dA \Sigma_{\text{H}_2} / \int dA \dot{\Sigma}_* = M_{\text{H}_2}/\dot{M}_*$.

FIG. 10.— Comparison of the molecular gas depletion time and the gas surface densities on GMC scales to their distribution on the resolution scale in our simulations, $\Delta = 40$ pc. Adopted star formation efficiency increases from the left to the right: $\epsilon_{\text{ff}} = 0.01\%$, 1% , and 100% . The color map shows the mass-weighted distribution of computational cells for which we define $\Sigma_{\text{H}_2,40\text{ pc}} = f_{\text{H}_2} \rho \Delta$ with f_{H_2} given by the model of Krumholz et al. (2009) (see the beginning of Section 5) and $\tau_{\text{dep,H}_2} = M_{\text{H}_2}^{\text{cell}} / \dot{M}_{\text{H}_2}^{\text{cell}} = f_{\text{H}_2} \rho \Delta^3 / (M_{\text{H}_2}^{\text{cell}} (< 1 \text{ Myr}) / (1 \text{ Myr}))$, where in each cell, $M_{\text{H}_2}^{\text{cell}} (< 1 \text{ Myr})$ is the total mass of stars younger than 1 Myr. Cells containing only a single stellar particle form the diagonal upper boundary of $\tau_{\text{dep,H}_2}$ distribution. Cells without young stellar particles are indicated by blue horizontal stripes on top of each axis. Orange points show the observed $\tau_{\text{dep,H}_2}$ in the Milky Way GMCs from Lada et al. (2010, circles), Heiderman et al. (2010, stars), and Vutsalchavakul et al. (2016, squares). A green polygon indicates the range of Σ_{H_2} and $\tau_{\text{dep,H}_2}$ observed in three nearby spiral galaxies by Rebolledo et al. (2015).

Σ_{H_2} agrees with the observed constant $\tau_{\text{dep,H}_2}$, and its origin in our simulations is discussed in Section 4.4 of Paper I. We also find that the scatter around the running median (not shown) is consistent with observations as well (see Figure 3 in Paper I).

5.2.2. $\tau_{\text{dep,H}_2}$ on tens of parsec scales

Although current observations in most galaxies probe star formation and molecular gas only on scales $\gtrsim 1$ kpc, observations of star-forming regions in the Milky Way allow us to examine these quantities on smaller scales. Furthermore, scales of $\lesssim 100$ pc are increasingly probed in nearby galaxies (Bolatto et al. 2011; Rebolledo et al. 2015; Leroy et al. 2017) and this allows us to compare results of our simulations on these scales as well.

Figure 10 shows the variation of $\tau_{\text{dep,H}_2}$ in the Milky Way (points, Heiderman et al. 2010; Lada et al. 2010; Vutsalchavakul et al. 2016) and three nearby spiral galaxies (trapezoidal region, Rebolledo et al. 2015) with the molecular gas depletion time on the scale of 40 pc in our simulations (blue color map) as a function of Σ_{H_2} . For this comparison we only show GMCs in the Milky Way that have sizes of $\gtrsim 10$ pc, to make the scales comparable to the scale probed in our simulations. Different panels show the distribution of the local depletion times in our simulations with different values of the star formation efficiency: $\epsilon_{\text{ff}} = 0.01\%$, 1% , and 100% .

As the figure shows, although the observed $\tau_{\text{dep,H}_2}$ vary substantially, their typical values can be reproduced only in runs with $\epsilon_{\text{ff}} \sim 1\%$, while runs with too low (high) ϵ_{ff} significantly overestimate (underestimate) $\tau_{\text{dep,H}_2}$ in star-forming regions. Note that in all runs the distribution of $\tau_{\text{dep,H}_2}$ is bimodal: $\tau_{\text{dep,H}_2}$ is either finite, which corresponds to star-forming gas, or infinitely long, i.e. the gas is non-star-forming. In the figure, $\tau_{\text{dep,H}_2}$ in the latter case is artificially set to 500 Gyr for illustration purposes. Different runs differ by the fraction of the molecular gas in the star-forming state and by the average $\tau_{\text{dep,H}_2}$ of such gas. The fraction of the star-forming gas is the lowest in the run with $\epsilon_{\text{ff}} = 100\%$ and this gas has the depletion times of only $\sim 2 - 200$ Myr. These short depletion times of star-forming H_2 are averaged with large amounts of the non-star-forming molecular gas in this run, so that the depletion time on $\gtrsim 1$ kpc scales in the $\epsilon_{\text{ff}} = 100\%$ case is only a factor of two shorter than in the $\epsilon_{\text{ff}} = 1\%$ run. This shows that

FIG. 11.— Effect of ϵ_{ff} and the feedback boost factor, b , on the τ_{dep} bias as a function of the spatial smoothing scale, L . The depletion time in a given aperture of size L is defined as $\tau_{\text{dep,H}_2}(L) \equiv \Sigma_{\text{H}_2,L} / \dot{\Sigma}_{\text{H}_2,L}$, where $\Sigma_{\text{H}_2,L}$ and $\dot{\Sigma}_{\text{H}_2,L}$ are the molecular gas and the SFR surface densities smoothed using a Gaussian filter with a width L . Star symbols indicate the median depletion time measured in the apertures centered on peaks in $\dot{\Sigma}_{\text{H}_2}$, while circles correspond to the apertures centered on peaks in Σ_{H_2} . To factor out the variation of the global molecular gas depletion time with the feedback strength, we divide $\tau_{\text{dep,H}_2}(L)$ by global $\tau_{\text{dep,H}_2}$. Dashed lines show the results obtained for M33 by Schruba et al. (2010). To match the temporal averaging of H α indicator used by Schruba et al. (2010), we estimate $\dot{\Sigma}_{\text{H}_2}$ using stars younger than 10 Myr.

while $\tau_{\text{dep,H}_2}$ on $\gtrsim 1$ kpc scales is relatively insensitive to ϵ_{ff} , its values on the scales of $\lesssim 100$ pc are quite sensitive to the efficiency and can thus be used to constrain it.

5.2.3. The scale dependence of $\tau_{\text{dep,H}_2}$

Results of the previous two sections clearly show that the distribution of $\tau_{\text{dep,H}_2}$ depends on the spatial scale. Indeed, $\tau_{\text{dep,H}_2}$ in a given ISM patch results from averaging over a distribution of gas and stars inside the patch, and thus $\tau_{\text{dep,H}_2}$ depends on the patch size, L : $\tau_{\text{dep,H}_2}(L)$. The quantity that particularly strongly depends on the spatial scale is scatter: when the size of the patch decreases, patch-to-patch variation of gas and stars contained inside a patch becomes stronger,

which leads to a stronger variation of the derived depletion time in each patch and thus larger scatter in $\tau_{\text{dep,H}_2}$.

Following Schruha et al. (2010), one of the ways to express the dependence of scatter on the spatial scale is to consider the scale dependence of the depletion time, $\tau_{\text{dep,H}_2}(L)$, measured in patches centered on the peaks of Σ_{H_2} , which thus are biased to long $\tau_{\text{dep,H}_2}(L)$, versus those measured in patches centered on the peaks of $\dot{\Sigma}_*$, which are biased to short $\tau_{\text{dep,H}_2}(L)$. The difference between these two estimates of $\tau_{\text{dep,H}_2}(L)$ is small on large scales and their values approximately equal to the global depletion time. At smaller scales, this difference increases, as shown in Figure 11, which compares $\tau_{\text{dep,H}_2}(L)$ observed in M33 by Schruha et al. (2010) to the results of our simulations.

In simulations, $\tau_{\text{dep,H}_2}(L)$ centered on gas or stars strongly depends on ϵ_{ff} and the feedback boost factor b , because stronger feedback-induced gas flux results in more expulsive evacuation of the gas from star-forming regions, which leads to a stronger spatial displacement of Σ_{H_2} and $\dot{\Sigma}_*$ peaks. As Figure 11 shows, the fiducial run that satisfied all previous constraints also provides a reasonably good match to the observed $\tau_{\text{dep,H}_2}(L)$. Overall, for the fiducial feedback strength, both gas- and stars-centered $\tau_{\text{dep,H}_2}(L)$ favors $\epsilon_{\text{ff}} \lesssim 10\%$. Note however, that there is a degeneracy between the feedback strength and ϵ_{ff} value: the simulation with $\epsilon_{\text{ff}} = 1\%$ and $b = 5$ produces the relation similar to the simulation with $\epsilon_{\text{ff}} = 10\%$ and $b = 1$.

It is also worth noting that Σ_{H_2} -centered $\tau_{\text{dep,H}_2}(L)$ is noticeably more sensitive to ϵ_{ff} and b values. The sensitivity is stronger, because at higher ϵ_{ff} or b , the gas lifetime in the star-forming state is shorter, young stars are more sporadic, and thus it is less probable for a given patch centered on a Σ_{H_2} peak to contain young stars. As a result, $\tau_{\text{dep,H}_2}(L)$ at high ϵ_{ff} or b becomes highly biased to very large values. On the contrary, $\dot{\Sigma}_*$ -centered patches almost always contain molecular gas, because its abundance does not significantly decrease at stronger feedback (see Section 5.1.2). As a result, for $\dot{\Sigma}_*$ -centered patches, the bias also increases with ϵ_{ff} and b ($\tau_{\text{dep,H}_2}(L)$ becomes shorter), but this change is much milder than for Σ_{H_2} -centered patches.

Such strong dependence of Σ_{H_2} -centered $\tau_{\text{dep,H}_2}(L)$ on star formation and feedback parameters can provide tight constraints on these parameters. These constraints can be improved significantly if the scale dependence of $\tau_{\text{dep,H}_2}$ is measured in a larger sample of galaxies. Note however that more comprehensive comparison must include the effects of the intrinsic variation of ϵ_{ff} and the metallicity dependence of the molecular gas fraction on GMC scale, which are not accounted for in our simulations.

6. COMPARISON WITH PREVIOUS STUDIES

In previous sections, we showed that the simple theoretical framework presented in Paper I and Section 4.1 explains how local star formation and feedback parameters affect the global star formation in our L_* -sized galaxy simulations, both qualitatively and quantitatively. Here we illustrate how our framework can also explain the results of other recent galaxy simulations done with different numerical methods and implementations of star formation and feedback, both in isolated setups and in the cosmological context. Specifically, we will use our model to interpret trends (or lack thereof) of the depletion times with the local star formation efficiency, ϵ_{ff} , the feedback strength, and the adopted star formation thresholds.

For example, our framework predicts that in the simulations that adopt high ϵ_{ff} values and implement efficient feedback the depletion time is almost completely insensitive to the value of ϵ_{ff} . This is because in this regime τ_{dep} is controlled by the time that gas spends in the non-star-forming state which does not depend on ϵ_{ff} explicitly. This explains why τ_{dep} is insensitive to the variation of ϵ_{ff} in the simulations of Hopkins et al. (2017a); this behavior is also reproduced in our simulations (see Figures 1 and 3 above). In this regime, our framework also predicts a nearly linear scaling of τ_{dep} with the feedback strength parameter ξ , as is indeed observed in simulations (Hopkins et al. 2017a; Orr et al. 2017; Benincasa et al. 2016).

For smaller values of $\epsilon_{\text{ff}} \approx 1 - 10\%$, when the two terms in Equation (14) contribute comparably to the total depletion time, the model predicts that τ_{dep} should scale with ϵ_{ff} weakly (sublinearly). This was indeed observed in a number of simulations carried out in this regime (Saitoh et al. 2008; Dobbs et al. 2011; Agertz et al. 2013, 2015; Benincasa et al. 2016). In this case, sublinear scaling is also expected with the strength of feedback, ξ , which is also confirmed by simulations (Hopkins et al. 2011; Agertz et al. 2013, 2015; Benincasa et al. 2016).

For simulations with $\epsilon_{\text{ff}} \lesssim 1\%$ or when the feedback implementation is inefficient, $\xi \ll 1$, our model predicts that the depletion time is controlled by the second term in Equation (14) and that it scales inversely with ϵ_{ff} : $\tau_{\text{dep}} \sim \epsilon_{\text{ff}}^{-1}$. Such scaling was observed in the simulations without feedback by Agertz et al. (2013, 2015), while in the simulations using the same galaxy model but with the efficient feedback, τ_{dep} was found to be only weakly dependent on ϵ_{ff} .

The weak dependence or complete insensitivity of τ_{dep} to ϵ_{ff} at intermediate and high ϵ_{ff} explains why different galaxy simulations with widely different $\epsilon_{\text{ff}} \sim 1\% - 100\%$ all produce realistic global depletion times. However, as our results of Section 5 show, these simulations make drastically different predictions for the star-forming and molecular gas mass fractions, which can be used to constrain ϵ_{ff} in this regime (see Section 5.1). A similar idea was reported previously by Hopkins et al. (2012, 2013b), who showed that the fraction of gas in the dense molecular state with $n > 10^4 \text{ cm}^{-3}$ strongly depends on the local efficiency ϵ_{ff} and the feedback implementation. Specifically, simulations with high ϵ_{ff} and efficient feedback have a small dense gas mass fraction due to efficient conversion of dense gas into stars and its dispersal by feedback. This effect can explain why in the simulations with $\epsilon_{\text{ff}} = 100\%$ reported by Orr et al. (2017), the Kennicutt-Schmidt relation between the surface densities of SFR and dense and cold gas ($n > 10 \text{ cm}^{-3}$ and $T < 300 \text{ K}$) is considerably higher than the observed relation for molecular gas. In these simulations, the SFR is likely realistic because the depletion time of the total gas is expected to be insensitive to ϵ_{ff} . The dense gas fraction, on the contrary, is expected to be small, which leads to the small surface density of such gas and thus high Kennicutt-Schmidt relation as in Orr et al. (2017).

Our model also predicts that τ_{dep} depends on the star formation threshold differently in different regimes. For low ϵ_{ff} , τ_{dep} only weakly depends on the threshold value, while at high ϵ_{ff} , τ_{dep} decreases when the threshold encompasses more gas from a given distribution (see top middle and left panels in Figure 3). The former weak trend agrees with the results of Saitoh et al. (2008), who found that for $\epsilon_{\text{ff}} \sim 1.5\%$, τ_{dep} decreased only by a factor of $\sim 1.5 - 2$ when the density thresh-

old was varied from $n_{\text{sf}} = 100 \text{ cm}^{-3}$ to 0.1 cm^{-3} . Similarly, Hopkins et al. (2011) and Benincasa et al. (2016) found almost no dependence of τ_{dep} on n_{sf} . On the contrary, in simulations of Agertz et al. (2015) with $\epsilon_{\text{ff}} = 10\%$, τ_{dep} varied relatively strongly with variation of n_{sf} , as expected for high ϵ_{ff} . We note that to observe the variation of τ_{dep} when a combination of thresholds in different physical variables is used, all thresholds must be varied simultaneously. Varying only one threshold may not matter if another variable defines the star-forming gas. This is likely why Hopkins et al. (2017a) found that τ_{dep} is insensitive to variation of star formation thresholds, when thresholds in different variables were changed.

7. SUMMARY AND CONCLUSIONS

Using a simple physical model presented in Semenov et al. (2017, see also Section 4.1 above) and a suite of L_* -sized galaxy simulations, we explored how the global depletion times in galaxies, $\tau_{\text{dep}} = M_{\text{g}}/\dot{M}_*$, and the gas mass fractions in the star-forming and molecular states depend on the choices of the parameters of local star formation and feedback.

In our model, τ_{dep} is expressed as a sum of contributions from different physical processes, which include dynamical processes in the ISM, the conversion of gas into stars in star-forming regions, and the dispersal of such regions by stellar feedback. Some of these processes explicitly depend on the parameters of the *local* star formation and feedback model, such as a star formation efficiency per freefall time, ϵ_{ff} , and a feedback boost factor, b . Others do not have such explicit dependence and may be affected by these parameters only indirectly. This leads to two distinct regimes, in which terms with and without such explicit dependence dominate.

We demonstrated these regimes in a suite of L_* -sized galaxy simulations, in which we systematically varied ϵ_{ff} , b , and the thresholds used to define the star-forming gas. We also showed that the trends of τ_{dep} and the star-forming gas mass fraction exhibited in the simulations can be reproduced by our model both qualitatively and quantitatively after a minimal calibration of the model parameters. The main results of our simulations and the predictions of our model can be summarized as follows:

1. When ϵ_{ff} or b are large, the contribution of processes without explicit dependence on ϵ_{ff} dominates and τ_{dep} is insensitive to ϵ_{ff} , which is usually referred to as the “self-regulation” in the literature. However, in this regime, the mass fractions of the star-forming, f_{sf} , and the molecular, f_{H_2} , gas *do* depend sensitively on ϵ_{ff} and τ_{dep} scales almost linearly with the feedback strength factor for $b \gtrsim 1$.
2. Conversely, when ϵ_{ff} or b are sufficiently small, τ_{dep} is dominated by the processes that explicitly depend on the local gas depletion time, $t_* = t_{\text{ff}}/\epsilon_{\text{ff}}$ in Equation (1), and thus on ϵ_{ff} , but not on the feedback strength. In this case, the model predicts $\tau_{\text{dep}} \propto \epsilon_{\text{ff}}^{-1}$ and only weak dependence of f_{sf} and f_{H_2} on ϵ_{ff} , the behavior confirmed by our simulations.
3. The star formation threshold controls the mass fraction of the star-forming gas, the extent of star-forming regions, and their average properties, such as the average freefall time. We find that when ϵ_{ff} is small and the threshold is such that only a small fraction of the ISM gas is star-forming, τ_{dep} and f_{sf} are sensitive to the threshold value.

4. When ϵ_{ff} is large or feedback is efficient (i.e., when the first term in Equation 14 dominates), f_{sf} is small and most of the star-forming gas has density or virial parameter close to the star formation threshold. In this case global star formation and the molecular mass fraction, f_{H_2} , become sensitive to the value of the threshold.

The dependence of global star-forming properties of galaxies on the parameters of the local star formation and feedback model can be used to constrain the values of these parameters using observations of global galaxy properties. For example, the global depletion times of the total and molecular gas constrain the feedback strength, but cannot constrain the value of ϵ_{ff} due to their weak dependence on this parameter. However, the value of ϵ_{ff} can be constrained using the mass fraction of gas in the star-forming or molecular state. In addition, we showed that ϵ_{ff} can be constrained using the distribution of local depletion times in star-forming regions and measurements of $\tau_{\text{dep,H}_2}$ for gas patches of different sizes centered on the peaks of the molecular gas surface density.

Using our simulation suite, we demonstrated that it is possible to find a combination of the local star formation and feedback parameters that satisfies all of these observational constraints. Our fiducial run with $\epsilon_{\text{ff}} = 1\%$, the fiducial feedback boost $b = 1$, and the star formation threshold based on the virial parameter, $\alpha_{\text{vir}} < \alpha_{\text{vir,sf}} = 10$, is able to match all considered observations reasonably well. The low values of $\epsilon_{\text{ff}} \sim 1\%$ are also consistent with previous inferences (e.g., Krumholz et al. 2012, and references therein). We admit that the obtained constraints on ϵ_{ff} and other parameters are specific to the scales close to our resolution, i.e. ~ 40 pc, and an additional study is required to explore the scale dependence of these constraints on smaller spatial scales. We note, however, that the observed depletion times in GMCs on parsec scales also favor $\epsilon_{\text{ff}} \sim 1\% - 10\%$ (e.g., Heiderman et al. 2010; Gutermuth et al. 2011), while simulations with a few parsec resolution adopting higher ϵ_{ff} seem to underpredict the amount of dense star-forming gas (see the end of Section 6).

We also showed that our model explains the results of a number of recent studies that explored the effects of the local star formation and feedback model on the global properties of simulated galaxies. This broad consistency confirms that our model accurately describes the origin of global star-forming properties in galaxy simulations and thus allows us to understand the role played by gas dynamics, star formation and feedback in shaping these properties. Understanding the role of these processes in simulations also sheds light on their role in real galaxies, which is an essential step towards understanding of how real galaxies form and evolve.

We are grateful to Clarke Esmerian and Philip Mansfield whose comments helped to improve our draft. AK is grateful to the Cosmology Hub at the University College London for hospitality during completion of this paper. This work was supported by a NASA ATP grant NNN12ZDA001N, NSF grant AST-1412107, and by the Kavli Institute for Cosmological Physics at the University of Chicago through grant PHY-1125897 and an endowment from the Kavli Foundation and its founder, Fred Kavli. The simulation and analyses presented in this paper have been carried out using the Midway cluster at the University of Chicago Research Computing Center, which we acknowledge for support. Analyses presented in this paper were greatly aided by the following free software packages: `ytt` (Turk et al. 2011),

NumPy (Van Der Walt et al. 2011), SciPy (Jones et al. 2001-2016), Matplotlib (Hunter 2007), and GitHub (<https://github.com/>). We have also used the Astro-

physics Data Service (ADS) and arXiv preprint repository extensively during this project and writing of the paper.

APPENDIX

A. SUMMARY OF MODEL PARAMETERS

Our model equations,

$$\tau_{\text{dep}} = (1 + \xi)\tau_+ + \left(1 + \frac{\tau_+}{\tau_{-,d}}\right) \frac{\tau_{\text{ff}}}{\epsilon_{\text{ff}}}, \quad (\text{A1})$$

$$f_{\text{sf}} = \frac{1}{\epsilon_{\text{ff}}} \frac{\tau_{\text{ff}}}{\tau_{\text{dep}}}, \quad (\text{A2})$$

are derived from the mass conservation equation between star-forming and non-star-forming states in the ISM, as explained in Section 4.1 and Paper I. The parameters used in our model and their meanings are summarized in Table 1.

As we showed in Section 4.2.4, the model equations describe our simulation results even if we assume all the model parameters, including τ_{ff} , fixed. However, the accuracy of our model can be improved if the variation of τ_{ff} is incorporated.

To account for the variation of τ_{ff} with ξ and ϵ_{ff} , we note that star-forming gas is removed at a rate $\dot{M}_* + F_{-,fb} \propto (1 + \xi)\epsilon_{\text{ff}}$ and therefore τ_{ff} increases from $\tau_{\text{ff}}^{\text{dr}}$ to $\tau_{\text{ff}}^{\text{sr}}$ when $(1 + \xi)\epsilon_{\text{ff}}$ increases and galaxy switches from the dynamics-regulation (thus the superscript “dr”) to the self-regulation (“sr”) regime. Note that the dependence of τ_{ff} on the combination $(1 + \xi)\epsilon_{\text{ff}}$ is itself a prediction of the model. This prediction is confirmed by the simulation results shown in Figure 12, as τ_{ff} from all simulations with different ϵ_{ff} and ξ scale as a function of $(1 + \xi)\epsilon_{\text{ff}}$.

We then can interpolate τ_{ff} between $\tau_{\text{ff}}^{\text{dr}}$ and $\tau_{\text{ff}}^{\text{sr}}$ as a function of $\psi \equiv (1 + \xi)\epsilon_{\text{ff}}$ using a simple fitting formula shown with the

TABLE 1
DEFINITIONS OF THE QUANTITIES USED IN OUR MODEL

Quantity	Definition	Meaning	Model ^a
Modeled properties of the galaxy			
τ_{dep}	M_g/\dot{M}_*	Global depletion time of total gas	Equation (14)
f_{sf}	M_{sf}/M_g	Star-forming gas mass fraction	Equation (15)
τ_{ff}	$(1/t_{\text{ff}})_{\text{sf}}^{-1}$	Average freefall time in star-forming gas	Equations (A3–A6) ^b
Model parameters			
τ_*	M_{sf}/\dot{M}_*	Global depletion time of star-forming gas	$\tau_{\text{ff}}/\epsilon_{\text{ff}}$
τ_+	Equation (7)	Dynamical timescale on which non-star-forming gas becomes star-forming	$100 (\alpha_{\text{vir,sf}}/10)^{-0.5}$ Myr
$\tau_{-,d}$	Equation (9)	Timescale on which star-forming gas is dynamically dispersed	Spline ^c $\tau_{-,d}(\alpha_{\text{vir,sf}})$
ξ	Equation (8)	Average feedback mass-loading factor on the scale of star-forming regions	$60 b^{0.75}$
$\tau_{\text{ff}}^{\text{dr}}$		τ_{ff} in the dynamics-regulated regime	Spline ^c $\tau_{\text{ff}}^{\text{dr}}(\alpha_{\text{vir,sf}})$
$\tau_{\text{ff}}^{\text{sr}}$		τ_{ff} in the self-regulated regime	Equation (A11)
Simulation parameters controlling local star formation and feedback			
ϵ_{ff}	Equation (2)	Star formation efficiency per freefall time	
$\alpha_{\text{vir,sf}}$	see Section 2.2	Star formation threshold in virial parameter, $\alpha_{\text{vir}} < \alpha_{\text{vir,sf}}$	
n_{sf}	see Section 2.2	Star formation threshold in gas density, $n > n_{\text{sf}}$	
b	see Section 2.2	Boost factor of momentum injected per supernova	

^a The last column indicates model predictions for τ_{dep} , f_{sf} , and τ_{ff} and calibrated values for model parameters. Listed calibrations are obtained for the α_{vir} -based star formation threshold. Calibrations for the density-based threshold are provided at the end of Appendix A.

^b The model predicts the position and the width of τ_{ff} transition between $\tau_{\text{ff}}^{\text{dr}}$ and $\tau_{\text{ff}}^{\text{sr}}$.

^c The values of $\tau_{-,d}$ and $\tau_{\text{ff}}^{\text{dr}}$ are obtained directly from the $n - \sigma_{\text{tot}}$ distribution in our simulation with $\epsilon_{\text{ff}} = 0.01\%$ and fiducial $b = 1$ and $\alpha_{\text{vir,sf}} = 10$ (see the end of Appendix A).

solid line in Figure 12:

$$\tau_{\text{ff}} = \tau_{\text{ff}}^{\text{dr}} + f(\psi) (\tau_{\text{ff}}^{\text{sr}} - \tau_{\text{ff}}^{\text{dr}}), \quad (\text{A3})$$

$$f(\psi) = \frac{1}{\pi} \arctan \left(\frac{\log(\psi) - \log(\psi_{\text{cr}})}{w} \right) + \frac{1}{2}, \quad (\text{A4})$$

in which the position, ψ_{cr} , and the width, w , of transition can be predicted by our model. Specifically, from Equation (20), the transition happens at

$$\psi_{\text{cr}} = \left(1 + \frac{\tau_+}{\tau_{-,d}} \right) \frac{\overline{\tau_{\text{ff}}}}{\tau_+}, \quad (\text{A5})$$

where for simplicity, we assume average $\overline{\tau_{\text{ff}}} = 4$ Myr, representative of our simulation results. The width of the transition can be estimated assuming that as $(1 + \xi)\epsilon_{\text{ff}}$ increases from very low values, the transition appears when $\dot{M}_* + F_{-,fb}$ becomes comparable to $F_{-,d}$. This yields $(1 + \xi)\epsilon_{\text{ff}} \sim \tau_{\text{ff}}^{\text{dr}}/\tau_{-,d}$ and thus the width is

$$w = \log(\psi_{\text{cr}}) - \log(\tau_{\text{ff}}^{\text{dr}}/\tau_{-,d}). \quad (\text{A6})$$

In the dynamics-regulation regime, i.e. at small $(1 + \xi)\epsilon_{\text{ff}}$, $\tau_{\text{ff}}^{\text{dr}}$ is determined by the high-density tail of the star-forming gas PDF and is independent of the star formation. In the self-regulation regime, i.e. at large $(1 + \xi)\epsilon_{\text{ff}}$, $\tau_{\text{ff}}^{\text{sr}}$ increases as the high-density tail is dispersed and the star-forming gas stays close to the star formation threshold. These trends of τ_{ff} in the limiting regimes are apparent in the results of our simulation suite shown in Figure 12.

Equations (A3–A6) augment the main equations of our model (A1 and A2) with the variation of τ_{ff} with our model parameters: ϵ_{ff} , ξ , τ_+ , $\tau_{-,d}$, $\tau_{\text{ff}}^{\text{sr}}$, $\tau_{\text{ff}}^{\text{dr}}$. To calibrate the dependence of these parameters on our simulation parameters — i.e. local efficiency ϵ_{ff} , feedback boost factor b , and star for-

FIG. 12.— Comparison of our model prediction for the variation of the freefall time in the star-forming gas, τ_{ff} , to the results of our simulations. To measure τ_{ff} in the dynamics-regulation (small $(1 + \xi)\epsilon_{\text{ff}}$) and self-regulation (large $(1 + \xi)\epsilon_{\text{ff}}$) regimes and the parameters of the transition between these regimes, we use the same runs which were used to calibrate $(1 + \xi)\tau_+$ and $\tau_+/\tau_{-,d}$ in Section 4.2.4 (indicated by circled points). The predictions of our model agree with the results of all simulations, except for the run with $b = 0$ and $\epsilon_{\text{ff}} = 100\%$ (empty point), which does not remain in equilibrium due to the rapid global gas consumption.

mation threshold $\alpha_{\text{vir,sf}}$ — we assume

$$\xi = \xi_0 b^\beta, \quad (\text{A7})$$

$$\tau_+ = (100 \text{ Myr}) (\alpha_{\text{vir,sf}}/10)^\gamma, \quad (\text{A8})$$

$$\tau_{\text{ff}}^{\text{sr}} = (\tau_{\text{ff}}^{\text{sr}})_0 (\psi/100)^a (\alpha_{\text{vir,sf}}/10)^b. \quad (\text{A9})$$

Here we assume that at fiducial $\alpha_{\text{vir,sf}} = 10$, $\tau_+ \sim 100$ Myr, as indicated by the results in Paper 1. The value of τ_+ does depend on the star formation threshold, because threshold determines when the transition from the non-star-forming to the star-forming state happens in the evolution of each gas parcel. Equation (A9) incorporates the dependence of $\tau_{\text{ff}}^{\text{sr}}$ on $\psi \equiv (1 + \xi)\epsilon_{\text{ff}}$ and star formation threshold discussed above.

Next, as detailed in Sections 4.2.4 and 4.2.5, we use three runs in the self-regulation regime with different feedback boost, b , and threshold, $\alpha_{\text{vir,sf}}$, to estimate

$$(1 + \xi)\tau_+ \sim (6 \text{ Gyr}) b^{0.75} (\alpha_{\text{vir,sf}}/10)^{-0.5}, \quad (\text{A10})$$

$$\tau_{\text{ff}}^{\text{sr}} \sim (6 \text{ Myr}) (\psi/100)^{0.035} (\alpha_{\text{vir,sf}}/10)^{0.4}, \quad (\text{A11})$$

which imply $\xi_0 = 60$, $\beta = 0.75$, $\gamma = -0.5$, $(\tau_{\text{ff}}^{\text{sr}})_0 = 6 \text{ Myr}$, $a = 0.035$, and $b = 0.4$. Note, in particular, that $\xi \approx 60 b^{0.75}$ which implies that our fiducial feedback ($b = 1$) is rather efficient and $\xi \gg 1$ in Equation (A1).

Finally, the last two parameters, $\tau_{\text{ff}}^{\text{dr}}$ and $\tau_{-,d}$, are measured as functions of $\alpha_{\text{vir,sf}}$ directly from the $n - \sigma_{\text{tot}}$ distribution in our run with $\epsilon_{\text{ff}} = 0.01\%$ (the bottom left panel in Figure 5). To this end, we note that because of dynamics-regulation regime, this distribution would not change if $\alpha_{\text{vir,sf}}$ was varied. We then measure $\tau_{\text{ff}}^{\text{dr}}(\alpha_{\text{vir,sf}})$ as $\langle 1/t_{\text{ff}} \rangle^{-1}$ in gas with $\alpha_{\text{vir}} < \alpha_{\text{vir,sf}}$ and $\tau_{-,d}(\alpha_{\text{vir,sf}})$ from $f_{\text{sf}}(\alpha_{\text{vir,sf}})$ using Equation (17): $\tau_{-,d} = \tau_+ / (1/f_{\text{sf}} - 1)$. We spline $\tau_{\text{ff}}^{\text{dr}}(\alpha_{\text{vir,sf}})$ and $f_{\text{sf}}(\alpha_{\text{vir,sf}})$ and show them with blue lines in the bottom two panels of the middle column in Figure 3. For example, at our fiducial threshold of $\alpha_{\text{vir,sf}} = 10$, $\tau_{\text{ff}}^{\text{dr}} \sim 2.5 \text{ Myr}$ and $f_{\text{sf}} \sim 20\%$, which implies $\tau_{-,d} \sim \tau_+ / 4 \sim 25 \text{ Myr}$.

For the density-based star formation threshold we study only the dependence on n_{sf} but not on b . In other words, we replace Equations (A7–A9) with

$$\xi = \xi_0, \quad (\text{A12})$$

$$\tau_+ = (100 \text{ Myr}) (n_{\text{sf}}/100 \text{ cm}^{-3})^\gamma, \quad (\text{A13})$$

$$\tau_{\text{ff}}^{\text{sr}} = (\tau_{\text{ff}}^{\text{sr}})_0 (n_{\text{sf}}/100 \text{ cm}^{-3})^{-1/2}. \quad (\text{A14})$$

Note that the slope in the last equation is not a parameter because in contrast to the α_{vir} -based threshold, the dependence of $\tau_{\text{ff}}^{\text{sr}}$ on the density threshold follows from definition because in this regime, all star-forming gas has density $\sim n_{\text{sf}}$. For the same reason, $\tau_{\text{ff}}^{\text{sr}}$ does not depend on ψ for a density-based threshold.

The value $(\tau_{\text{ff}}^{\text{sr}})_0 = 5 \text{ Myr}$ is measured directly from the simulation with $\epsilon_{\text{ff}} = 100\%$ and $n_{\text{sf}} = 100 \text{ cm}^{-3}$, and using another run with lower n_{sf} we get

$$(1 + \xi)\tau_+ \sim (4.5 \text{ Gyr}) (n_{\text{sf}}/100 \text{ cm}^{-3})^{0.5}, \quad (\text{A15})$$

and thus $\xi_0 = 45$ and $\gamma = 0.5$.

B. MODEL FOR MOLECULAR GAS MASS FRACTION

Similarly to star-forming gas above a given threshold, molecular gas distribution is also shaped by dynamical and feedback-driven gas flows. Therefore, similarly to Section 4.1, mass conservation can be considered for the molecular state of the ISM to derive the relation between the molecular mass fraction, $f_{\text{H}_2} = M_{\text{H}_2}/M_{\text{g}}$, and the timescales of relevant processes supplying and removing molecular gas. In the equation for total molecular gas mass conservation,

$$\dot{M}_{\text{H}_2} = F_+^{\text{H}_2} - F_-^{\text{H}_2} - \dot{M}_*, \quad (\text{B1})$$

FIG. 13.— Comparison of our model predictions for the variation of the global molecular mass fraction, $f_{\text{H}_2} \equiv M_{\text{H}_2}/M_{\text{g}}$, with the results of the simulations. We average the total molecular mass in the simulations between 300 and 600 Myr, defining it as a sum of molecular masses in individual cells, which are computed using Krumholz et al. (2009) model (see the beginning of Section 5 for details). To obtain model predictions, we interpolate f_{H_2} between its values at low and high $(1 + \xi)\epsilon_{\text{ff}}$ calibrated using the simulations in corresponding regimes (large circled points). The value of $(1 + \xi)\epsilon_{\text{ff}}$ at which this transition occurs and the width of the transition are predicted by the model (Equations A5 and A6). Empty red point indicates the run with $b = 0$ and $\epsilon_{\text{ff}} = 100\%$, which does not remain in equilibrium due to the rapid global gas consumption.

we parametrize relevant fluxes as

$$F_+^{\text{H}_2} \equiv \frac{(1 - f_{\text{H}_2})M_{\text{g}}}{\tau_+^{\text{H}_2}}, \quad (\text{B2})$$

$$F_-^{\text{H}_2} \equiv \frac{f_{\text{H}_2}M_{\text{g}}}{\tau_-^{\text{H}_2}}, \quad (\text{B3})$$

$$\dot{M}_* \equiv \frac{f_{\text{sf}}M_{\text{g}}}{\tau_*}. \quad (\text{B4})$$

I.e., $F_+^{\text{H}_2}$ and $F_-^{\text{H}_2}$ are parametrized analogously to F_+ and F_- in Section 4.1 and the equation for \dot{M}_* repeats Equation (10).

Then, assuming steady state with $\dot{M}_{\text{H}_2} \approx 0$, substitution of Equations (B2)–(B4) into Equation (B1) yields

$$f_{\text{H}_2} \approx \frac{1 - (\tau_+^{\text{H}_2}/\tau_*)f_{\text{sf}}}{1 + (\tau_+^{\text{H}_2}/\tau_-^{\text{H}_2})}, \quad (\text{B5})$$

where f_{sf} can be computed using Equation (15).

At low ϵ_{ff} , $\tau_* = \tau_{\text{ff}}/\epsilon_{\text{ff}} \rightarrow \infty$, and thus $f_{\text{H}_2} \sim [1 + (\tau_+^{\text{H}_2}/\tau_-^{\text{H}_2})]^{-1}$, which is analogous to Equation (17), with $\tau_+^{\text{H}_2}$ and $\tau_-^{\text{H}_2}$ independent of star formation and feedback. At high ϵ_{ff} , all terms in Equation (B5) are relevant and $\tau_-^{\text{H}_2}$ depends on star formation and feedback parameters in a non-trivial way. This non-trivial dependence is more complex than a simple scaling with local depletion time τ_* — as was the case for the star-forming gas removal time $\tau_- \approx \tau_{-,fb} = \tau_*/\xi$ — because $\tau_-^{\text{H}_2}$ also depends on the dynamics of non-star-forming molecular gas and the details of its dissociation.

Thus, $\tau_-^{\text{H}_2}$ cannot be easily related to the parameters of sub-grid star formation and feedback which does not allow to use Equation (B5) for predicting how f_{H_2} depends on the parameters of star formation and feedback. However, this dependence can be calibrated using the same approach that we used to model variation of the freefall time in star-forming gas, τ_{ff} (Appendix A).

The approach is similar because the change of both τ_{ff} and f_{H_2} reflects the response of the gas PDF to the chang-

ing feedback-induced flux parametrized by $(1+\xi)\epsilon_{\text{ff}}$, and thus f_{H_2} variation with $(1+\xi)\epsilon_{\text{ff}}$ is qualitatively similar to that of τ_{ff} . Indeed, as Figure 13 shows, at $(1+\xi)\epsilon_{\text{ff}} < 0.1$, the value of $f_{\text{H}_2} \sim 20\%$ remains independent of ξ and ϵ_{ff} because feedback is too weak to affect the gas PDF. Between $(1+\xi)\epsilon_{\text{ff}} \sim 0.1$ and 1, the value of f_{H_2} decreases by a factor of 2 as feedback clears the high-density tail of the molecular gas distribution, and at $(1+\xi)\epsilon_{\text{ff}} > 1$ the decrease of f_{H_2} slows down as the non-star-forming molecular gas accumulates above the star formation threshold. As the black curve shows, such variation of f_{H_2} with $(1+\xi)\epsilon_{\text{ff}}$ can be approximated by the same fitting formula as the one used for τ_{ff} (Equations A3–A6), with the limiting

values of f_{H_2} at low and high $(1+\xi)\epsilon_{\text{ff}}$ calibrated using the simulations: $f_{\text{H}_2}^{\text{dr}} = 23\%$ and $f_{\text{H}_2}^{\text{sr}} = 0.05 [(1+\xi)\epsilon_{\text{ff}}/60]^{-0.1}$.

The discussed effect of star formation and feedback on f_{H_2} also allows us to predict variation of f_{H_2} with the star formation threshold. Namely, in the dynamics-regulation regime, we expect $f_{\text{H}_2} \sim 23\%$ to be independent of the star formation threshold because the ISM gas distribution remains independent of star formation. In the self-regulation regime, f_{H_2} decreases when the threshold is shifted to higher $\alpha_{\text{vir,sf}}$ or lower n_{sf} , because the region in the $n - \sigma_{\text{tot}}$ plane corresponding to the non-star-forming molecular gas shrinks.
