ABSTRACT

We developed a chemical network for modeling the chemistry and non-ideal MHD effects from the collapsing dense molecular clouds to protostellar disks. First, we re-formulated the cosmic-ray desorption rate by considering the variations of desorption rate over the grain size distribution. We find that the differential desorption of volatile species is amplified by the grains larger than $0.1 \mu m$, because larger grains are heated to a lower temperature by cosmic-rays and hence more sensitive to the variations in binding energies. As a result, atomic nitrogen N is ∼2 orders of magnitude more abundant than CO ; $\overline{N_2H}^+$ also becomes a few times more abundant than HCO⁺ due to the increased gas-phase N_2 . However, the changes in ionization fraction due to freeze-out and desorption only have minor effects on the non-ideal MHD diffusivities. Our chemical network confirms that the very small grains (VSGs: below a few 100) weakens the efficiency of both ambipolar diffusion and Hall effect. In collapsing dense cores, a maximum ambipolar diffusion is achieved when truncating the MRN size distribution at 0.1 μ m, and for a maximum Hall effect, the truncation occurs at 0.04μ m. We conclude that the grain size distribution is crucial to the differential depletion between CO and N_2 related molecules, as well as to the non-ideal MHD diffusivities in dense cores.

Key words: interstellar dust grain, astrochemistry, cosmic rays, magnetohydrodynamics

1 INTRODUCTION

In dense molecular cloud cores that are slightly ionized [\(Bergin](#page-12-0) [& Tafalla](#page-12-0) [2007\)](#page-12-0), magnetic fields are expected to partially decouple from neutral matter through non-ideal MHD effects, including ambipolar diffusion (AD), Ohmic dissipation, and Hall effect (e.g. [Nakano et al.](#page-12-1) [2002\)](#page-12-1). The non-ideal MHD effects are essentially determined by chemistry and microscopic physical processes [\(Op](#page-13-0)[penheimer & Dalgarno](#page-13-0) [1974;](#page-13-0) [Umebayashi & Nakano](#page-13-1) [1990\)](#page-13-1). In this way, chemistry actually has a significant impact on the dynamics and evolution of the system, from the collapsing cloud to the planet forming disk. However, until recently, chemistry models in this context are mostly simplified, with little attention paid to how different chemical effects affect the level of non-ideal MHD self-consistently.

When solving the chemical network for non-ideal MHD effects, existing literature often considers a simplified chemical network and treats different molecular and ionic species collectively (e.g., [Ume](#page-13-1)[bayashi & Nakano](#page-13-1) [1990;](#page-13-1) [Nishi et al.](#page-12-2) [1991;](#page-12-2) [Kunz & Mouschovias](#page-12-3) [2009;](#page-12-3) [Marchand et al.](#page-12-4) [2016;](#page-12-4) [Wurster](#page-13-2) [2016;](#page-13-2) [Zhao et al.](#page-13-3) [2016\)](#page-13-3). In these chemical networks, heavy ions are denoted collectively as *m* +

and molecules collectively as m , where m^+ and m are usually as-sumed to be HCO⁺ and CO, respectively. Recently, [Dzyurkevich et](#page-12-5) [al.](#page-12-5) [\(2017\)](#page-12-5) has developed a more complete chemical network (H-C-O chemistry) for non-ideal MHD effects, yet the effect of grain size on the Hall diffusivity is not fully revealed. Hall effect can dominate over ambipolar diffusion when including grains of ∼10–20 nanometer size, but the values of both diffusivities are not necessarily large enough to allow disk formation. Indeed, there exists an optimal grain size ($a_{\text{min}} \approx 0.04 \ \mu \text{m}$) to achieve the strongest Hall effect, which we will clarify in this work.

In cold dense cores of molecular clouds, the majority of molecules are frozen onto grain surfaces. The large CO freeze-out implies that $HCO⁺$ will no longer be the main positive charge carrier in dynamically evolved starless cores (i.e., prestellar cores), but H3⁺ and its deuterated isotopologues instead [\(Caselli et al.](#page-12-6) [2003;](#page-12-6) [Flower et al.](#page-12-7) [2005;](#page-12-7) [Tassis et al.](#page-13-4) [2012\)](#page-13-4). Such a change in ion composition in dense cores has not been considered self-consistently in previous networks for non-ideal MHD diffusivities [\(Kunz &](#page-12-3) [Mouschovias](#page-12-3) [2009;](#page-12-3) [Marchand et al.](#page-12-4) [2016;](#page-12-4) [Wurster](#page-13-2) [2016;](#page-13-2) [Zhao et](#page-13-3) [al.](#page-13-3) [2016;](#page-13-3) [Dzyurkevich et al.](#page-12-5) [2017\)](#page-12-5). We will show that the freeze-out of molecules has limited effect on the non-ideal MHD diffusivities, because the fluid conductivities are dominated by small grains instead of molecular ions; however, it can affect somewhat the polar-

[†] Present address: Giessenbachstr. 1, D-85748, Garching, Germany

ity and strength of the Hall effect in the intermediate density range 109–10¹¹ cm−³ for certain choices of grain size.

Another unsolved puzzle in astrochemistry is the survival of nitrogen bearing species in the gas phase to higher densities than those at which most carbon bearing species are already depleted out [\(Tafalla et al.](#page-13-5) [2004;](#page-13-5) [Belloche & André](#page-12-8) [2004;](#page-12-8) [Bergin et al.](#page-12-9) [2002\)](#page-12-9). While the difference in binding energies of CO and N_2 is only about 10% [\(Bergin & Langer](#page-12-10) [1997;](#page-12-10) [Öberg et al.](#page-13-6) [2005\)](#page-13-6) and hence is not considered as the origin of the differential depletion between nitrogen and carbon bearing species, it is believed that the loss of gaseous CO may account for the increase in abundances of N_2H^+ [\(Aikawa et al.](#page-12-11) [2001;](#page-12-11) [Bergin et al.](#page-12-9) [2002;](#page-12-9) [Jørgensen et al.](#page-12-12) [2004\)](#page-12-12) and thus NH3 [\(Geppert et al.](#page-12-13) [2004;](#page-12-13) [Aikawa et al.](#page-12-14) [2005\)](#page-12-14). However, it is still a second-order effect compared to the direct freeze-out of neutrals [\(Bergin & Tafalla](#page-12-0) [2007\)](#page-12-0). Alternatively, reducing the sticking coefficients of N_2 onto the grains by one order of magnitude can also enhance the abundances of both NH_3 and N_2H^+ [\(Flower](#page-12-7) [et al.](#page-12-7) [2005\)](#page-12-7), yet the approach is somewhat ad hoc. In this work, we present a new way of enhancing the gas-phase abundances of N, N_2 and N_2H^+ by including the grains size distribution into the formulation of cosmic ray desorption rate. However, due to the large binding energy for NH_3 adopted in this work, it is still difficult to maintain a large amount of gas-phase $NH₃$ that are efficiently formed via the usual gas-phase route from N_2 [\(Caselli et al.](#page-12-15) [2017\)](#page-12-15). More accurate measurements on the binding energies of molecules, as well as the inclusion of surface chemistry are required to better resolve these puzzles.

The rest of the paper is organized as follows. Section [2](#page-1-0) describes the set up of the chemical network and the modeling of reaction rates. In Section [3,](#page-3-0) we show the effect of grain size distribution on the differential desorption of volatile species, followed by a more complete discussion of the effect of grain size on nonideal MHD diffusivities. Finally, we summarize our main result in Section [4.](#page-11-0)

2 CHEMICAL NETWORK

We developed a reduced chemical network (Table [1\)](#page-1-1) including the 21 major neutral species in dense molecular cloud, 31 corresponding ion species, electron, and neutral and singly charged grain species. We consider over 500 reactions including gas phase reactions, recombination of charged species on grains, as well as freeze-out onto and thermal desorption of molecules off grains. In contrast to some existing networks (e.g., [Garrod et al.](#page-12-16) [2008\)](#page-12-16), we include all possible charge transfer reactions involving grains (for each size bin; hence the total number of reactions depends on the number of bins), which are crucial for obtaining correct ion abundances in the high density regimes where grains are the dominant charge carriers.

We use the standard grain size distribution $n(a) \propto a^{-\text{Ind}}$ with a fixed power law index *Ind* between the minimum size *a*min and maximum size *a*max. The entire size range is divided logarithmically into 20 size bins. The total grain mass is fixed at $q = 1\%$ of the gas mass. The density of grain material is set as $\rho_g = 3.0 \text{ g cm}^{-3}$.

2.1 Reactions

The primary mission of a chemical network is to determine the abundance of each species at any given time by solving the coupled rate equations. The rate equation for each species *i* of number density n_i can be expressed by the difference in its formation and

destruction:

$$
\frac{dn_i}{dt} = \sum_{j,k} k_{jk} n_j n_k + \sum_l k_l n_l - n_i \sum_m k_{im} n_m
$$

+
$$
(k_{\text{des}} + k_{\text{crd}} + k_{\text{crd},\text{fl}}) n_{i,s} - k_{\text{acc}} n_i,
$$
 (1)

where we include formation of species *i* by two-body reactions (k_{ik}) and cosmic-ray ionization (k_l) , and destruction of species *i* by twobody reactions (k_{im}) , freeze-out onto dust grains (k_{acc}) , thermal (k_{des}) and cosmic-ray desorption from dust grains (k_{crd}) , as well as desorption by cosmic-ray induced secondary UV photons $(k_{\text{crd,fl}})$.

The gas-phase reaction rates are taken from UMIST database [\(McElroy et al.](#page-12-17) [2013;](#page-12-17) see also [Tomida et al.](#page-13-7) [2013](#page-13-7) and [Marchand et](#page-12-4) [al.](#page-12-4) [2016\)](#page-12-4), formulated by the Arrhenius representation,

$$
k(T) = \alpha \left(\frac{T}{300 \, K}\right)^{\beta} \exp\left(-\frac{\gamma}{T}\right) \,,\tag{2}
$$

where α is the pre-exponential factor, β characterizes the temperature dependence of the rate coefficient, and γ is the activation energy or energy barrier of the reaction in units of degrees K.

We consider only singly charged grains, which is appropriate for the grain charge population in dense cores [\(Draine & Sutin](#page-12-18) [1987;](#page-12-18) [Ivlev et al.](#page-12-19) [2015b\)](#page-12-19). The reaction rates between gas-phase species and grains are given by [\(Kunz & Mouschovias](#page-12-3) [2009\)](#page-12-3),

$$
\alpha_{e^-g^0} = \pi a^2 \left(\frac{8k_B T}{\pi m_e}\right)^{1/2} \left[1 + \left(\frac{\pi e^2}{2ak_B T}\right)^{1/2}\right] \mathcal{P}_e,
$$
 (3)

$$
\alpha_{\rm ig^0} = \pi a^2 \left(\frac{8k_{\rm B}T}{\pi m_{\rm i}} \right)^{1/2} \left[1 + \left(\frac{\pi e^2}{2a k_{\rm B}T} \right)^{1/2} \right] \mathcal{P}_{\rm i} \,, \tag{4}
$$

$$
\alpha_{e^-g^+} = \pi a^2 \left(\frac{8k_B T}{\pi m_e}\right)^{1/2} \left[1 + \left(\frac{e^2}{ak_B T}\right)\right]
$$

$$
\times \left[1 + \left(\frac{2}{2 + (ak_B T/e^2)}\right)^{1/2}\right] \mathcal{P}_e,
$$
 (5)

$$
\alpha_{\text{ig}-} = \pi a^2 \left(\frac{8k_{\text{B}}T}{\pi m_{\text{i}}} \right)^{1/2} \left[1 + \left(\frac{e^2}{ak_{\text{B}}T} \right) \right]
$$

$$
\times \left[1 + \left(\frac{2}{2 + (ak_{\text{B}}T/e^2)} \right)^{1/2} \right] \varphi_{\text{i}} ; \tag{6}
$$

where k_B is the Boltzmann constant, m_i and m_e are the ion and

electron mass, respectively, and \mathcal{P}_i and \mathcal{P}_e are the sticking probabilities of ions or electrons onto grains, whose values are assigned as 1.0 and 0.6, respectively [\(Umebayashi](#page-13-8) [1983;](#page-13-8) [Kunz & Mouschovias](#page-12-3) [2009\)](#page-12-3).

The rate coefficients for charge transfer between charged grains are given by,

$$
\alpha_{g^-g^+} = \pi a_{\text{sum}}^2 \left(\frac{8k_B T}{\pi m_{\text{red}}} \right)^{1/2} \left[1 + \left(\frac{e^2}{a_{\text{sum}} k_B T} \right) \right]
$$

$$
\times \left[1 + \left(\frac{2}{2 + (a_{\text{sum}} k_B T / e^2)} \right)^{1/2} \right],
$$
 (7)

where a_{sum} is the sum of the radii of two grains, and m_{red} (≡ $m_{\rm g}$ + $m_{\rm g}$ -/($m_{\rm g}$ + + $m_{\rm g}$ -)) is the reduced mass of the two grains.

The accretion rate of each species onto dust grains is given by,

$$
k_{\rm acc} = \pi a^2 \left(\frac{8k_{\rm B}T}{\pi m_{\rm i}}\right)^{1/2} n_{\rm g}(a),\tag{8}
$$

where $n_g(a)$ is the total number density of dust grains with size *a*. The thermal desorption rate of species *i* is given by

$$
k_{\text{des}} = v_0(i) \exp\left(\frac{-E_{\text{des}}(i)}{k_{\text{B}}T_{\text{d}}}\right),\tag{9}
$$

where T_d is the dust grain temperature that is set to the gas temperature for our application, and $v_0(i)$ is the characteristic vibration frequency for the absorbed species*i*, given by the following relation,

$$
v_0(i) = \sqrt{\frac{2n_s E_{\text{des}}(i)}{\pi^2 m_i}},\tag{10}
$$

where $n_s = 1.5 \times 10^{15}$ cm⁻² is the number of surface sites per cm² on grains.

The cosmic-ray particles of few $10¹$ to few $10²$ MeV per nucleon can impulsively heat dust grains to a higher temperature Te (depending on the cosmic ray energy and grain size). The grain subsequently cools through desorption of volatile species, e.g., CO. The rate of such cosmic-ray induced desorption can be approximated by [\(Hasegawa & Herbst](#page-12-20) [1993\)](#page-12-20):

$$
k_{\text{crd}}(i, a) = f(T_{\text{e}}(a))k_{\text{des}}(i, T_{\text{e}}(a)), \qquad (11)
$$

where $f(T_e(a))$ is an estimation of the fraction of time spent by a grain with radius *a* at an elevated temperature *T*e, defined as the ratio of the cooling timescale by desorption of volatiles to the time interval of successive heating by cosmic-rays. The latter is about 10^6 yrs for 0.1 μ m grains and cosmic-ray ionization rate of 10−¹⁷ s −1 [\(Léger et al.](#page-12-21) [1985\)](#page-12-21); this timescale is inversely proportional to the cross-section of the grain ($\propto a^2$).

The elevated temperature a grain can reach via impulsive heating is also sensitive to the grain size. Cosmic-ray particles deposit more energy when penetrating through larger grains ($\propto a$), but find it difficult to heat up the whole grain to high temperatures due to a larger grain volume. We extend the volumic specific heat formula up to 300 K from Fig. 1 of [\(Léger et al.](#page-12-21) [1985\)](#page-12-21),

$$
Cv(T) = 1.4 \times 10^3 T^2 \text{ erg cm}^{-3} \text{ K}^{-1}, T < 50 \text{ K},
$$
\n
$$
= 2.2 \times 10^4 T^{1.3} \text{ erg cm}^{-3} \text{ K}^{-1}, 50 \text{ K} < T < 150 \text{ K},
$$
\n
$$
= 4.4 \times 10^5 T^{0.7} \text{ erg cm}^{-3} \text{ K}^{-1}, 150 \text{ K} < T < 300 \text{ K}.
$$
\n
$$
(12)
$$

The energy deposit to a grain with radius *a* by impinging Fe nuclei with ∼20 MeV per nucleon is estimated by

$$
\Delta E_{\rm dep} = 3.8 \times 10^5 \left(\frac{a}{0.1 \mu m} \right) \text{ eV} \,, \tag{13}
$$

which corresponds to heating up the grains of 0.1 μ m to 70 K and 0.2 μ m to 43 K. Smaller grains can reach much higher $T = \sigma$ 0.2 μ m to 43 K. Smaller grains can reach much higher T_e , e.g., \sim 193 K for 0.03 μ m grains and over 600 K (extrapolated) for grains $≤0.01$ μm.

The subsequent cooling of the grain is mainly achieved through evaporation of CO and other volatile species. According to [Hasegawa & Herbst](#page-12-20) [\(1993\)](#page-12-20), the evaporation timescale is inversely proportional to k_{des} of CO molecules ($\approx 10^{-5}$ s for 0.1 μ m), which
is applicable to grains with enough surface sites for volatile abis applicable to grains with enough surface sites for volatile absorbates. From the initial deposited energy ΔE_{dep} , we can estimate the maximum number of CO molecules that would be evaporated into the gas as $N_{evap} = \Delta E_{dep}/E_{des}(CO)$. N_{evap} is usually a small fraction of the total number of surface sites; but for grains smaller than ~0.03 μm, N_{evap} ≈10⁶ becomes comparable to the number of surface sites (assuming a few ice layers). Therefore, we only apply the scaling of evaporation timescale from [Hasegawa & Herbst](#page-12-20) [\(1993\)](#page-12-20) to grains with $a \in [0.03, 0.25]$ μ m, corresponding to a temperature range of about [200, 35] K (hence the final desorption rate has a weak dependence on T_e for a given species, consistent with [Hasegawa & Herbst](#page-12-20) [1993\)](#page-12-20).

For larger grains ($>0.25 \mu$ m), spot heating by cosmic-rays will start to dominate over whole grain heating [\(Léger et al.](#page-12-21) [1985;](#page-12-21) [Shen](#page-13-9) [et al.](#page-13-9) [2004\)](#page-13-9). For smaller grains with much higher *T*e, most CO and other volatile species on the grain surface are rapidly depleted through evaporation with timescale $\langle 10^{-9}$ s, which only removes $\leq 10\%$ of the total deposited energy E_{dep} . However, because of the high temperature, sublimation of H_2O becomes very efficient [\(Tie](#page-13-10)[lens](#page-13-10) 2005 , each $H₂O$ molecule takes away five times the energy of each CO molecule). The timescale of water sublimation for grains smaller than 0.01 μ m can be estimated as ~10⁻⁸ s given T_e ~600 K.
For simplicity, these additional processes are not considered in this For simplicity, these additional processes are not considered in this study (detailed treatment of water sublimation on small grains may potentially affect the abundances of species with large binding energies).

Based on these assumption, the duty cycle can be obtained by scaling both the timescale of evaporative cooling and the time interval between successive heating. The resulting duty cycle $f(T_e(a))$ can vary by more than 10 orders of magnitude $(10^{-26} - 10^{-12} \text{ s}^{-1})$ along the standard MRN (Mathis-Rumpl-Nordsieck; [Mathis et al.](#page-12-22) [1977\)](#page-12-22) size distribution; smaller grains have smaller duty cycles per grain because they are struck less frequently by cosmic rays and they spend shorter times at the elevated temperature (see also [Acharyya](#page-12-23) [et al.](#page-12-23) [2011\)](#page-12-23), while larger grains have larger cross-section for incoming cosmic rays and they cool down slowly since their peak temperatures are closer to the ambient gas temperature.

The final value of $\langle k_{\text{crd}}(i) \rangle$ for species *i* is obtained by averaging over the grain size distribution (weighted by grain surface area) as:

$$
\langle k_{\rm crd} \rangle = \frac{\sum_{a} k_{\rm crd} \pi a^2 n(a)}{\sum_{a} \pi a^2 n(a)}, \tag{14}
$$

which is equivalent to treating each surface species as a separate species in each size bin, $¹$ $¹$ $¹$ given enough surface sites for the ad-</sup> sorbed species at each size bin. As an example, the desorption rate $k_{\text{crd}}(\text{CO}, a)$ for CO takes value between ~10⁻¹⁷–10⁻¹³ s⁻¹ for the

^{[1](#page-1-2)} The cosmic-ray desorption term in the rate equation Eq. 1 for a size

4 *B. Zhao et al.*

standard MRN distribution, with larger values of k_{crd} for larger *a*, and the weighted desorption rate $k_{\text{crd}}(i) \approx 1.04 \times 10^{-14} \text{ s}^{-1}$ (very similar to the values derived by [Hasegawa & Herbst](#page-12-20) [\(1993\)](#page-12-20) using 0.1 μ m grains).

Cosmic rays also induce secondary UV photons when interacting with H_2 molecules – the so called H_2 fluorescence in the Lyman and Wemer bands. The resulting flux of UV photons can be estimated by:

$$
F_{\rm UV} \approx 1830 \left(\frac{\zeta^{\rm H_2}}{10^{-17} \, s^{-1}} \right) \, cm^{-2} \, s^{-1} \tag{15}
$$

[\(Cecchi-Pestellini & Aiello](#page-12-24) [1992;](#page-12-24) [Ivlev et al.](#page-12-19) [2015b\)](#page-12-19), assuming the typical interstellar dust gas and dust properties. The corresponding rate of photo-desorption by such a fluorescence can be expressed as,

$$
k_{\rm crd,fl} = \frac{F_{\rm UV}}{4n_{\rm s}N_{\rm l}} Y_i \,, \tag{16}
$$

where $N_1=2$ is the number of ice layers that can be affected by an incoming UV photon for photo-desorption, and Y_i is the photodesorption yield per photon. For simplicity, we set $Y_i=10^{-3}$ for all desorbing species.

The coupled ODEs (ordinary differential equations) are solved using DVODE library^{[2](#page-3-1)} with sparse matrix turned off, due to the small number of species yet a large number of reactions for each species.

3 RESULT

We evolve the chemical network for 10^5 years for the freeze-out mechanism to take effect [\(Flower et al.](#page-12-7) [2005\)](#page-12-7), while the ion chemistry reaches equilibrium as quickly as a few $10¹$ years [\(Caselli et al.](#page-12-25) [2002b\)](#page-12-25). In the high density regions, we adopt a barotropic equation of state (EOS) described in Appendix [A](#page-12-26) to mimic the change of temperature at high densities including those for protostellar disks. The cosmic-ray ionization rate $({\zeta_0^{H_2}} = 1.3 \times 10^{-17} \text{ s}^{-1})$ also at-
tenuates exponentially at high densities following the relation given tenuates exponentially at high densities following the relation given in [Nakano et al.](#page-12-1) [2002](#page-12-1) (see also, Eq. 1 in [Zhao et al.](#page-13-3) [2016\)](#page-13-3), until a lower limit of 1.1×10^{-22} s⁻¹ (corresponding to the ionization by radioactive decay of long-lived ⁴⁰K) is reached radioactive decay of long-lived 40 K) is reached.

In this section, we demonstrate that grain size distribution can significantly affect cosmic-ray desorption as well as nonideal MHD effects. In particular, (1) the abundance differentiation among volatile species is sensitive to the maximum grain size $(a_{\text{max}} > 0.1 \ \mu \text{m})$; (2) ambipolar diffusivity is sensitive to the amount of VSGs (a few to tens of nanometer, see also [Zhao et al.](#page-13-3) [2016\)](#page-13-3); (3) Hall diffusivity is generally sensitive to grain size distribution in terms of sign and magnitude, but reaches a maximum level at densities below 10¹³ cm⁻³ when $a_{\text{min}} \approx 0.04 \ \mu \text{m}$ (in contrast to [Dzyurkevich et al.](#page-12-5) [2017\)](#page-12-5).

3.1 Amplified Differential Depletion of Volatile Species Due to Cosmic-ray Desorption

Conventionally, the small difference in binding energies among volatile species are considered to have negligible effect on their gas-

distribution is,

$$
\Sigma_a \left[k_{\text{crd}}(a) \frac{n_{i,s}}{\Sigma_a \pi a^2 n(a)} \pi a^2 n(a) \right] = \langle k_{\text{crd}} \rangle n_{i,s}
$$

 2 available at <http://www.radford.edu/~thompson/vodef90web/>

phase abundances. However, with the new formulation of cosmicray desorption rate which includes the dependence on grain size, the effect of binding energies on the abundances of volatiles is amplified by the variations in the elevated temperature. As a result, the small difference in binding energies can be the origin of the differential depletion among volatiles in this paradigm.^{[3](#page-3-2)}

Fig. [1](#page-4-0) shows the abundances of the main ion and neutral species relative to H_2 using the new formulation of cosmic-ray desorption rate (Eq. [11\)](#page-2-1). With the standard MRN size distribution, the gasphase atomic N is two orders of magnitude more abundance than gas-phase CO (in the density range between a few 10^5 and a few 10^{10} cm⁻³), while the abundances of N₂ and O₂ are higher than CO by a factor of few (consistent with observational constraints by [Maret et al.](#page-12-27) [2006;](#page-12-27) see also [van Dishoeck & Blake](#page-13-11) [1998\)](#page-13-11). The excess of N_2 over CO in the gas phase also leads to an excess of N_2H^+ over HCO^+ by a factor of a few in the density range of dense cores. In contrast, when the conventional pre-factor for the cosmic-ray desorption rate $f(70 \text{ K}) = 3.16 \times 10^{-19}$ (derived with 0.1 μ m grains) is used instead, the difference in abundances among volatile species becomes almost negligible (Fig. [2\)](#page-4-1), which recovers the claims of existing studies (e.g., [Flower et al.](#page-12-7) [2005\)](#page-12-7).

The differential depletion of volatile species is clearly amplified by adopting the new cosmic-ray desorption rate that varies with grain sizes. Fig. [3](#page-5-0) compares for the main volatile species the cosmic-ray desorption rates $k_{\text{crd}}(i, a)$ (computed via Eq. [11](#page-2-1)[–13\)](#page-2-2) and the averaged value $\langle k_{crd}(i) \rangle$, along with the conventional rate for 0.1 μ m grain from [Hasegawa & Herbst](#page-12-20) [\(1993\)](#page-12-20). Apparently, the averaged desorption rates $\langle k_{\text{crd}}(i) \rangle$ (circled crosses in Fig. [3\)](#page-5-0) of different volatile species are more separated from each other than the conventional desorption rates computed using 0.1μ m grain (dashed horizontal lines). The enhanced differential depletion is caused by the large variation of $k_{\text{crd}}(i, a)$ (among different species) in the grain size range larger than [∼]0.1 µm; these grains are only heated by cosmic rays to lower elevated temperatures $T_e(a)$ (e.g. ~40 K) and are more sensitive to the difference in binding energies among volatile species. For example, $k_{\text{crd}}(i, 0.2 \mu m)$ of volatile species with small binding energies (e.g., N and N₂) reaches ~10⁻¹¹-10⁻¹⁰ s⁻¹, compared to 10^{-15} s⁻¹ for less volatile species (e.g., O). Therefore, the averaged $\langle k_{\text{crd}}(i) \rangle$ (weighted by grain surface area) lean towards larger values for more volatile species (e.g., N and N2) but smaller values for less volatile species (e.g., O, H_2O). We have also tested models with longer evolution time 10^6 yrs and 10^7 yrs, and the effect of differential depletion is almost identical.

Note that on the freeze-out timescale (\sim 10⁵ yrs), the majority of desorption of volatile species (*E*des∼1000 K such as CO, N2, $O₂$, C, N, and O) owes to the impulsive heating by cosmic-rays. In comparison, the cosmic-ray induced UV photons contribute most to the desorption of species such as OH and H2O that have large binding energies E_{des} . Indeed, $k_{\text{crd}}(i, a)$ is a decreasing function of *a* at larger grain sizes, because the evaporative cooling timescale is derived by assuming CO as the primary volatile species to cool the grains [\(Hasegawa & Herbst](#page-12-20) [1993\)](#page-12-20), and within the duty cycle, the non-volatile species are difficult to evaporate into gas-phase when the elevated temperature is low. A more strict treatment for the evaporative cooling process including the contributions from both CO and $H₂O$ ice may provide more accurate results for these non-volatile species. Again, we are aware of the disagreements over

³ Indeed, more complete chemical networks including grain surface reactions are needed to fully understand the differential depletion of volatile species in dense molecular clouds; we will leave it to future investigations.

Figure 1. Fractional abundances of the main ion and neutral species computed with the new formulation of cosmic-ray desorption rate for a standard MRN size distribution. In the right panel, N atom is ~2 orders of magnitude more abundant than CO for number densities between 10^5 – 10^{11} cm⁻³.

Figure 2. Fractional abundances of the main ion and neutral species computed with the conventional $f(70 K)$ pre-factor. Other parameters remain the same as in Fig. [1.](#page-4-0) The abundances of volatile species in the right panel are nearly indistinguishable from each other.

Figure 3. Comparison of cosmic-ray desorption rates among volatile species. Solid lines represent the desorption rate per grain $k_{\text{crd}}(i, a)$ for a given species i and grain radius a . The circled crosses mark the averaged desorption rate for each species. Long dashed lines are the desorption rate computed using the conventional $f(70 \text{ K})$ pre-factor. The value of binding energies are taken from [Sipila et al.](#page-13-12) [\(2015\)](#page-13-12).

binding energies among existing literature, and improved measurements of binding energies (e.g. [Cazaux et al.](#page-12-28) [2017;](#page-12-28) [Shimonishi](#page-13-13) [et al.](#page-13-13) [2018\)](#page-13-13) are needed to refine the cosmic-ray desorption model presented here.

3.2 Freeze-Out and Relative Abundance of Ions

As shown in § [3.1](#page-3-3) above, the chemical abundances are strongly affected by the freeze-out and desorption processes. In particular, the dominant ion species in dense cores is no longer the commonly assumed HCO⁺ (Fig. [4a;](#page-6-0) see also [Umebayashi & Nakano](#page-13-1) [1990;](#page-13-1) [Zhao et al.](#page-13-3) [2016;](#page-13-3) [Marchand et al.](#page-12-4) [2016\)](#page-12-4) but H_3^+ instead for number densities below 10^{11} cm⁻³ for the standard MRN size distribution (see Fig. [1](#page-4-0) above), consistent with the result of [Flower et al.](#page-12-7) [\(2005\)](#page-12-7).

However, the grain size distribution can also affect the relative abundances among ion species via the change of surface area for freeze-out. As shown in Fig. [4b,](#page-6-1) when using a truncated MRN distribution with $a_{\text{min}}=0.1 \mu \text{m}$, H_3^+ only starts to dominate the ion

abundances for densities between $10^8 - 10^{11}$ cm⁻³. In the low density regime, $HCO⁺$ is still the most abundant ion species up to $\sim 8 \times 10^6$ cm⁻³, when N₂H⁺ overtakes HCO⁺. In comparison, with the standard MRN distribution (Fig. [1\)](#page-4-0), N_2H^+ starts to dominate over HCO⁺ at relatively low densities ~5×10⁴ cm⁻³, but they both are much less abundant than H_3^+ (10⁵–10¹¹ cm⁻³ cm⁻³). It is likely that neither size distributions can well characterize the grain properties in dense cores over the long time evolution (e.g., [Hirashita](#page-12-29) [2012\)](#page-12-29). We also show an intermediate case with $a_{\text{min}}=0.04 \ \mu \text{m}$ in Appendix C , the dominant ion species switches from $HCO⁺$ to N_2H^+ at number density around 8×10^5 cm⁻³, and H_3^+ dominates over both between $5 \times 10^{6} - 10^{11}$ cm⁻³. The change of the dominant ion species is regulated by the level of depletion of volatile species (e.g., CO and N_2), which is sensitive to the grain surface area for freeze-out.

Observationally, the relative abundances among the main ion species may provide an alternative way of determining the average grain size $\langle a \rangle$ in dense cores. For instance, if the abundance of H_3^+ could be inferred either directly or via comparison of H_2D^+ and

(a) Freeze-out and desorption: Off (b) Freeze-out and desorption: On

Figure 4. Fractional abundances of the main ion species computed without freeze-out/desorption (left panel) and with freeze-out/desorption (right panel) for the truncated MRN size distribution with a_{min} =0.1 μ m.

other molecular ion observations with chemical models, one can obtain an estimate of the grain size by comparing the abundance of H_3^+ with that of N_2H^+ (or HCO^+) at given densities (slightly larger $\langle a \rangle$ makes it harder for H_3^+ to dominate over the other two ions). Furthermore, with a proper limit on the maximum grain size constrained by existing observations (if any), the minimum grain size can be inferred (assuming a certain power law index for the size distribution), and vice versa.

3.3 Effect of Chemistry on Non-ideal MHD Diffusivities

With the ionization fraction from the chemical network, it is straightforward to obtain the three non-ideal MHD diffusivities: η_{AD} , η_{Ohm} , η_{Hall} (Appendix [B;](#page-12-31) see also, [Wardle & Ng](#page-13-14) [1999;](#page-13-14) [Zhao et al.](#page-13-3) [2016\)](#page-13-3). Despite the pronounced effect of freeze-out and desorption processes on the abundance of ions, they only have limited influence on the non-ideal MHD effects that are instead modulated by the grain size distribution [\(Wardle & Ng](#page-13-14) [1999;](#page-13-14) [Padovani et al.](#page-13-15) [2014;](#page-13-15) [Zhao et al.](#page-13-3) [2016;](#page-13-3) [Dzyurkevich et al.](#page-12-5) [2017\)](#page-12-5). However, disagreement still exists among literatures in terms of the effect of grain size on magnetic diffusivities. We now utilize our chemical network to clarify the disagreement, with a particular emphasis on Hall diffusivity, which is not covered in details in [Zhao et al.](#page-13-3) [\(2016\)](#page-13-3).

3.3.a Limited Influence of Freeze-out and Desorption on Magnetic Diffusivities

We again vary the minimum grain size a_{min} of the size distribution, but keep the power index of -3.5 and $a_{\text{max}} = 0.25 \mu \text{m}$. Similar to [Li et al.](#page-12-32) [\(2011\)](#page-12-32) and [Zhao et al.](#page-13-3) [\(2016\)](#page-13-3), we adopt the simple relation between magnetic field and density [\(Nakano et al.](#page-12-1) [2002\)](#page-12-1),

$$
|\mathbf{B}| = 0.143 \left[\frac{n(\text{H}_2)}{\text{cm}^{-3}} \right]^{0.5} \mu \text{G}, \qquad (17)
$$

to estimate the magnetic field strength. The resulting magnetic diffusivities for different grain sizes are shown in Fig. [5,](#page-7-0) with freezeout/desorption turned on or off. Overall, the magnetic diffusivities are very similar between the two cases, indicating that changes in ion abundances^{[4](#page-6-2)} due to freeze-out and/or desorption only have limited effect on the magnetic diffusivities.

The most obvious difference between the two cases is the Hall diffusivity in the density range $\sim 10^{9}$ – 10^{11} cm⁻³ when using $a_{\text{min}} = 0.1 \ \mu \text{m}$. In the case without freeze-out and desorption, η_{Hall} briefly switches to positive sign in the vicinity of 10^{10} cm⁻³, causing a wider density range ($\approx 10^9 - 10^{11}$ cm⁻³) to have lowered causing a wider density range $({\sim}10^{9}$ – 10^{11} cm⁻³) to have lowered values of η_{Hall} . In contrast, the case with freeze-out and desorption (bottom panels of Fig. [5\)](#page-7-0) shows a more smooth negative value of η_{Hall} in the similar density range. The reason for such a difference is evident when comparing Fig. [6](#page-8-0) and Fig. [7](#page-9-0) where we plot the contributions of the main charged species to the three components of fluid conductivity (parallel σ_{\parallel} , Pedersen $\sigma_{\rm P}$, and Hall $\sigma_{\rm H}$ defined
in Appendix B). The principal term that determines Hall diffusivity in Appendix \overline{B}). The principal term that determines Hall diffusivity is the Hall conductivity $\sigma_{\rm H}$, which carries a sign for each charged species (Eq. B₆). In the case without freeze-out and desorption, σ_H becomes positive near 10^{10} cm⁻³ because the total contribution of σ_H from ions (especially HCO⁺ and H₃O⁺) surpasses $\sigma_H(g^-)$.
However, when freeze-out and desorption are turned on σ_V is al-However, when freeze-out and desorption are turned on, σ_H is always dominated by g^- in low density regimes ($\leq 10^{11}$ cm⁻³). In fact, when we adopt $a_{\text{min}} \approx 0.15 \ \mu \text{m}$ for the freeze-out/desorption

⁴ The change in Hall parameter (defined in Appendix [B\)](#page-12-31) by switching the dominant ion species from HCO⁺ to H₃+ has even less effect (\leq 5%).

Figure 5. Non-ideal MHD diffusivities computed without (top three panels) and with (bottom three panels) freeze-out/desorption for different size distributions with $a_{\text{min}} = 0.005 \,\mu\text{m}$ (MRN: black), $a_{\text{min}} = 0.04 \,\mu\text{m}$ (blue), $a_{\text{min}} = 0.1 \,\mu\text{m}$ (red), $a = 1.0 \,\mu\text{m}$ (green). Ambipolar diffusion is at a maximum level over the density range when $a_{\text{min}} = 0.1 \mu \text{m}$, while Hall effect is more efficient for disk formation when $a_{\text{min}} = 0.04 \mu \text{m}$.

case, η_{Hall} presents similar sign change between $10^9-10^{10} \text{ cm}^{-3}$.
Therefore it is a general behavior of Hall diffusivity that rather de-Therefore, it is a general behavior of Hall diffusivity that rather depends on the choice of grain size than on freeze-out/desorption. As grain size increases, the abundance of g^- reduces, so that positive Hall diffusivity extends to wider and wider regions in the lower density regime $(\leq 10^{11} \text{ cm}^{-3})$.

3.3.b Optimal Grain Size for Hall Diffusivity

In fact, there exists an optimal grain size $a_{\text{min}} \approx 0.04 \ \mu \text{m}$ for which Hall diffusivity η_{Hall} reaches a maximum level at number densities below $\leq 10^{11}$ cm⁻³. According to Eq. [B3](#page-12-34) in Appendix [B,](#page-12-31) large η_{Hall}
requires both Hall conductivity σ_{tot} and Pedersen conductivity σ_{tot} requires both Hall conductivity σ_H and Pedersen conductivity σ_P to be small, and at the same time $\sigma_H \ge \sigma_P$. As shown in Fig. [8](#page-10-0) for $a_{\text{min}} \approx 0.04 \ \mu \text{m}$, the two conductivity components σ_{H} and σ_{P} are roughly equal to each other ($\lesssim 10^{11}$ cm^{−3}). The Hall diffusivity $\eta_{\rm Hall}$
reaches a maximum here because (1) for larger $a \to (\geq 0.04 \ \mu \text{m})$. reaches a maximum here because (1) for larger $a_{\text{min}} \approx 0.04 \,\mu\text{m}$, σ_H starts to decrease below $\sigma_{\rm P}$, and (2) for smaller $a_{\rm min}$ ($\leq 0.04 \,\mu{\rm m}$), $\sigma_{\rm H}$ increases first and followed by the increase of $\sigma_{\rm P}$ ($\leq 0.01 \mu$ m). $\eta_{\rm Hall}$ tends to be reduced either way. The key is that Hall conductivity $\sigma_{\rm H}$ generally increases with decreasing abundance of g−, and Pederson conductivity $\sigma_{\rm P}$ starts to be significantly dominated by VSGs when $a_{\text{min}} \leq 0.02 \ \mu \text{m}$. Note that the trend presented here is essentially

the same as that shown in Appendix A of [Zhao et al.](#page-13-3) [\(2016\)](#page-13-3), except that the main focus was previously ambipolar diffusivity.

At high densities ($\ge 10^{13}$ cm⁻³), the Hall diffusivity is mostly positive and increases monotonically with increasing grain size. More specifically, the overall magnitude of Hall diffusivity at densities $\ge 10^{11}$ cm⁻³ (protostellar disk density) is quite low when $a_{\text{min}} \leq 0.01 \mu \text{m}$; and it increases by a few orders of magnitude when $a_{\text{min}} \geq 0.02 \mu \text{m}$. It is consistent with the behaviors of Pederson and Hall conductivities in this grain size range.

3.3.c Comparison with Other Work

Comparing our result of Hall diffusivity with that of [Dzyurkevich](#page-12-5) [et al.](#page-12-5) [\(2017\)](#page-12-5), we agree on the fact that larger grain sizes (>0.1 μ m) greatly reduces the Hall diffusivity due to the reduction of the abundance of g^- and hence $\sigma_H(g^-)$. However, we do notice a few differences: ences:

(1) The existence of a maximum level of Hall diffusivity (for number densities $\leq 10^{11}$ cm⁻³) when $a_{\text{min}} \approx 0.04$ µm (or $\langle a \rangle \approx 0.063 \mu m$) is not discussed in [Dzyurkevich et al.](#page-12-5) [\(2017\)](#page-12-5).

(2) The sign of Hall diffusivity becoming negative (for number densities $\leq 10^{11}$ cm⁻³) applies to all cases with $a_{\text{min}} \leq 0.1 \mu$ m (or $\leq a \leq 0.14 \mu$ m). In constrast, Davanche et al. (2017) show that $\langle a \rangle \approx 0.14 \mu m$). In constrast, [Dzyurkevich et al.](#page-12-5) [\(2017\)](#page-12-5) show that

Figure 6. Components of conductivity tensor and the contributions from major charged species, for the truncated MRN size distribution with $a_{\text{min}} = 0.1 \,\mu\text{m}$ and $a_{\text{max}} = 0.25 \,\mu\text{m}$, with freeze-out and desorption turned off.

the behavior of Hall diffusivity η_{Hall} (as well as η_{Ohmic} and η_{AD}) in the cases with $\langle a \rangle = 0.05 \ \mu \text{m}$ and $\langle a \rangle = 0.1 \ \mu \text{m}$ are almost identical to each other (their Fig. 2), which is different from what we found using our network: η_{Hall} in their two cases differs by more than 1 order of magnitude; the sign change only occurs in the case with $\langle a \rangle = 0.1 \mu m$ but not for $\langle a \rangle = 0.05 \mu m$.

(3) The statement in [Dzyurkevich et al.](#page-12-5) [\(2017\)](#page-12-5) that Hall effect al-ways dominates ambipolar diffusion for grain sizes below^{[5](#page-8-1)} 0.02 μ m is no longer true when $a_{\text{min}} < 0.004 \ \mu \text{m}$. Recall that (§ [3.3.b;](#page-7-1) see also [Zhao et al.](#page-13-3) [2016\)](#page-13-3) σ_{H} starts to increase when a_{min} drops below 0.04 μ m, yet σ P increases more rapidly when a_{min} <0.02 μ m and becomes larger than σ_H when $a_{\text{min}} < 0.004 \ \mu \text{m}$. Therefore, AD regains the dominance over Hall effect as tiny grains with size comparable to PAHs are included, but neither diffusivities are large enough for efficient magnetic decoupling. For example, Fig. [9](#page-11-1) shows the magnetic diffusivities for a size distribution with $a_{\text{min}} = 10$, where both η_{AD} and η_{Hall} are orders of magnitude smaller than the models with larger a_{min} (Fig[.5\)](#page-7-0).

Besides the Hall diffusivity, the result of Ohmic and ambipolar diffusivity (first two panels of Fig. [5\)](#page-7-0) is essentially the same as in [Zhao et al.](#page-13-3) [\(2016\)](#page-13-3) computed using a more simplified network (see their § 4.2, § 4.4, and Appendix A). The main result remains the same: removal of VSGs (a few to tens of nanometer) significantly enhances the ambipolar diffusivity. Note that we incorporated a barotropic EOS in this work, hence the high temperature in the high density regime ($\geq 10^{11}$ cm⁻³) causes the magnetic diffusivities to

⁵ We obtain a value of a_{min} ∼0.03 μ m (or <*a*>=0.048 μ m) for the similar effect, but the Hall effect only dominate over AD in a limited density range near 10^8 cm^{-3} .

Figure 7. Same as Fig. [6,](#page-8-0) but with freeze-out and desorption turned on.

be higher than the values shown in [Zhao et al.](#page-13-3) [\(2016\)](#page-13-3) that assumes a constant *T* of 10 K. In fact, when the same EOS is used, the results from the two networks almost overlap with each other, which validates the convergence of both chemical networks.

To summarize, the magnetic diffusivities are very sensitive to the grain size distribution. In the low density regime $(<10^{10} \text{ cm}^{-3})$ where the diffusion of magnetic fields matters the most for disk formation and growth, ambipolar diffusivity η_{AD} reaches a maximum level for disk formation when the MRN size distribution is truncated at 0.1 μ m, and Hall diffusivity η_{Hall} reaches a maximum level when the distribution is truncated at 0.04 μ m.^{[6](#page-9-1)} Note that when choosing

 6 The optimal grain size for Hall effect also depends slightly on the cosmicray ionization rate $\zeta_0^{H_2}$, which changes to $a_{\text{min}} \sim 0.03 \mu$ m for $\zeta_0^{H_2} = 5.0 \times 10^{-17} \text{ s}^{-1}$ and $a_{\text{min}} \sim 0.07 \mu$ m for $\zeta_0^{H_2} = 1.0 \times 10^{-18} \text{ s}^{-1}$ (not shown). $a_{\text{min}} = 0.04 \ \mu \text{m}$, the resulting η_{AD} is not far from its maximum level with $a_{\text{min}} = 0.1 \mu \text{m}$. Nevertheless, the presence of VSGs reduces the strength of both ambipolar and Hall diffusivities. Furthermore, the Ohmic dissipation only becomes comparable to the other two effects at very high densities (a few ~10¹² cm⁻³), similar to the conclusions of other work (e.g., [Zhao et al.](#page-13-3) [2016;](#page-13-3) [Marchand et al.](#page-12-4) [2016\)](#page-12-4).

However, the magnitude of η_{AD} roughly scales with $1/\sqrt{\zeta}$ and the optimal grain size of 0.1 μ m stays the same for different $\zeta_0^{H_2}$.

Figure 8. Components of conductivity and the contributions from major charged species, for the truncated MRN size distribution with $a_{\text{min}} = 0.04 \ \mu \text{m}$ and $a_{\text{max}} = 0.25 \,\mu\text{m}$. This size distribution produces the strongest Hall effect (at densities $\leq 10^{11} \text{ cm}^{-3}$). Freeze-out and desorption are turned off.

3.4 Chemical Abundances at High Densities: Tracers for Protostellar Disks

By including the barotropic EOS (Appendix [A\)](#page-12-26), thermal desorption of molecules due to an increased gas temperature is simultaneously modeled with the chemical network, which can be used to analyze the chemical tracers in protostellar disks. As shown in Fig. [1,](#page-4-0) thermal desorption efficiently operates for most species at densities $\geq a$ few 10^{11} cm⁻³, above which neutral-neutral reactions dominate the chemistry. At number densities between $10^{12} - 10^{13}$ cm⁻³, the main gas-phase species are CO , O_2 , N, N_2 , CO_2 , and a small fraction of CH4. As temperature rises even higher (∼200–300 K) at number densities >10¹³ cm⁻³, H₂O start to return to gas-phase via thermal desorption, and most O_2 are turned into CO_2 by reacting with CO. But the abundances of $CO₂$, N and CH₄ continue to decrease towards even higher densities beyond the range considered here,

leaving only CO, H_2O and N_2 as the most abundant species in early protostellar disks (see also, e.g., [Molyarova et al.](#page-12-35) [2017\)](#page-12-35) based on our network. Note that grain surface chemistry is very important for the more complex species (e.g. $CH₃OH$ and other complex organic molecules) which best trace the high density and warm regions surrounding the central protostar, including protostellar disks; we will describe this more detailed chemical work in a future paper.

In comparison, the fractional abundances of ions at high densities are more than ten orders of magnitude lower than the major neutral species. Our result shows that HCO⁺ remains as a good ionic tracer in the bulk part of the protostellar disk, along with H_3O^+ which is hard to observe. N_2H^+ should only trace the outer part of the disk and show as a ring structure. Note that the ionization fraction presented here is regulated by the simple exponential attenuation of cosmic-rays; improving the cosmic-ray attenuation

Figure 9. Magnetic diffusivities computed with freeze-out/desorption for $a_{\text{min}} = 10$ (mimic a population of PAHs).

function or including other sources of ionization (e.g., X-ray, thermal ionization; see [Armitage](#page-12-36) [2011;](#page-12-36) [Bai](#page-12-37) [2011a\)](#page-12-37) should provide a more realistic ionization fraction in different parts of the protostellar disk. We will explore such topics in an upcoming work.

4 DISCUSSION & SUMMARY

The new chemical network presented here is still under development, with a few main ingredients to be implemented, including multiple grain charging (e.g., [Ivlev et al.](#page-12-38) [2016\)](#page-12-38), grain surface chemistry (e.g., [Harada et al.](#page-12-39) [2017\)](#page-12-39). Multiple charging becomes important for large grains at high temperature (e.g., [Draine & Sutin](#page-12-18) [1987\)](#page-12-18), and should be investigated in detail for our modeling of protoplanetary disks next.

We noticed that a parallel work by [Iqbal & Wakelam](#page-12-40) [\(2018\)](#page-12-40) that includes grain surface chemistry also uses a similar formulation of cosmic-ray desorption rate. However, they assume a constant evaporative cooling timescale of 10^{-5} s for all grain sizes, which leads to a significant over-estimation of the impact of small grains on the gas-phase abundances (cosmic-ray desorption rate increased by many orders of magnitude for all species). In fact, the chemical abundances computed using the conventional pre-factor $f(70 \text{ K})$ is already quite high compared to observations (see Fig. 9 of [Shen et](#page-13-9) [al.](#page-13-9) [2004\)](#page-13-9). As stated by [Hasegawa & Herbst](#page-12-20) [\(1993\)](#page-12-20), the evaporative cooling timescale is inversely proportional to k_{des} , and the value of 10^{-5} s is only suitable for 0.1 μ m with 70 K. For grains with enough surface sites (>0.03 μ m) this timescale can be properly enough surface sites ($>0.03 \mu$ m), this timescale can be properly calculated using different T_e for the given grain size *a* (see § [2.1\)](#page-1-3). Within the size range $[0.03, 0.25]$ μ m, slightly small grains can be cooled down by tens of K from the peak temperature (T_e) by evaporating only \sim 10⁵ CO molecules, while the temperature of larger grains is difficult to reduce, with the reduction of a few K requiring the evaporation of a few 10^6 CO molecules (values obtained by integrating Eq. [12\)](#page-2-3). Therefore, larger grains stay at their elevated temperatures for a much longer time, allowing a sufficient desorption of volatile species from their surfaces. In comparison, the peak temperature of small grains is so high that the majority of CO and other volatiles evaporate almost instantly, the small grain then cools down via sublimation of H_2O while desorpting other non-volatile

species. Nonetheless, the evaporation timescale of volatile species on small grains should be rather rapid.

Furthermore, according to the formulation by [\(Hasegawa &](#page-12-20) [Herbst](#page-12-20) [1993\)](#page-12-20), the rate of cosmic-ray desorption should have a weak dependence on T_e for a given species, since both the duty cycle $f(T_e(a))$ and the desorption rate $k_{des}(i, T_e(a))$ in Eq. [11](#page-2-1) have similar exponential dependence on T_e . Adopting a constant evaporating cooling time of 10^{-5} s for 70 K alone but much higher $T_e(a)$ K in $k_{\text{des}}(i, T_{e}(a))$ is responsible for the large effect of cosmic-ray desorption on the chemical abundances shown in [Iqbal & Wakelam](#page-12-40) [\(2018\)](#page-12-40). Nevertheless, our new formulation of cosmic-ray desorption is still based on [Hasegawa & Herbst](#page-12-20) [\(1993\)](#page-12-20) and [Acharyya et al.](#page-12-23) [\(2011\)](#page-12-23), which is a crude approximation to the stochastic process of impinging cosmic-ray particles on grain surfaces.

Despite the simplified chemical model we adopted here, we are able to extract a few novel effects of the grain size distribution on the desorption of volatile species and on the non-ideal MHD diffusivity, along with the key factors operating behind these effects:

(1) The rate of direct desorption of volatile species by cosmicray from grains with different sizes can vary by many orders of magnitude over the range of grain size in the standard MRN size distribution, due to the large difference in the elevated temperature of grains of different sizes, instead of a constant 70 K [\(Hasegawa &](#page-12-20) [Herbst](#page-12-20) [1993\)](#page-12-20).

(2) The desorption of volatile species by cosmic-ray is very sensitive to the presence of grains larger than $0.1 \mu m$, because they are heated by cosmic-ray to a lower temperature (∼40 K) and the difference in desorption rates among volatile species due to the slight difference in binding energies is amplified. The resulting chemical abundances show an increased amount of nitrogen bearing species in the gas-phase. Particularly, atomic nitrogen N is about two orders of magnitude more abundant than CO, while gas-phase N_2 is a few times more than CO. Accordingly, N_2H^+ becomes a more abundant tracer than HCO⁺ in dense cores, which provides a natural way to explain the well known difference between the distribution of CO and N_2 related molecules (such as N_2H^+) in dense cores (e.g., [Caselli et al.](#page-12-41) [2002a,](#page-12-41)[b\)](#page-12-25).

(3) Small grains (\leq few 100) dominate the cosmic-ray desorption rate of non-volatile species such OH and $H₂O$. However, for such species, direct cosmic-ray desorption is much less efficient than the desorption by cosmic-ray induced UV photons.

(4) Freeze-out of molecules changes the dominant ion in dense cores from the commonly assumed $HCO⁺$ to $H₃⁺$, yet the relative abundance between H_3^+ and HCO^+ (N₂H⁺) at given densities also changes with grain size. The relation of ion densities, if observed, may provide a potential way to constrain the grain size in dense cores. Besides, the change in the dominant ion species in the gasphase has very limited effect on the magnetic diffusivities.

(5) The magnetic diffusivities are highly dependent on the grain size distribution. We confirm the role of VSGs in weakening the efficiency of both ambipolar diffusion [\(Padovani et al.](#page-13-15) [2014;](#page-13-15) [Zhao](#page-13-3) [et al.](#page-13-3) [2016\)](#page-13-3) and Hall effect with or without freeze-out and desorption. At densities below $\sim 10^{10}$ cm⁻³, the maximum ambipolar diffusion is achieved when using a truncated MRN size distribution with $a_{\text{min}} \sim 0.1 \mu \text{m}$; and to reach a maximum Hall effect, $a_{\text{min}} \sim 0.04 \ \mu \text{m}$ is optimal.

Our chemical network can be either tabulated to provide the magnetic diffusivities for non-ideal MHD simulations or used to post-process the simulation results of dense cores and protostellar disks. Although much work remains to be done, our results have shown that grain evolution in dense molecular clouds has a profound influence on both the chemical and dynamical evolution of the system, which deserves more self-consistent study in the future.

ACKNOWLEDGEMENTS

We thank Wing-Fai Thi, Seyit Höcük, and Olli Sipilä for inspiring discussions. BZ and PC acknowledge support from the European Research Council (ERC; project PALs 320620). Z.-Y. L. is supported in part by NASA NNX14AB38G and NSF AST-1716259.

APPENDIX A: EQUATION OF STATE

We use a broken power law profile for the equation of state (EOS), fitted to mimic the radiative transfer results of [Tomida et al.](#page-13-7) [\(2013\)](#page-13-7):

$$
T = \begin{cases} T_0 + 1.5 \frac{\rho}{10^{-13}} & \text{for } \rho < 10^{-12} \\ (T_0 + 15)(\frac{\rho}{10^{-12}})^{0.6} & \text{for } 10^{-12} \le \rho \le 10^{-11} \\ 10^{0.6} (T_0 + 15)(\frac{\rho}{10^{-11}})^{0.44} & \text{for } 10^{-11} \le \rho \le 3 \times 10^{-9} \end{cases}
$$
(A1)

where $T_0 = 10$ K. The comparison for different EOS is shown in Fig. [A1.](#page-13-16) The same EOS is adopted in the study of disk formation by [Zhao et al.](#page-13-17) [\(2018\)](#page-13-17).

APPENDIX B: MAGNETIC DIFFUSIVITY AND CONDUCTIVITY

The three non-ideal MHD coefficients can be expressed in terms of the components of the conductivity tensor σ (e.g., [Wardle](#page-13-18) [2007\)](#page-13-18):

$$
\eta_{AD} = \frac{c^2}{4\pi} \left(\frac{\sigma_P}{\sigma_P^2 + \sigma_H^2} - \frac{1}{\sigma_{\parallel}} \right),
$$
 (B1)

$$
\eta_{\text{Ohm}} = \frac{c^2}{4\pi\sigma_{\parallel}}, \tag{B2}
$$

$$
\eta_{\text{Hall}} = \frac{c^2}{4\pi} \left(\frac{\sigma_{\text{H}}}{\sigma_{\text{P}}^2 + \sigma_{\text{H}}^2} \right); \tag{B3}
$$

where the parallel σ_{\parallel} , Pedersen $\sigma_{\rm P}$, and Hall $\sigma_{\rm H}$ conductivities are related to the Hall parameter $\beta_{\rm CUT}$ as: related to the Hall parameter β_{i, H_2} as:

$$
\sigma_{\parallel} = \frac{ecn(\mathrm{H}_2)}{B} \sum_{i} Z_i x_i \beta_{i, \mathrm{H}_2}, \qquad (B4)
$$

$$
\sigma_{\rm P} = \frac{ecn(\rm H_2)}{B} \sum_{i} \frac{Z_i x_i \beta_{i, \rm H_2}}{1 + \beta_{i, \rm H_2}^2}, \tag{B5}
$$

$$
\sigma_{\rm H} = \frac{ecn(\rm H_2)}{B} \sum_{i} \frac{Z_i x_i}{1 + \beta_{i,H_2}^2};
$$
 (B6)

where x_i is the abundance of charged species i with respect to H_2 molecules. The Hall parameter β_{i,H_2} is the key quantity that determines the relative importance of the Lorentz and drag forces determines the relative importance of the Lorentz and drag forces for each charged species i in a sea of neutral H_2 molecules. It is defined as:

$$
\beta_{i, \text{H}_2} = \left(\frac{Z_i e B}{m_i c}\right) \frac{m_i + m_{\text{H}_2}}{\mu m_{\text{H}} n(\text{H}_2) < \sigma v >_{i, \text{H}_2}},\tag{B7}
$$

where m_i and $Z_i e$ are the mass and the charge of charged species i, respectively, and $\langle \sigma v \rangle$; H_2 is the momentum transfer rate coef-
ficient, parametrized as a function of temperature (Pinto & Galli ficient, parametrized as a function of temperature [\(Pinto & Galli](#page-13-19) [2008\)](#page-13-19), which quantifies the collisional coupling between neutral $(H₂)$ and charged *(i)* species.

APPENDIX C: CHEMICAL ABUNDANCES FOR $a_{\text{min}} = 0.04 \ \mu \text{m} \ \text{CASE}$

Fig.[C1](#page-14-0) shows the fractional abundances computed using a truncated MRN size distribution with $a_{\text{min}} = 0.04 \ \mu \text{m}$, which is used for the discussion in § [3.2.](#page-5-1)
