Abstract

In this letter, we consider the multiple-input multiple-output (MIMO) radar waveform design in the presence of signal-dependent clutters and additive white Gaussian noise. By imposing the constant modulus constraint (CMC) and waveform similarity constraint (SC), the signal-to-interference-plus-noise (SINR) maximization problem is non-convex and NP-hard in general, which can be transformed into a sequence of convex quadratically constrained quadratic programming (QCQP) subproblems. Aiming at solving each subproblem efficiently, we propose a low-complexity method termed Accelerated Gradient Projection (AGP). In contrast to the conventional IPM based method, our proposed algorithm achieves the same performance in terms of the receive SINR and the beampattern, while notably reduces computational complexity.

Keywords: MIMO radar, Waveform design, Constant modulus constraint (CMC), Similarity constraint (SC), Signal-to-interference-plus-noise (SINR), Quadratically constrained quadratic programming (QCQP)

1. Introduction

MIMO radar has been intensively studied as a new paradigm of the radar system [1, 2, 3, 4]. By allowing individual waveforms to be transmitted at each antenna, MIMO radar is able to exploit extra degrees of freedom in contrast to its phased-array counterpart, and therefore achieves a more favorable performance. In the existing literature [5, 6, 7, 8], radar waveform optimization can be classified into two categories: waveform design by only considering the radar transmitter [5, 6] and waveform design by jointly considering radar transmitter and receive filter [7, 8], where we focus on the second category.

Pioneered by the exploration of [9], the transmit waveform is designed by maximizing the receive SINR in the presence of the signal-dependent clutters and the Gaussian noise. In practice, for the use of non-linear power amplifiers in the numerous radar systems, the CMC is typically involved, which is important to the SINR performance of the radar [9]. In addition, the SC enables a flexible tradeoff between the output SINR and the desired autocorrelation properties by controlling the similarity between the reference waveform and its optimized counterpart. However, the waveform design with both CMC and SC leads to the non-convexity and the NP-hardness of the problem. To overcome such a challenge, the previous works [10, 11] either omit or relax these constraints in favour of the existing solvers, which result in suboptimal solutions and high computational costs.

Inspired by the recent research [11], where the non-convex waveform design problem is relaxed to a sequence of convex QCQP subproblems, we develop in this letter a different iterative relaxing scheme to produce the sequential QCQP subproblems and a novel AGP algorithm to solve each subproblem. Furthermore, the proposed AGP involves two parts: the fast iterative shrinkagethresholding algorithm (FISTA) procedure and the customized projection procedure, where the former is based on the convex optimization theory and the latter is highly dependent on the specific feasible region formulated by the CMC and SC. In contrast to the conventional IPM that is employed in [11], our proposed algorithm obtains a comparable performance in terms of the receive SINR as well as the beampattern. In addition, the AGP shares a much lower computational complexity, and directly solves the complex convex QCQP subproblems without converting them into the real representations [11].

2. System Model

We consider a colocated narrow band MIMO radar system with N_T transmit antennas and N_R receive antennas. We suppose that $\mathbf{t} = [\mathbf{t}_1^T, ..., \mathbf{t}_N^T]^T \in \mathbb{C}^{N_T N \times 1}$ is the vectorized transmit wavform, where $(\cdot)^T$ denotes the transpose, N is the number of samples, and $\mathbf{t}_n \in \mathbb{C}^{N_T \times 1}$, n = 1, ..., N, stands for the *n*-th sample across the N_T antennas. Then the receive waveform $\mathbf{r} \in \mathbb{C}^{N_R N \times 1}$ is given by [8]

$$\mathbf{r} = \alpha_0 \mathbf{M}(\phi_0) \mathbf{t} + \sum_{m=1}^M \alpha_m \mathbf{M}(\phi_m) \mathbf{t} + \mathbf{n}$$
(1)

where $\mathbf{n} \in \mathbb{C}^{N_R N \times 1}$ stands for the circular complex white Gaussian noise with zero mean and covariance matrix $\sigma_n^2 \mathbf{I}$, α_0 and α_m represent the complex amplitudes of the target and the *m*-th interference source, ϕ_0 and ϕ_m are the angle of the target and the angle of the *m*-th interference source, respectively, $\mathbf{M}(\phi)$ denotes the steering matrix of a Uniform Linear Array (ULA) with half-wavelength separation between the antennas, which is given by

$$\mathbf{M}(\phi) = \mathbf{I}_N \otimes [\mathbf{a}_r(\phi)\mathbf{a}_t(\phi)^T]$$
(2)

where \mathbf{I}_N is the $N \times N$ identity matrix, \otimes denotes the Kronecker product, \mathbf{a}_t and \mathbf{a}_r are the transmit and the receive steering vectors, respectively.

As mentioned above, aiming for maximizing the output SINR, we propose to jointly optimize the transmit waveform and the receive filter. Without loss of generality, we employ a linear Finite Impulse Response (FIR) filter $\mathbf{f} \in \mathbb{C}^{N_R N \times 1}$ to process the received echo wave. This is given as

$$r = \mathbf{f}^H \mathbf{r} = \alpha_0 \mathbf{f}^H \mathbf{M}(\phi_0) \mathbf{t} + \sum_{m=1}^M \alpha_m \mathbf{f}^H \mathbf{M}(\phi_m) \mathbf{t} + \mathbf{f}^H \mathbf{n}$$
(3)

where $(\cdot)^H$ denotes the Hermitian transpose. As a result, the output SINR can be expressed as

$$SINR = \frac{\sigma \left| \mathbf{f}^H \mathbf{M}(\phi_0) \mathbf{t} \right|^2}{\mathbf{f}^H \tilde{\mathbf{S}}(t) \mathbf{f} + \mathbf{f}^H \mathbf{f}}$$
(4)

where $\sigma = E[|\alpha_0|^2]/\sigma_n^2$, with $E[\cdot]$ being the statistical expectation, and

$$\tilde{\mathbf{S}}(t) = \sum_{m=1}^{M} I_m \mathbf{M}(\phi_m) \mathbf{t} \mathbf{t}^H \mathbf{M}^H(\phi_m)$$
(5)

where $I_m = E[|\alpha_m|^2]/\sigma_n^2$.

3. Problem Formulation

Following the approach in [11], we incorporate the CMC and SC in the maximization of the output SINR, resulting in an optimization problem as follows

$$\max_{\mathbf{f},\mathbf{f}} \quad \frac{\sigma \left| \mathbf{f}^{H} \mathbf{M}(\phi_{0}) \mathbf{f} \right|^{2}}{\mathbf{f}^{H} \tilde{\mathbf{S}}(t) \mathbf{f} + \mathbf{f}^{H} \mathbf{f}}$$

$$s.t. \quad |t(k)| = 1/\sqrt{N_{T} N}$$

$$\|\mathbf{t} - \mathbf{t}_{0}\|_{\infty} \leq \varepsilon$$
(6)

0

where t(k) is the k-th entry of $\mathbf{t}, k = 1, ..., N_T N, \|\cdot\|_{\infty}$ denotes the infinity norm, and \mathbf{t}_0 represents the reference waveform. By taking into account the CMC, the SC can be rewritten as

$$\arg t(k) \in [\omega_k, \omega_k + \delta] \tag{7}$$

where ω_k and δ are respectively given by

$$\omega_k = \arg t_0(k) - \arccos(1 - \varepsilon^2/2)$$

$$\delta = 2\arccos(1 - \varepsilon^2/2)$$
(8)

where $t_0(k)$ is the k-th entry of \mathbf{t}_0 , and the prespecified parameter ε ($0 \le \varepsilon \le 2$) stands for the similarity between \mathbf{t} and \mathbf{t}_0 . In addition, noting that \mathbf{f} is

unconstrained [8], the optimization of (6) is equivalent to

$$\max_{\mathbf{t}} \quad \mathbf{t}^{H} \boldsymbol{\Psi}(\mathbf{t}) \mathbf{t}$$

s.t. $|t(k)| = 1/\sqrt{N_T N}$
 $\arg t(k) \in [\omega_k, \omega_k + \delta]$ (9)

where $\Psi(\mathbf{t})$ is a positive-semidefinite matrix in terms of the output SINR and is given by

$$\Psi(\mathbf{t}) = \mathbf{M}^{H}(\phi_0) [\tilde{\mathbf{S}}(t) + \mathbf{I}]^{-1} \mathbf{M}(\phi_0).$$
(10)

According to the previous study [9], it is possible to obtain a suboptimal SINR by assuming $\Psi = \Psi(\mathbf{t})$ with a fixed \mathbf{t} and optimizing \mathbf{t} with the new Ψ iteratively. However, even for a fixed Ψ , the optimization of \mathbf{t} is still non-convex and NPhard due to the equality constraints involved. In the next section, by referring to the method of Successive QCQP Refinement—Binary Search (SQR-BS) [11], we introduce a low-complexity algorithm to solve (9).

4. Proposed Algorithm

As analyzed above, we denote $\mathbf{P} = (\Psi - \lambda \mathbf{I})$, where \mathbf{I} is a identity matrix, $\lambda \geq \lambda_{\max}(\Psi)$ and $\lambda_{\max}(\Psi)$ is the maximum eigenvalue of Ψ , which guarantees that \mathbf{P} is negative-semidefinite. Hence, the optimization problem of (9) is equivalent to the following non-convex problem

$$\max_{\mathbf{t}} \quad \mathbf{t}^{H} \mathbf{P} \mathbf{t}$$

$$s.t. \quad |t(k)| = 1/\sqrt{N_T N} \qquad (11)$$

$$\arg t(k) \in [\omega_k, \omega_k + \delta].$$

It is easy to see that the feasible region for each entry of **t** can be viewed as a circular arc from A to B as shown in Figure 1. For notational convenience, we denote $x_k = \text{Re}(t(k)), y_k = \text{Im}(t(k))$. The optimization problem of (11) can be relaxed as the following convex QCQP problem

$$\max_{\mathbf{t}} \quad \mathbf{t}^{H} \mathbf{P} \mathbf{t}$$

$$s.t. \quad |t(k)| \le 1/\sqrt{N_{T}N}$$

$$c_{x}x_{k} + c_{y}y_{k} \ge c_{x}^{2} + c_{y}^{2}$$
(12)

where

$$c_x = \frac{\cos(\omega_k) + \cos(\omega_k + \delta)}{2}$$

$$c_y = \frac{\sin(\omega_k) + \sin(\omega_k + \delta)}{2}$$
(13)

represent the abscissa and the ordinate of the point C, respectively, as shown in Figure 1. The feasible region of each t(k) is labeled by zone I, which is the convex hull composed by the circular arc and the line segment.

Figure 1: Feasible region for each dimension.

Noting that the relaxation becomes closer to (11) as the value of δ becomes smaller, the author of [11] reduces δ by half and equally divides the feasible region into two parts. By iteratively selecting the part in which the optimized **t** locates and fixing **P** with a given **t** as analyzed in the last section, the sequential convex QCQP subproblems in the form of (12) are obtained. The number of times of dividing is given in advance, and each dividing is called one refinement where the result is iteratively calculated via the conventional IPM, which we refer readers to [11] for more details.

For clarity, here we note the following two remarks:

- (1) Remark 1: Compared with the SQR-BS algorithm in [11], we do not fix the number of the refinements which is equal to iterations, and reduce δ until it is sufficiently small.
- (2) Remark 2: It is worth highlighting that the feasible region in (12) is convex, which enables a closed-form projector to be used in the gradient projection method. We hereby propose the AGP approach that involves of two steps: the FISTA procedure and the projection procedure. In the first step, we compute the gradient of the objective function, and obtain the descent direction by the FISTA method. Then we project the obtained point onto the feasible region by a specifically tailored orthogonal projector.

In what follows, we discuss the details of the AGP algorithm.

4.1. FISTA Procedure

The FISTA procedure accelerates the iterative shrinkage-thresholding algorithm (ISTA) by introducing a smart interpolation factor, which leads to a faster convergence rate compared to that of the ISTA method [12]. Both algorithms are computational-efficient for unconstrained convex optimization problems.

Firstly, we denote $\mathbf{y}(\mathbf{t}) = \mathbf{t}^H \mathbf{P} \mathbf{t}$, and then the gradient of the objective function in (12) can be caculated as

$$\mathbf{g}(\mathbf{t}) = \nabla_{\mathbf{t}} \mathbf{y}(\mathbf{t}) = (\mathbf{P} + \mathbf{P}^H)\mathbf{t} = 2\mathbf{P}\mathbf{t}$$
(14)

since \mathbf{P} is a Hermitian matrix. Secondly, we derive the Hessian matrix as

$$\mathbf{H} = \frac{\partial^2 \mathbf{y}(\mathbf{t})}{\partial \mathbf{t} \partial \mathbf{t}^H} = \mathbf{P} + \mathbf{P}^H = 2\mathbf{P}.$$
 (15)

Thirdly, we set the stepsize $\tau = 1/\lambda_{\max}(\mathbf{H})$, where $\lambda_{\max}(\mathbf{H})$ is the maximum eigenvalue of \mathbf{H} , namely the Lipschitz constant of the objective function. As a result, the iterative procedure can be simply described as

$$\mathbf{v}^{(n)} = \mathbf{t}^{(n)} + c_k(\mathbf{t}^{(n)} - \mathbf{t}^{(n-1)})$$

$$\mathbf{t}^{(n+1)} = \mathbf{v}^{(n)} - \tau \cdot 2\mathbf{P}\mathbf{v}^{(n)}$$
 (16)

where $c_k = (k-1)/(k+2)$ is the interpolation factor, and **v** is the transitive vector.

4.2. Projection Procedure

As discussed above, we assume that the optimization is unconstrained, i.e., the feasible region is the whole complex plane for each t(k). Inspired by [13], we design a projection procedure that projects each t(k) onto the zone I as shown in Figure 2. In what follows, we derive the projector under the two possible cases, i.e., the angle δ corresponding to the zone I is less or greater than π .

Figure 2: Projection procedure for each dimension. (a) $\delta \leq \pi$; (b) $\delta \geq \pi$.

When $\delta \leq \pi$, as shown in Figure 2 (a), the real and the imaginary axes are labeled by x_k and y_k , respectively. The two extreme points of zone I are marked with $A(a_x, a_y)$ and $B(b_x, b_y)$, respectively, given by

$$a_x = \cos(\omega_k), b_y = \sin(\omega_k)$$

$$b_x = \cos(\omega_k + \delta), a_y = \sin(\omega_k + \delta)$$
(17)

and $C(c_x, c_y)$ denotes the midpoint of line segment AB as defined in (13). Then we draw two radial lines l_A and l_B which are both vertical to AB and start at A and B, respectively, and furthermore, by adding the radial lines OA and OB, the whole complex plane \mathbb{C} is divided into 5 zones, i.e., I, II, III(A), III(B), IV. Given any $Q(x_k, y_k) \in \mathbb{C}$, we can obtain the nearest point $R(x_k^*, y_k^*) \in I$ via the projection procedure. If $Q \in I$, the projection is itself; if $Q \in II$, R is the foot of the perpendicular with AB through Q; if $Q \in III(A)$ or $Q \in III(B)$, the nearest point is A or B, respectively; if $Q \in IV$, R is the normalization of Q. To sum up, the projection can be formulated as

$$R = \begin{cases} Q, \ c_x x_k + c_y y_k \ge c_x^2 + c_y^2, |OQ| \le 1, \\ F, \ c_x x_k + c_y y_k \le c_x^2 + c_y^2, \\ k_l x_k + d_B \le y_k \le k_l x_k + d_A, \\ A, \ a_y x_k - a_x y_k \le 0, y_k \ge k_l x_k + d_A, \\ B, \ b_y x_k - b_x y_k \ge 0, y_k \le k_l x_k + d_B, \\ Q/|OQ|, \ others \end{cases}$$
(18)

where $k_l = (a_y + b_y)/(a_x + b_x)$ represents the slope of l_A and l_B , $d_A = a_y - a_x k_l$ and $d_B = b_y - b_x k_l$ represent the intercepts of l_A and l_B , respectively, and $F(x_f, y_f)$ is the foot of the perpendicular on AB, which can be expressed as

$$x_{f} = \frac{c_{x}^{2} + c_{y}^{2} - c_{y}(y_{k} - k_{l}x_{k})}{c_{x} + k_{l}c_{y}}$$

$$y_{f} = \frac{c_{x}^{2} + c_{y}^{2} - c_{x}x_{f}}{c_{y}}.$$
(19)

Particularly, if $c_x = 0$, $F = (x_k, c_y)$; if $c_y = 0$, $F = (c_x, y_k)$.

When $\delta \geq \pi$, as shown in Figure 2 (b), following the similar procedure of (18), the projection can be derived as

$$R = \begin{cases} Q, \ c_x x_k + c_y y_k \le c_x^2 + c_y^2, |OQ| \le 1, \\ F, \ c_x x_k + c_y y_k \ge c_x^2 + c_y^2, \\ k_l x_k + d_B \le y_k \le k_l x_k + d_A, \\ A, \ a_y x_k - a_x y_k \le 0, y_k \ge k_l x_k + d_A, \\ B, \ b_y x_k - b_x y_k \ge 0, y_k \le k_l x_k + d_B, \\ Q/|OQ|, \ others. \end{cases}$$
(20)

where the only differences comparing with (18) are the signs of inequalities when $Q \in I$ where $Q \in II$, and $F(x_f, y_f)$ can be also calculated by (19). For clarity, we summarize the proposed approach for solving the QCQP subproblems in Algorithm 1.

Remark 3: The complexity of the AGP mainly comes from the computation of the FISTA in (16) with $3N_T^2N^2 + 3N_TN$ complex flops and the tailored projection with $42N_TN$ complex flops, leading to a total computational complexity of $\mathcal{O}(N_T^2N^2)$ for each iteration. For converging to a suboptimal solution, the iteration number needed for the proposed algorithm is $\mathcal{O}(\log(1/\zeta))$ where ζ is

Algorithm 1 Accelerated Gradient Projection (AGP)

Require: P, \mathbf{t}_0 , ζ (the desired threshold value), Num (the maximum number of iterations), δ and ω_k , $k = 1, ..., N_T N$. Compute $\mathbf{g}(\mathbf{t})$, t, Set n = 1, $\mathbf{t}^{(1)} = \mathbf{t}^{(0)} = \mathbf{t}_0$, Compute $\mathbf{t}^{(2)}$ and it's projection $\mathbf{t}^{(2)*}$, Set n = n + 1, while $\mathbf{t}^{(n)*} - \mathbf{t}^{(n-1)*} > \zeta$ and n < Num doCompute $\mathbf{t}^{(n+1)}$ by (16), for $k = 1, ..., N_T N$ do Project $t^{(n+1)}(k)$ to $t^{(n+1)*}(k)$ with the given δ , ω_k , $k = 1, ..., N_T N$ to get the projection $\mathbf{t}^{(n+1)*}$ end for Set n = n + 1. end while Ensure: $\mathbf{t}^* = 1/\sqrt{N_T N} \exp(j \arg(\mathbf{t}^{(n)*}))$ for problem (11).

the desired threshold value. On the other hand, the computational costs for the IPM is $\mathcal{O}(N_T^{3.5}N^{3.5})$ [14] and the number of iterations is $\mathcal{O}(\log(1/\zeta))$ as well [15].

5. Numerical Results

In this section, we provide numerical results to evaluate the performance in terms of the SINR and the beampattern $P(\phi)$ between the AGP and the IPM, and use chirp waveform as our benchmark. The reference waveform $\mathbf{t}_0 \in \mathbb{C}^{N_T N \times 1}$ can be obtained by stacking the columns of \mathbf{T}_0 , which is the orthogonal chirp waveform matrix defined as

$$T_0(k,n) = \frac{\exp[j2\pi k(n-1)/N] \exp[j\pi (n-1)^2/N]}{\sqrt{N_T N}}$$
(21)

where $k = 1, ..., N_T$, n = 1, ..., N. We assume the number of samples N = 16, and the number of transmit and the receive antennas $N_T = 4$, $N_R = 8$ respectively. In addition, we consider a scenario with three fixed signal-dependent clutters and additive white Gaussian disturbance with variance $\sigma_n = 0$ dB. The power of the target echo and the three interfering sources are $|\alpha_0|^2 = 10$ dB, $|\alpha_1|^2 = |\alpha_2|^2 = |\alpha_3|^2 = 30$ dB, respectively, and the angle of the target and the three interferences are $\phi_0 = 15^\circ$, $\phi_1 = -50^\circ$, $\phi_2 = -10^\circ$, $\phi_3 = 40^\circ$, respectively.

We first show the performance obtained by the two approaches in Figure 3 in terms of the SINR and the beampattern. When $\varepsilon = 0.4$, Figure 3 (a) shows very close SINR results of the both approaches, while the beampattern resulting form the IPM exhibits better suppression performance. As the similarity loose, the beampattern of the AGP outperform the IPM when $\varepsilon = 1.2$ as shown in Figure 3 (b), and the difference of the SINR is less than 0.25dB.

Figure 3: The SINR in each iteration and the beampattern $P(\phi)$ of the optimal waveform for the AGP and the IPM approaches: (a) $\varepsilon = 0.4$; (b) $\varepsilon = 1.2$.

Figure 4: (a) The SINR with increasing transmit antennas. (b) The CPU time with increasing transmit antennas.

We further compare the SINR and the execution time of increasing transmit antennas for both approaches in Figure 4, where all the parameters remain the same with that of Figure 3 but $\varepsilon = 0.5$. Figure 4 (a) indicates the AGP obtain the notably superior performance than IPM as N_T increases. In addition, the simulation is performed on an Intel Core i5-6200U CPU @ 2.3GHz 12GB RAM computer. As shown in Figure 4 (b), the average CPU time of the AGP is remarkably shorter than the IPM for solving the optimization problem of (11).

6. Conclusion

A low-complexity gradient projection approach has been proposed for solving the MIMO radar waveform design problem with CMC and SC constraints. By relaxing the feasible region, the key projection procedure is elaborately devised on the basis of the FISTA method. Numerical results reveal that the proposed AGP algorithm possesses a superior performance in terms of the SINR and the beampattern compared with the conventional IPM, with a much lower complexity.
