Abstract

The accuracy and efficiency of a density functional is dependent on the basic ingredients it uses, and how the ingredients are built into the functional as a whole. An iso-orbital indicator based on the electron density, its gradients, and the kinetic energy density, has proven an essential dimensionless variable that allows density functionals to recognise and correctly treat various types of chemical bonding, both strong and weak. Density functionals constructed around the iso-orbital indicator usually require dense real-space grids for numerical implementation that deteriorate computational efficiency, with poor grid convergence compromising the improved accuracy. Here, a novel iso-orbital indicator is proposed based on the same ingredients that retains the capability to identify the same chemical bonds while significantly relieving the requirement of dense grids. Furthermore, the novel iso-orbital indicator gives an improved recognition for tail regions of electron densities and is constraint-free for the exchangecorrelation potential. The novel iso-orbital indicator is therefore expected to be the prime choice for further density functional development.

Introduction

Density functional theory (DFT) is, in principle, exact for the ground state energy and electron density of a system of electrons under a scalar external potential, conventionally solved through a set of Kohn–Sham (KS) auxiliary single-particle Schrödinger-like equations.^{1,2} In practice however, the exchange-correlation energy, an essential but usually small portion of the total energy, must be approximated as a functional of the electron density. The computational efficiency of this scheme and the accuracy of modern exchange-correlation approximations has resulted in DFT becoming one of the most widely used electronic structure theories and arguably the only practical method for high-throughput discovery of novel materials currently available.

Exchange-correlation approximations can be broadly categorised by the ingredients used into 5 levels of increasing non-locality.³ The accuracy of an approximation usually increases when more ingredients are included through increased flexibility though this enhancement is often accompanied by a deterioration of efficiency, especially when non-local information is included. It is therefore critical to understand the ingredients of common density functional approximations and how they can be utilised to increase the accuracy of a functional whilst maximising the possible computational efficiency. As functionals of higher levels are usually developed based on functionals of lower levels, knowledge obtained for the ingredients and their combinations in lower-level functionals can be transferred to the development of more complex functionals at higher levels.

The lowest three levels of efficient semi-local functionals include the local spin density approximation (LSDA),^{2,4–8} the generalised gradient approximation (GGA),^{4,9–16} and meta-GGA.^{17–30} LSDA uses only the electron density and recovers the uniform electron gas (UEG) limit. GGAs add the electron density gradient from which two standard dimensionless variables are constructed; $s = |\nabla n|/(2k_{\rm F}n)$ with $k_{\rm F} = (3\pi^2 n)^{1/3}$ relevant for exchange, and $t_c = |\nabla n|/(2k_s n)$ with $k_s = \sqrt{4k_F/\pi}$ for correlation³¹ measure the inhomogeneity of electron densities at the length scales of local Fermi wavelength $2\pi/k_{\rm F}$ and Thomas screening length $1/k_s$, respectively. Commonly used meta-GGAs include one more ingredient, the kinetic energy density $\tau(\mathbf{r}) = 1/2 \sum_{i}^{\text{occ.}} |\nabla \varphi_i(\mathbf{r})|^2$ where $\{\varphi_i\}$ are KS orbitals.

The inclusion of τ in meta-GGAs naturally arises from the Taylor expansion of the exact spherically averaged exchange hole³² and provides a simple and straightforward way to make a correlation functional exactly one-electron self-interaction free.¹⁹ The flexibility due to the inclusion of τ improves the accuracy of meta-GGAs over GGAs, by either better fitting to experimental data empirically^{18,23,29,33} or satisfying more exact constraints and appropriate norms non-empirically.^{21,24,27,30,34} Early attempts^{21,24} and the recent Tao-Mo functional³⁴ construct non-empirical meta-GGAs through an iso-orbital indicator defined as,

$$z = \frac{\tau^{\rm vW}}{\tau},\tag{1}$$

where $\tau^{vW}(\mathbf{r}) = |\nabla n(\mathbf{r})|^2 / 8n(\mathbf{r})$ is the von-Weiszäcker kinetic energy density that recovers τ in the single orbital limit. Whilst z can identify single orbital densities, z = 0, and slowly varying densities, $z \approx 1$, it is unable to distinguish slowly varying densities from the non-covalent closed shell overlap densities important in intermediate-range van-der-Waals bonding.³⁵ A different indicator widely used in empirical constructions^{23,25,29} is,

$$t^{-1} = \frac{\tau}{\tau^{\text{UEG}}},\tag{2}$$

where $\tau^{\text{UEG}} = (3/10)(3\pi^2)^{2/3}n^{5/3}$ is the kinetic energy density of uniform electron gas. Whilst the t^{-1} indicator has been shown to differentiate covalent from non-covalent bonding it cannot uniquely identify single-orbital regions for which $t^{-1} = 5s^{2/3}$. This is likely one of the major reasons for overfitting in the M06L meta-GGA and the resulting numerical stability problem.³⁵ t^{-1} is semi-infinite, $[0, \infty]$, and usually mapped to a finite domain via $w = (1 - t^{-1})/(1 + t^{-1}) = (\tau^{\text{UEG}} - \tau)/(\tau^{\text{UEG}} + \tau)$. A further iso-orbital indicator has been constructed,

$$\alpha = \frac{\tau - \tau^{\rm vW}}{\tau^{\rm UEG}},\tag{3}$$

which is able to uniquely identify single orbital, slowly varying and non-covalent overlap densities as $\alpha = 0$, ≈ 1 and $\gg 1$ respectively. This indicator was included alongside z in earlier meta-GGA functionals^{21,24} to enforce the correct fourth-order gradient expansion,³⁶ though its importance for characterising bonding densities was not fully recognised until later.³⁵ The α variable is directly related to the electron localization function (ELF) of Refs.^{37,38} as $f_{\rm ELF} = 1/(1 + \alpha^2)$ which has been used to give a rigorous topological classification of chemical bonding.³⁹⁻⁴¹ In addition, recent α dependent functionals³⁰ have been found to effectively handle properties that have traditionally been challenging for semi-local functionals,⁴²⁻⁴⁶ including the intermediate-range van-der-Waals bonding⁴⁵ and metal-insulator transitions.⁴⁶

Despite the general success enjoyed by recent meta-GGA functionals for a wide range of systems,^{21,23,28–30,44–47} it has been observed that many meta-GGAs suffer numerical instabilities in self-consistent field (SCF) calculations,^{47,48} and have an unacceptably slow convergence with respect to the density of the numerical integration points.⁴⁹ The increased computational cost of dense numerical grids severely limits the usefulness of many meta-GGA functionals and restricts the complexity of systems to which they can be applied. Additionally, the uncertainty in overall grid convergence necessitates a time-consuming validation that calculated properties are properly converged in grid density, placing an undesirable burden of expertise on the user.

Within α -based functionals, it is understood that this numerical sensitivity originates from sharp oscillations in the exchange-correlation potential that are only properly captured by very fine grids,⁴⁷ particularly in inter-shell regions where the local orbital overlap character can vary rapidly. Here we show that the rapid variations in the derivatives of α are largely responsible for these undesirable oscillations. Further, we propose a modified iso-orbital indicator quantity, termed β , from which new functionals can be constructed that do not suffer this problem,

$$\beta(\mathbf{r}) = \frac{\tau(\mathbf{r}) - \tau^{\mathrm{vW}}(\mathbf{r})}{\tau(\mathbf{r}) + \tau^{\mathrm{UEG}}(\mathbf{r})}$$
(4)

$$= \alpha(\mathbf{r}) \left(\frac{\tau^{\text{UEG}}(\mathbf{r})}{\tau(\mathbf{r}) + \tau^{\text{UEG}}(\mathbf{r})} \right).$$
(5)

The β variable contains similar information about local orbital overlap environments to α whilst having smoother derivatives more easily amenable to evaluation on numerical grids. This allows local orbital overlap information to be used in functionals at the meta-GGA level and higher without suffering the numerical problems associated with analogous functions of the α variable.

Table 1: Values of common iso-orbital indicators for important chemical envi-ronments.

Region	t^{-1}	z	α	β
Single orbital	$5s^{2}/3$	1	0	0
Slowly varying density	≈ 1	≈ 0	≈ 1	$\approx \frac{1}{2}$
Non-covalent bonding	$\gg 1$	≈ 0	$\gg 1$	$\frac{1}{2} \ll \tilde{\beta} < 1$

The close relationship between the α and β variables can be shown by examining their limits in the three important orbital overlap regions. Firstly, in single orbital regions $\tau(\mathbf{r}) = \tau^{vW}(\mathbf{r})$ and $\alpha(\mathbf{r}) = \beta(\mathbf{r}) = 0$. This bound is important in exchange-correlation functional development, allowing the strong lower bound on exchange energy as well as correlation energy to be enforced for all spin-unpolarised single-orbital systems.^{30,50,51} Secondly, in slowly varying densities $\tau^{vW}(\mathbf{r}) \to 0$ and $\tau(\mathbf{r}) \approx \tau^{\text{UEG}}(\mathbf{r})$, so $\alpha(\mathbf{r}) \approx 1$ and $\beta(\mathbf{r}) \approx 1/2$. Finally, in non-covalent density overlap regions where $n(\mathbf{r}) \to 0$, $\tau^{\text{UEG}}(\mathbf{r}) \to 0$ as $n(\mathbf{r})^{5/3}$ while $\tau(\mathbf{r}) - \tau^{vW}(\mathbf{r}) \to 0$ as $n(\mathbf{r})$, and thus the denominator, $\tau^{\text{UEG}}(\mathbf{r})$, decays faster than the numerator, $\tau(\mathbf{r}) - \tau^{vW}(\mathbf{r})$, leading to $\alpha(\mathbf{r}) \to \infty$. Here $\beta(\mathbf{r})$ approaches 1 however, since both its numerator and denominator decay as $n(\mathbf{r})$. The relations between α, β and other

iso-orbital indicators are summarised in Table 1.

Figure 1: Radial plots of $\alpha(r)$ and $\beta(r)$ functions and their density derivatives for the lithium and carbon atoms. The α (solid red) and β (dashed blue) functions and density derivatives are plotted for the majority (Maj., \blacktriangle) and minority(Min., \blacktriangledown) spin from self-consistent PBE¹¹ densities. Radial distances are in units of Bohr.

This similarity between α and β in highlighting local orbital overlap environment is shown graphically in Figures 1 a) and b) for the lithium and carbon atoms respectively. The lithium and carbon atoms were chosen as typically difficult systems with pronounced numerical sensitivity for density functionals. The similar inter-shell peak behaviour is clearly visible for both variables as a rise away from single orbital like values of the 1s core. The difference between α and β is seen in the tail region of the carbon atom for the majority spin electrons, where α diverges upwards whilst β decays slowly towards 0. For the minority spin, both α and β approach 0 in the tail region. In general, β consistently indicates the tail regions of all densities with 0 as $\tau^{vW}(\mathbf{r})$ is the leading order of $\tau(\mathbf{r})$ there, and identifies tail regions completely when combined with the dimensionless reduced density gradient, s, that is divergent. This is impossible for α which can have different values of $\alpha(\mathbf{r}) = 0$ for the tail regions of single orbital systems and $\alpha \to \infty$ otherwise.

The benefit of β over α for functional development is most clearly seen in the derivatives with respect to density, exemplified in Figure 1 c) and d) for the lithium and carbon atoms respectively. The derivative of β with respect to density does not show the same rapid variation as that of α in valence regions where density is significant. Similar behaviour is observed for $|\nabla n|$ and τ derivatives, as noted for α in Ref.⁴⁷ and in the more complex molecular systems presented in supplementary material Section 1.

These much better behaved derivatives of β over those of α are expected to remedy the numerical problems observed in α -dependent meta-GGA functionals. To validate this, we modify the existing *meta-GGA made simple 2* (MS2) functional⁵² by substituting 2β in place of α within the exchange enhancement factor $F_{\mathbf{x}}(s, \alpha)$, defined by

$$E_{\mathbf{x}}^{\mathrm{meta-GGA}}[n] = \int e_{\mathbf{x}}^{\mathrm{UEG}}(n) F_{\mathbf{x}}^{\mathrm{meta-GGA}}(s,\alpha) d\mathbf{r}, \tag{6}$$

where $e_x^{\text{UEG}}(n) = -3(3\pi^2)^{1/3}n^{4/3}/4\pi$ is the exchange energy density of uniform electron gas. MS2 has a simple construction of $F_x^{\text{MS2}}(s, \alpha) = F_x^1(s) + f_x^{\text{MS2}}(\alpha)[F_x^0(s) - F_x^1(s)]$ with

$$f_{\rm x}^{\rm MS2}(\alpha) = \frac{(1-\alpha^2)^3}{1+\alpha^3 + b\alpha^6}$$
(7)

that interpolates between $F_x^0(s)$, a GGA for single-orbital systems ($\alpha = 0$), and $F_x^1(s)$, a GGA for slowly-varying densities ($\alpha \approx 1$), and extrapolates to ($\alpha \gg 1$) for noncovalent bonds.

This functional was chosen for the relatively simple construction and well reported numerical instabilities.⁴⁷ Modification of the simple exchange enhancement factor for β dependence was trivial by replacing α with 2β to guarantee the interpolation between $F_x^0(s)$ for single orbital systems ($2\beta = \alpha = 0$) and $F_x^1(s)$ for slowly varying densities ($2\beta \approx \alpha \approx 1$). The Table 2: Parameters for the MS2 and MS2 β functionals. The notation of Ref.⁵² is followed, with constants $k_0 = 0.174$ and $\mu_{\text{GE}} = 10/81$. [†]The original publication of MS2³⁵ gives c = 0.14601. We find this gives a small error (on the order of μE_{h}) in the exchange energy of the hydrogen atom that is corrected using c = 0.14607. We note however, that this change has a completely negligible impact on MS2 predicted atomisation energies and barrier heights.

MS2	$\kappa = 0.504$	b = 4.0	$c=0.14607^{\dagger}$
$MS2\beta$	$\kappa=0.504$	$b = (27b^{\rm MS2} - 9)/64$	c = 0.14607

resulting β -modified meta-GGA functional is termed MS2 β . The parameter *b* is determined such that $f_x^{\text{MS2}\beta}(\beta = 1) = f_x^{\text{MS2}}(\alpha \to \infty)$ for noncovalent bonds. These minor adjustments to the balances between internal parameters to preserve exact constraints obeyed by the parent functional are summarised in Table 2 and detailed in supplementary material. MS2 β was implemented into the TURBOMOLE package⁵³ using the XCFUN library⁵⁴ to automatically evaluate functional derivatives. We present MS2 β simply as a convenient means for preliminary investigation of the β variable rather than as a viable general functional.

Figure 2: Convergence behaviour with respect to numerical grid density of conventional and β -modified meta-GGA made simple 2 (MS2) functional⁵² for (a) lithium and (b) carbon atoms. Difference in self-consistent atomic total energy relative to the total energy from a converged grid of 520 points ($E_{\text{conv.}}$) for the MS2 (red, \times) and MS2 β (blue, dashed, +) functionals using the aug-cc-pVQZ basis set.⁵⁵ An acceptable convergence is assumed when difference remains below the SCF convergence tolerance of $1\mu E_{\text{h}}$ (dotted line).

The grid convergence of the MS2 and MS2 β functionals is shown in Figure 2 as a plot of the difference in self-consistent electronic energy relative to the same calculation using a very fine benchmark grid, as a function of grid point density, for the carbon and lithium atoms. In both cases the β -modified functional shows a convergence in total energy at lower grid density than the parent α functional, indicated by the difference to the benchmark grid energy remaining below the SCF convergence threshold of $1\mu E_h$.

As previously noted, the sensitivity of α -dependent functionals to numerical integration grid point density is understood as an effect of rapid oscillations in the exchange-correlation potential, expressed in the generalised Kohn–Sham scheme^{47,56,57} as,

$$\int \varphi_p \hat{v}_{\rm xc} \varphi_q d\mathbf{r} = \int \varphi_p \frac{\partial e_{\rm xc}}{\partial n} \varphi_q d\mathbf{r} + \int \frac{\partial e_{\rm xc}}{\partial \nabla n} \cdot \nabla(\varphi_p \varphi_q) d\mathbf{r} + \frac{1}{2} \int \nabla \varphi_p \cdot \left(\frac{\partial e_{\rm xc}}{\partial \tau}\right) \nabla \varphi_q d\mathbf{r} \qquad (8)$$

Here, $e_{\rm xc}$ is the exchange-correlation energy density of a meta-GGA functional. Hence, functionals showing sharp oscillations in functional derivatives will show sharp variations in exchange-correlation potential that are challenging to capture in numerical integration schemes. By modifying meta-GGA functionals to use the β indicator in place of α , oscillations in functional derivatives are minimised and the resulting exchange-correlation potential is smoothed, as exemplified by MS2 and MS2 β which have the same exchange enhancement factor form in terms of α or 2β dependence. We can therefore understand the reduced grid sensitivity of the β -modified functional as a consequence of smoother functional derivatives in the inter-shell and valence regions producing smoother exchange-correlation potentials that can be more easily captured by numerical integration grids.

The divergences of derivatives at tails seen in Figures 1 c) and d) are not problematic for the exchange-correlation potential of any analytic β -dependent meta-GGAs because $e_x^{\text{UEG}}(n)$ decays faster than the divergence of β derivatives there. However, the divergences of α derivatives at tails are much stronger than those of β , as also seen in Figures 1 c) and d), and can cause problems for the exchange-correlation potential of α -dependent metaGGAs. At the tail regions, τ decays as n, whilst τ^{UEG} decays more quickly as $n^{5/3}$, so the derivative of α with respect to, for example, τ diverges as $n^{-5/3}$, faster than the decay of $e_x^{\text{UEG}}(n)$ proportional to $n^{4/3}$. This can potentially lead to divergences of exchange-correlation potential for α -dependent meta-GGAs as long as the derivative of $F_x^{\text{meta}-\text{GGA}}(s,\alpha)$ with respect to α is non-zero at the tail. Such non-zero values are encountered by the meta-GGA made very simple (MVS)⁵¹ and SCAN³⁰ meta-GGAs at the tail regions of single-orbital systems. This behaviour is avoided in β as the decay of both the numerator and denominator is determined by τ as decaying with n.

The potential divergence of exchange-correlation potential at tail regions resulting from the strong divergence of α derivatives is undesirable and problematic especially for the construction of pseudo-potentials from isolated atoms, acting as a hitherto unrecognised additional constraint on α dependent functional design. This constraint was not previously noticed and is not obeyed by the MVS⁵¹ and SCAN³⁰ functionals, though it is fortuitously obeyed by MS2. This constraint is not necessary in β dependent functionals however, as the asymptotic behaviour of β is properly controlled and thus β offers simplicity and greater flexibility in functional design compared to the α indicator.

Table 3: Mean error (ME) and mean absolute error (MAE) in kcal mol⁻¹ for the small test sets of atomisation energy (AE6) and reaction barrier height (BH6) for the MS2 and MS2 β functionals. All calculations were performed fully self-consistently with the 6-311++G(3df,3pd) basis set^{58,59} on a dense numerical grid (Turbomole level 7).

	MS2	$MS2\beta$
AE6 (ME)	-0.78	3.95
AE6 (MAE)	4.40	6.10
BH6 (ME)	-5.79	-6.32
BH6 (MAE)	5.79	6.32

To show that the MS2 β functional retains the ability to effectively distinguish different chemical environments we calculate the mean error (ME) and mean absolute error (MAE) of small data sets of atomisation energies (AE6) and barrier heights (BH6),^{60,61} the results for which are shown in Table 3. For these small datasets the accuracy of the β -modified

Figure 3: Convergence of mean absolute error for the AE6 and BH6 small molecule data sets, 60,61 with respect to increasing numerical grid density for the MS2 (red, ×) and MS2 β (blue, dashed, +) functionals. The presence of both angular and radial grid components and the variety of molecules in the sets prevents a simple quantitative measure of grid density. As such, grid density is reported as the chosen TURBOMOLE grid level, such that a higher grid level (larger x axis value) directly corresponds to more dense integration grids, though steps between levels may not be uniform. All calculations were performed fully self-consistently with the 6-311++G(3df,3pd) basis set.^{58,59}

functional is slightly reduced compared to the original. This is to be expected as the MS2 functional contains two free parameters fit to minimise MAE in these data sets that may not be optimal for β . We conclude therefore that whilst it is possible to use 2β directly in place of α in existing functionals, some adjustment of internal parameters and interpolation-extrapolation functions is likely to be necessary to construct useful general β dependent functionals.

A comparison of the data set grid convergence for the MS2 and MS2 β functionals is summarised in Figure 3 as a comparison of increasing grid density with respect to the densest grid. A similar trend to the convergence of atomic total energies, Figure 2, is seen with MS2 β reaching a converged error at coarser numerical grids than the parent MS2 functional. We note that whilst convergence for the BH6 set is relatively rapid for both functionals much greater variation is seen for the atomisation energies in the AE6 set, consistent with the larger energy scale of the test set.

Figure 4: Dissociation curve of the argon dimer. Calculated using MS2 (red, \times) and MS2 β (blue, +) functionals. Calculations performed self-consistently using the aug-cc-pV5Z basis set and a very fine numerical grid (grid 7 of the TURBOMOLE program). A benchmark curve (black) is included from Ref.⁶²

The different behaviour of the α and β variables is most pronounced in regions of nonbonded density overlap where $\alpha(\mathbf{r}) \gg 1.0$ and β is in the region $0.5 < \beta(\mathbf{r}) < 1.0$. This difference is most clearly examined in the Ar₂ dissociation curve, for which it has been shown meta-GGA functionals can be accurate around equilibrium.^{30,45,52} The dissociation curves for Ar₂ are shown in Figure 4 for both the conventional and β -modified MS2 functionals with benchmark data included from Ref.⁶² for comparison. In contrast to the small test sets, MS2 β closely matches the performance of the original MS2 functional across the whole of the binding curve, suggesting that the MS2 interpolation-extrapolation function may be as appropriate for 2β as it is for α in non-covalently bound systems.

In conclusion, we have identified the source of the numerical sensitivities commonly suffered in calculations employing meta-GGA functionals as resulting from sharp oscillations in the functional derivatives of the commonly employed dimensionless variable α . We have addressed these sensitivities by constructing a related dimensionless variable, β , which imparts similar information about local orbital overlap environment whilst having smoother functional derivatives. The enhanced numerical stability, improved recognition of tail regions, and freedom from constraints on exchange-correlation potential presented by β are an appealing opportunity for enhancing the numerical performance of future functionals for both the meta-GGA level and higher level fully non-local functionals.

We have used the simple MS2 meta-GGA functional to show a simple proof of concept by substituting 2β for α in the functional with minimal adjustment of internal parameters. We find improved numerical performance in all cases, with the new functional giving converged properties from much coarser integration grids than the original MS2 functional. Whilst the MS2 β functional preserves much of the good accuracy of its progenitor, a slight degradation of accuracy is observed for small molecule test sets though performance is preserved for the non-covalently bound Ar₂ diatomic. This suggests a need for the underlying functional to be adjusted for β rather than naive substitution if good performance for appropriate norms is to be preserved alongside an adherence to exact constraints. We are optimistic that wholly novel functionals utilising the β iso-orbital indicator can provide ever greater accuracy and utility for the wider DFT community.

Acknowledgements

We thank Jefferson Bates for his invaluable technical advice in running and modifying the TURBOMOLE package. We also thank John Perdew, Adrienn Ruzsinszky, Mark Pederson, Weitao Yang, Arun Bansil, Samuel Trickey, Susi Lehtola and Albert Bartok-Partay for their fruitful discussions around the ideas presented here. The work at Tulane University was supported by the start-up funding from Tulane University, and by the U.S. DOE, Office of Science, Basic Energy Sciences grant number DE-SC0235021(core research). Calculations were carried out on the Cypress cluster at Tulane University, and we thank Dr. Hoang Tran, Dr. Carl Baribault, and Dr. Hideki Fujioka for their computational support

Supplementary Material

Behaviour of α and β and their derivatives in a range of chemical environments

The α and β quantities and their d/dn, $d/d|\nabla n|^2$ and $d/d\tau$ derivatives are plotted for atomic and molecular systems, chosen to illustrate a range of chemically diverse systems. All evaluated from self consistent Perdew-Burke-Ernzerhof (PBE) densities.¹¹

A common scheme of α (blue) and β (red, dotted) for majority (\blacktriangle) and minority (\blacktriangledown) spin channels is used for all plots.

Figure 1: Radial plots of the α and β iso-orbital indicators for the lithium atom.

Figure 2: Radial plots of the α and β iso-orbital indicators for the carbon atom.

Figure 3: Radial plots of the α and β iso-orbital indicators for the argon atom.

Figure 4: The α and β iso-orbital indicators for the Ar₂ vand-der-Waals diatomic, plotted along the internuclear axis evaluated for self consistent PBE density. The origin is positioned at the bond center and argon atom position is marked with a dotted vertical line.

Figure 5: The α and β iso-orbital indicators for the Na₂ diatomic showing metallic bonding, plotted along the internuclear axis. The origin is positioned at the bond center and sodium atom position is marked with a dotted vertical line.

Figure 6: The α and β iso-orbital indicators for NaCl showing ionic bonding, plotted along the internuclear axis.

Figure 7: The α and β iso-orbital indicators for SiH₄ showing covalent bonding, plotted along one Si-H internuclear axis.

as $\alpha(\mathbf{r})$ is unbounded from above regions for which $\alpha(\mathbf{r}) > 3.0$ have been coloured red. Linear slices along the inter-molecular Figure 8: Contour plots of $\alpha(r)$ (left) and $\beta(r)$ (right) for the hydrogen bonded (H₂O)₂ water dimer evaluated for self consistent PBE density. Atomic positions are labelled, the labels for out of plane hydrogen atoms have been projected onto the plotting plane. As the range of the functions is different, colour mapping is not shared between plots. Additionally, axis (dotted black line on contour plot) are included, in which the slowly varying limits of 1.0 and 0.5 for α and β respectively are marked with a red doted line. Geometry is taken from the S22 test set,¹ optimised at the B3LYP level.²

Derivation of the $MS2\beta$ functional

The semilocal exchange functional can be written as a construction around an exchange enhancement factor modulating the exchange energy density of the uniform electron gas,

$$E_{\mathbf{x}}[n] = \int e_{\mathbf{x}}^{\mathrm{UEG}}(n) F_{\mathbf{x}}(s,\alpha) d\boldsymbol{r}, \qquad (1)$$

where $e_{\rm x}^{\rm UEG}(n) = -\frac{3}{4} \left(\frac{3}{\pi}\right)^{1/3} n(\boldsymbol{r})^{4/3}$ and $F_{\rm x}$ is the exchange enhancement factor.

The MS2 functional is designed to recover the second order gradient expansion of exchange and correlation energies of slowly varying densities. For slowly varying densities,

$$\lim_{|\nabla n| \to 0} \alpha = \frac{\tau^{\text{UEG}} + \frac{1}{72} \frac{|\nabla n|^2}{n} + \frac{1}{6} \nabla^2 n - \frac{|\nabla n|^2}{8n}}{\tau^{\text{UEG}}}$$
(2)

$$= 1 - \frac{1}{9}A + \frac{1}{6}B + O(\nabla^2), \tag{3}$$

where,

$$A = \frac{|\nabla n|^2}{e_{\rm x}^{\rm UEG}},\tag{4}$$

$$B = \nabla^2 n / \tau^{\text{UEG}},\tag{5}$$

Here, a similar derivation is made for the β quantity,

$$\lim_{|\nabla n| \to 0} \beta = \frac{\tau^{\text{UEG}} + \frac{1}{72} \frac{|\nabla n|^2}{n} + \frac{1}{6} \nabla^2 n - \frac{|\nabla n|^2}{8n}}{\tau^{\text{UEG}} + \frac{1}{72} \frac{|\nabla n|^2}{n} + \frac{1}{6} \nabla^2 n + \tau^{\text{UEG}}},\tag{6}$$

$$= \frac{1}{2} \left[1 - \frac{17}{144} A + \frac{1}{12} B \right] + O(\nabla^2).$$
(7)

The MS2 exchange enhancement function, $F_x^{MS2}(p, \alpha)$ is constructed as an interpolation, $f(\alpha)$, of two enhancement factor functions of the squared reduced density gradient,

$$p = s^{2} = \frac{1}{4(3^{2/3}\pi^{6/3})} \frac{|\nabla n|^{2}}{n^{8/3}},$$
(8)

built for the $\alpha = 0$ and $\alpha = 1$ limits as $F_{\mathbf{x}}^0(p)$ and $F_{\mathbf{x}}^1(p)$ respectively,

$$F_{\mathbf{x}}^{0}(p) = 1 + \kappa - \frac{\kappa}{1 + \frac{\mu^{\mathrm{GE}}p + c}{\kappa}}$$

$$\tag{9}$$

$$F_{\mathbf{x}}^{1}(p) = 1 + \kappa - \frac{\kappa}{1 + \frac{\mu^{\mathrm{GE}}p}{\kappa}},\tag{10}$$

where $\mu^{\text{GE}} = 10/81$, and $\kappa = 0.504$ and c = 0.14601 are parameters determined in Ref.⁵² F_x^0 and F_x^1 are independent of α , and hence β , though the κ and c parameters should be adjusted accordingly.

The enhancement factor interpolation is a direct function of α ,

$$f(\alpha) = \frac{(1 - \alpha^2)^3}{1 + \alpha^3 + b\alpha^6},$$
(11)

where b = 4.0 is a parameter controlling $\alpha > 1$ behaviour and is optimised simultaneously with κ in Ref.⁵² by fitting to atomisation energy and barrier height training sets, AE6⁶⁰ and BH6⁶¹ respectively. Here, we construct a similar interpolation function, exhibiting the same limiting behaviours, in terms of β . We write,

$$\lim_{|\nabla n| \to 0} f(\alpha) = \lim_{|\nabla n| \to 0} \frac{(1 - \alpha^2)^3}{1 + \alpha^3 + b\alpha^6}$$
(12)

$$= \left[-2\left(-\frac{1}{9}A + \frac{1}{6}B\right)\right]^3 + O(\nabla^6) \tag{13}$$

and this term only contributes to the order of ∇^6 and higher. We can therefore replace α by 2β in Eq. 11 without affecting the second order gradient expansion of the MS2 exchange enhancement factor F_x^{MS2} of Ref.⁵² We propose,

$$f_m(\beta) = \frac{\left[1 - (2\beta)^2\right]^3}{1 + (2\beta)^3 + b_m(2\beta)^6},\tag{14}$$

where the m subscript indicates a modified term. Firstly, we confirm that Eq. 14 exhibits the same behaviours as Eq. 11 with respect to the equivalent points highlighted in the main text,

$$f_m(\beta = 0) = f(\alpha = 0) = 1,$$
(15)

$$f_m(\beta = 0.5) = f(\alpha = 1) = 0, \tag{16}$$

the $\alpha \rightarrow \infty$ limit corresponds to $\beta \rightarrow 1$ giving,

$$f_m(\beta = 1) = \frac{(1-4)^3}{1+8+64b_m}.$$
(17)

The $f(\alpha)$ function gives,

$$f_m(\beta = 1) = \lim_{\alpha \to \infty} f(\alpha), \tag{18}$$

$$= -\frac{1}{b},\tag{19}$$

(20)

hence for $f_m(\beta \to 1)$ to coincide $f(\alpha \to \infty)$ then the b_m parameter is defined relative to the original b as,

$$b_m = \frac{27b - 9}{64}.$$
 (21)

Atomic Total Energies

Table 1: The total energies of the neon and argon atoms calculated in the augcc-pVQZ basis using a very fine (Turbomole Level 7) integration grid converged to $10^{-8}E_{\rm h}$ in the SCF cycle.

	MS2	$MS2\beta$
Ne	-128.96625003	-129.02147785
Ar	-527.53776112	-527.53776112

Magnetic Fields

We note that the required modification for kinetic energy density dependent functionals in strong magnetic fields^{3,4} of substituting the orbital kinetic energy density with the physical kinetic energy density, as derived by Dobson in Ref.,^{5,6} indicator quantity is equally applicable to the β quantity as α to construct current sensitive meta-GGA functionals.
